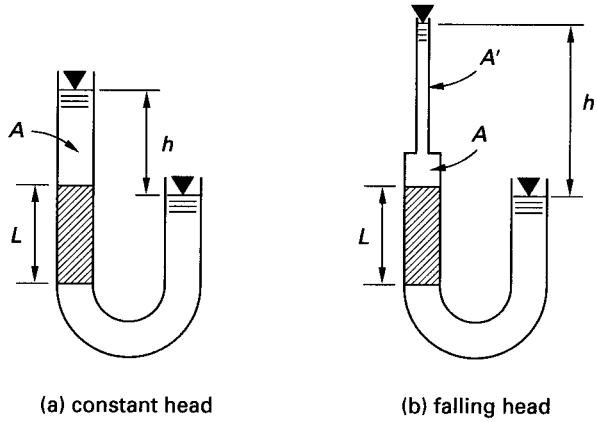
The area in Eq. 35.26 is the total cross-sectional area of the aquifer, not the actual area in flow. Water can only flow through the open spaces between the solids. This open space area is nA.

Typical values of the coefficient of permeability, K, are given in Table 35.11. Clays are considered relatively impervious, while sands and gravels are pervious. For comparison, the permeability of concrete is approximately 10^{-10} cm/s.

Table 35.11 *Typical Permeabilities*

group symbol	typical coefficient of permeability (cm/s)
GW	2.5×10^{-2}
GP	5×10^{-2}
GM	$> 5 \times 10^{-7}$
GC	$> 5 \times 10^{-8}$
SW	$> 5 \times 10^{-4}$
SP	$> 5 \times 10^{-4}$
SM	$> 2.5 \times 10^{-5}$
SM-SC	$> 10^{-6}$
SC	$> 2.5 \times 10^{-7}$
ML	$> 5 \times 10^{-6}$
ML-CL	$> 2.5 \times 10^{-7}$
CL	$> 5 \times 10^{-8}$
OL	–
MH	$> 2.5 \times 10^{-7}$
CH	$> 5 \times 10^{-8}$
OH	–

For uniform fine sands, permeability is approximately given by *Hazen's formula*, Eq. 35.28. D_{10} is the *effective grain size*—the diameter for which only 10% of the particles are finer.



$$K_{\text{cm/s}} \approx (D_{10,\text{mm}})^2 \qquad 35.28$$

Hazen's formula provides only a crude estimate. Accurate values are calculated from controlled permeability tests using constant- or falling-head *permeameters*. In a *constant-head test*, the volume of water, V, percolating through the soil over time is measured. The test is applicable to coarse-grained soils with $K > 10^{-3}$ cm/s.

$$K = \frac{VL}{hAt} \qquad \text{[constant head]} \qquad 35.29$$

In *falling-head tests*, the change in head over time is measured as the water percolates through the soil. The test is applicable to fine-grained soils with $K < 10^{-3}$ cm/s.

$$K = \left(\frac{A'L}{At}\right) \ln\left(\frac{h_i}{h_f}\right) \qquad \text{[falling head]} \qquad 35.30$$

(a) constant head (b) falling head

Figure 35.8 *Permeameters*

The permeability can also be determined with an in situ test in the field. For the *auger-hole method* (a falling-head test), the combination of area and length variables may be known as the *shape factor* or *conductivity coefficient*, F. For example, for a cased hole below the water table of length L and radius r whose impervious casing extends all the way to the hole bottom and whose liquid level rises from h_i to h_f in time t (approaching the water table level), the shape factor and permeability are

$$\mathrm{F} = \frac{11r}{2} \qquad 35.31$$

$$\begin{aligned}\mathrm{K} &= \left(\frac{\pi r^2}{Ft}\right) \ln\left(\frac{h_i}{h_f}\right) \\ &= \left(\frac{2\pi r}{11t}\right) \ln\left(\frac{h_i}{h_f}\right) \qquad \text{[auger hole]} \qquad 35.32\end{aligned}$$

Other in-field tests can use cased holes with constant head or uncased holes with constant and variable head. The shape factors for these tests are not the same as that in Eq. 35.31.

Example 35.7

The permeability of a semi-impervious soil was evaluated in a falling-head permeameter whose head decreased from 40 to 15 in (100 to 40 cm) in 5 min. The body diameter was 5 in (13 cm), the standpipe diameter was 0.1 in (0.3 cm), and the sample length was 2 in (8 cm). What was the permeability of the soil?

SI Solution

Use Eq. 35.30.

$$\begin{aligned}K &= \left(\frac{A'L}{At}\right) \ln\left(\frac{h_i}{h_f}\right) \\ &= \left(\frac{\frac{1}{4}\pi(0.3\text{ cm})^2(8\text{ cm})}{\frac{1}{4}\pi(13\text{ cm})^2(5\text{ min})\left(60\ \frac{\text{s}}{\text{min}}\right)}\right) \\ &\quad \times \ln\left(\frac{100\text{ cm}}{40\text{ cm}}\right) \\ &= 1.3 \times 10^{-5}\ \text{cm/s}\end{aligned}$$

Customary U.S. Solution

Use Eq. 35.30.

$$\begin{aligned}K &= \left(\frac{A'L}{At}\right) \ln\left(\frac{h_i}{h_f}\right) \\ &= \left(\frac{\frac{1}{4}\pi(0.1\text{ in})^2(2\text{ in})}{\frac{1}{4}\pi(5\text{ in})^2(5\text{ min})\left(60\ \frac{\text{sec}}{\text{min}}\right)}\right) \\ &\quad \times \ln\left(\frac{40\text{ in}}{15\text{ in}}\right) \\ &= 2.6 \times 10^{-6}\ \text{in/sec}\end{aligned}$$

16. CONSOLIDATION TESTS

Consolidation tests (also known as *confined compression tests* and *oedometer tests*) start with a disc of soil (usually clay) confined by a metal ring. The faces of the disc are covered with porous plates. The disc sandwich is loaded and submerged in water. Static loads are applied in increments, and the vertical displacement is measured with time for each load increment. The testing time is very long, usually 24 hr per load increment, since seepage through clay soils is very slow. When the displacement rate levels off, the final void ratio is determined for that increment. The load versus the void ratio for all increments is plotted together as an *e-log p curve*.[8]

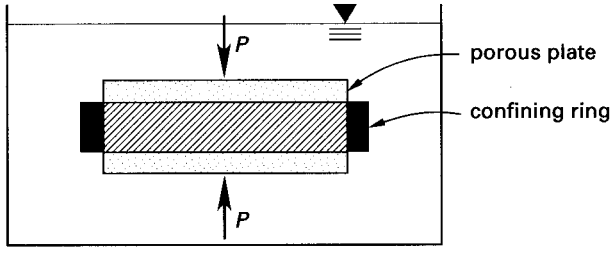


Figure 35.9 *Consolidation Test Apparatus*

Figure 35.10 shows an e-log p curve for a soil sample from which the load has been removed at point m, allowing the clay to recover.

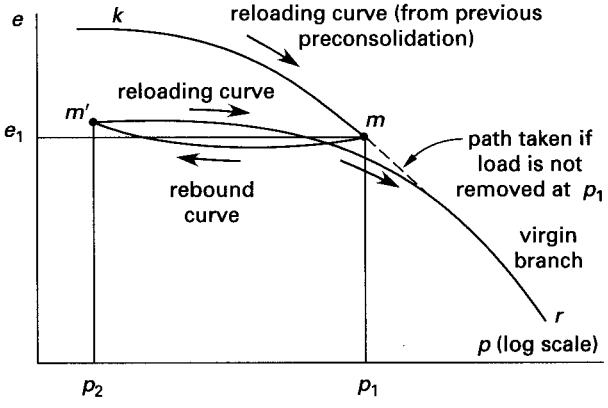

Figure 35.10 *e-log p Curve*

The line segment m-r is known as the *virgin compression line* or *virgin consolidation line*. In this region, the clay is considered to be *normally consolidated*, which means that the present load has never been exceeded.

Line m-m' is a *rebound curve*. Line m'-r is known as a *reloading curve*. Such curves result when a normally consolidated clay is unloaded and then reloaded. Since

[8]The use of pressure (p) instead of stress (σ) for the discussion on consolidation follows convention. Pressure refers to the external forces on the soil. Some soils texts substitute stress for pressure to emphasize that the soil response is dependent on internal forces in the soil, but otherwise the methodology is exactly the same.

it has carried a higher load in the past, the soil is considered to be *overconsolidated* or *preloaded* in the rebound-reload region.

Notice that point m' can only be reached by loading the soil to a pressure of p_1 and then removing the pressure. Although the pressure of the clay at p_2 is essentially the same as at the start of the test, the void ratio has been reduced.

The *overconsolidation ratio*, OCR, is defined by Eq. 35.33. p'_o is the present or in situ overburden pressure; $p'_{\max}$ is the maximum past pressure or *preconsolidation pressure*. An overconsolidation ratio of 1 means that the soil is normally consolidated; an overconsolidation ratio greater than 1 means that the soil is overconsolidated. In rare circumstances, such as during construction or rapid underwater deposition, a soil may be "underconsolidated"; that is, it has not yet come to equilibrium with its present load.

$$\text{OCR} = \frac{p'_{\max}}{p'_o} \qquad 35.33$$

The shape of the e-log p curve will depend on the degree of remolding or disturbance, as shown in Fig. 35.11. A highly disturbed soil will show a gradual transition between overconsolidated and normally consolidated behavior.

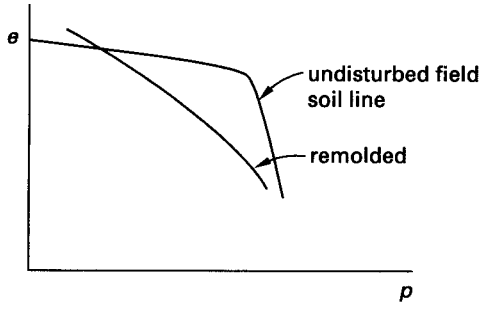

Figure 35.11 Consolidation Curves

Laboratory results can be used to find the preconsolidation pressure (point m in Fig. 35.10). One procedure is the *Casagrande Method*, as illustrated in Fig. 35.12. This procedure starts by drawing two lines—a tangent line and a horizontal line—through the point of maximum curvature, which is determined by eye. The resulting angle is bisected. Then a tangent extension (line k) is drawn to the virgin compression line. The intersection of this tangent and the bisection line defines the preconsolidation pressure, $p'_{\max}$.

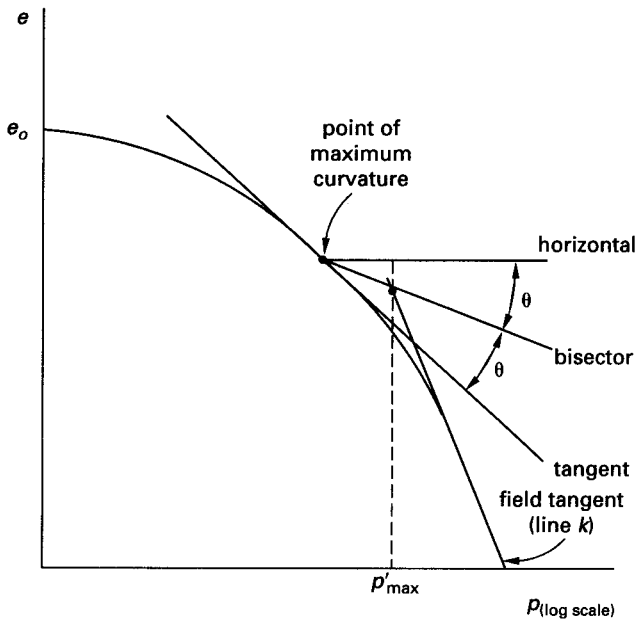

Figure 35.12 Casagrande Method

The field virgin compression line, line k in Fig. 35.12, can be used to predict consolidation of the soil under any loading greater than $p'_{\max}$. The *compression index*, C_c, or *compressibility index*, is the negative of the logarithmic slope of line k and is given by Eq. 35.34, where points 1 and 2 correspond to any two points on line k.[9]

$$C_c = \frac{e_1 - e_2}{\log_{10}\left(\frac{p_1}{p_2}\right)} \qquad 35.34$$

It is common practice to plot strain, ϵ, versus log p for consolidation test data, as well as void ratio versus log p as shown in Fig. 35.10. The slope of the ϵ-log p line is $C_{\epsilon c}$ and is related to the compression index, C_c.

$$C_{\epsilon c} = \frac{C_c}{1 + e_0} \qquad 35.35$$

If the clay is soft and near its liquid limit, the compression index can be approximated by Eq. 35.36.

$$C_c \approx (0.009)(\text{LL} - 10) \qquad 35.36$$

When the loading is removed from a soil sample, it will have a tendency to swell. The *swelling index* and *reconsolidation index* can be found from the (negative of the) logarithmic slopes of the rebound and reloading curves, respectively. For practical purposes, these indices are equal to each other and found as the slope of the line that bisects the rebound and reload curves.

17. DIRECT SHEAR TEST

The *direct shear test* is a relatively simple test used to determine the relationship of shear strength to consolidation stress. In this test, a disc of soil is inserted

[9] Although the compression index is, strictly speaking, the slope of the virgin compression line and therefore negative, it is typically reported and used as a positive number. Equation 35.33 is a convenient form for calculating C_c as a positive number.

into the direct shear box. The box has a top half and a bottom half that can slide laterally with respect to each other. A normal stress, σ_n, is applied vertically, and then one half of the box is moved laterally relative to the other at a constant rate. Measurements of vertical and horizontal displacement, δ, and horizontal shear load, P_h, are taken. The test is usually repeated at three different vertical normal stresses.

Because of the box configuration, failure is forced to occur on a horizontal plane. Results from each test are plotted as horizontal displacement versus horizontal stress, τ_h (horizontal force divided by the nominal area). *Failure* is determined as the maximum value of horizontal stress achieved. The vertical normal stress and failure stress from each test are then plotted in Mohr's circle space of normal stress versus shear stress.

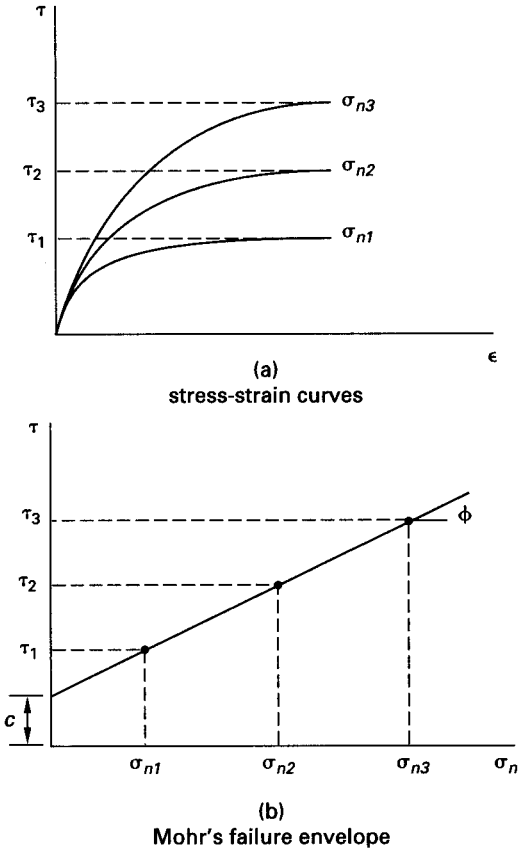

Figure 35.13 *Graphing Direct-Shear Test Results*

A line drawn through all of the test values is called the *failure envelope* (*failure line* or *rupture line*). The equation for the failure envelope is given by *Coulomb's equation*, which relates the strength of the soil, S, to the normal stress on the failure plane.[10,11,12]

$$S = \tau = c + \sigma \tan\phi \qquad 35.37$$

[10]Equation 35.37 is also known as the Mohr-Coulomb equation.
[11]The ultimate shear strength may be given the symbol S in some soils books.
[12]τ and σ in Coulomb's equation are the shear stress and normal stress, respectively, on the failure plane at failure.

ϕ is known as the *angle of internal friction*.[13] c is the *cohesion intercept*, a characteristic of cohesive soils. Representative values of ϕ and c are given in Table 35.12.

Table 35.12 *Typical Strength Characteristics*

group symbol	cohesion (as compacted) c lbf/ft² (kPa)	cohesion (saturated) c_{sat} lbf/ft² (kPa)	effective stress friction angle ϕ
GW	0	0	> 38°
GP	0	0	> 37°
GM	–	–	> 34°
GC	–	–	> 31°
SW	0	0	38°
SP	0	0	37°
SM	1050 (50)	420 (20)	34°
SM-SC	1050 (50)	300 (14)	33°
SC	1550 (74)	230 (11)	31°
ML	1400 (67)	190 (9)	32°
ML-CL	1350 (65)	460 (22)	32°
CL	1800 (86)	270 (13)	28°
OL	–	–	–
MH	1500 (72)	420 (20)	25°
CH	2150 (100)	230 (11)	19°
OH	–	–	–

(Multiply lbf/ft² by 0.04788 to obtain kPa.)

18. TRIAXIAL STRESS TEST

The *triaxial test* is a more sophisticated method than the direct shear test for determining the strength of soils. In the triaxial test apparatus, a cylindrical sample is stressed completely around its peripheral surface by pressurizing the sample chamber. This pressure is referred to as the *confining stress*. Then, the soil is loaded vertically to failure through a top piston. The confining stress is kept constant while the axial stress is varied. The radial component of the confining stress is called the *radial stress*, σ_R, and represents the minor principal stress, σ_3. The combined stresses at the ends of the sample (confining stress plus applied vertical stress) are called the *axial stress*, σ_A, and represent the major principal stress, σ_1.[14]

Results of a triaxial test at a given chamber pressure are plotted as a stress-strain curve. Two such examples are illustrated in Fig. 35.14. The axial component of

[13]In a physical sense, the angle of internal friction for cohesionless soils is the angle from the horizontal naturally formed by a pile. For example, a uniform fine sand makes a pile with a slope of approximately 30°. For most soils, the natural angle of repose will not be the same as the angle of internal friction, due to the effects of cohesion.
[14]In reality, the triaxial test apparatus is a "biaxial" device because it controls stresses in only two directions: radial and axial.

strain is measured and presented. The stress is the difference between the axial and radial stresses, also called the *deviator stress*, σ_D. The point of failure is usually chosen as the maximum deviator stress in the test (Fig. 35.14(a)). It can alternatively be chosen as the stress difference for which the strain is 20%, if the test does not reach a maximum before then (Fig. 35.14(b)).

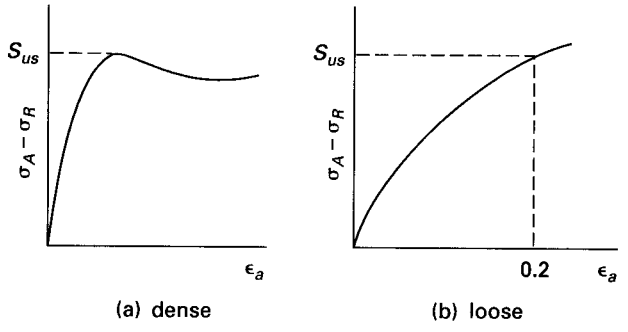

Figure 35.14 *Triaxial Test Stress-Strain Curves*

The normal and shear stresses on any plane can be found from the combined stress equations. The angle θ is measured counterclockwise from the horizontal (i.e., counterclockwise from the plane that σ_1 acts on). Compression is considered positive.

$$\sigma_\theta = \tfrac{1}{2}(\sigma_A + \sigma_R) + \tfrac{1}{2}(\sigma_A - \sigma_R)\cos 2\theta \qquad 35.38$$

$$\tau_\theta = \tfrac{1}{2}(\sigma_A - \sigma_R)\sin 2\theta \qquad 35.39$$

These equations generate points on Mohr's circle, which can easily be constructed once σ_A and σ_R are known. Representative test results are shown in Fig. 35.15 for two different samples that were both tested to failure. The failure envelope is the tangent to all of the Mohr's circles at failure.[15] The ultimate shear strength, s, can be read directly from the y-axis, or can be calculated from Eq. 35.37. The angle of internal friction can be calculated from Eq. 35.40.

$$\frac{\sigma_1}{\sigma_3} = \frac{1+\sin\phi}{1-\sin\phi} \qquad 35.40$$

[15]In the direct shear test, the stresses on the failure plane are measured directly, because the horizontal plane is forced to be the failure plane. In the triaxial test, the measured stresses are principal stresses, and therefore a Mohr's construction must be made to determine the stresses on the failure plane.

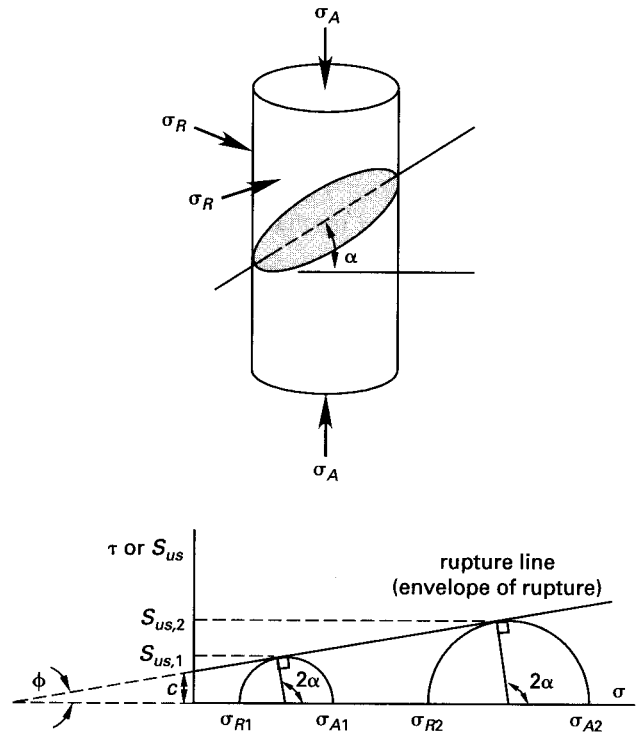

Figure 35.15 *Mohr's Circle of Stress*

The plane of failure is inclined at the following angle.

$$\alpha = 45^\circ + \tfrac{1}{2}\phi \qquad 35.41$$

For drained sands and gravels and for normally consolidated clays, the cohesion, c, is zero. Therefore, it is theoretically possible to draw the rupture line with only one test.

For saturated clays in quick (undrained) shear, it is commonly assumed that $\phi = 0$. This would be represented as a horizontal rupture line. For this condition only, the undrained strength, S_u, is

$$S_u = c = \frac{\sigma_D}{2} \qquad 35.42$$

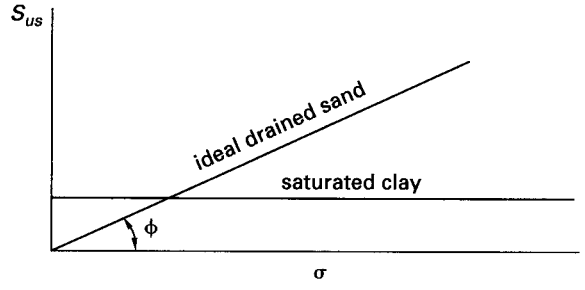

Figure 35.16 *Rupture Lines*

If a soil is saturated, an increase in load may be supported by either the soil grains at their contact points

or by an increase in the pore water pressure. How much each mode contributes to the support depends on the rate of loading and the permeability of the soil. Since water cannot carry a shear stress, the effective stress provides the shear strength of soils. The effective stress is the stress that is carried by the soil grains. The strength can be calculated from Eq. 35.43, where c' and ϕ' are the *effective stress parameters*.

$$s = c' + \sigma' \tan \phi' \qquad 35.43$$

The various categories of triaxial tests are shown in Fig. 35.13. Triaxial tests can be performed on consolidated or unconsolidated specimens, and they can be performed drained or undrained.

Table 35.13 *Categories of Triaxial Test*

	drained	undrained
consolidated	S-test CD test	R-test CU test
unconsolidated	(not performed)	Q-test UU test

The term "consolidated" refers to the state of the sample just prior to the shearing phase (when the axial stress, σ_A, is varied). In most triaxial tests, the soil is consolidated, which means that a stress simulating the in situ overburden stress is applied and the soil is allowed to drain freely until it is at equilibrium with this stress. The consolidation stress is applied as the pressure in the surrounding chamber.

The terms "drained" and "undrained" refer to conditions during the shearing phase. The distinction is only important for specimens that are fully saturated; for dry or partially saturated specimens, the behavior in an undrained test is similar to that in a drained test. In an undrained test, no pore water is allowed to move in or out of the sample, and the test is usually performed rapidly. In these tests, the shearing phase results in pore water pressure development. In a drained test, water is allowed to move in or out freely, and the test is performed slowly enough that the water drains before pore water pressure develops. The speed of testing is determined by the soil permeability. Clay soils must be tested quite slowly, and a drained test may take several weeks.

A slow, drained test following consolidation is known as an *S-test* (*slow test*) or a *consolidated-drained test* (*CD test*). A rapid, undrained test following consolidation is known as an *R-test* or *consolidated-undrained test* (*CU test*). The *Q-test* (*quick test*) is also known as an *unconsolidated-undrained test* (*UU test*).[16] In the Q-test, a chamber pressure is applied to the soil prior to the shearing phase but the soil is not allowed to drain or consolidate. Such a test is justified only with high-permeability (e.g., 10^{-3} cm/s or more) soils.[17]

R-tests are used to determine the effective stress parameters, c' and ϕ'. In the absence of pore pressure measurements, though, R-tests can only determine the total stress parameters c and ϕ.

Example 35.8

A sample of dry sand was taken and a triaxial test was performed. The added axial stress causing failure was 5.43 tons/ft^2 (520 kPa) when the radial stress was 1.5 tons/ft^2 (145 kPa). (a) What is the angle of internal friction? (b) What is the angle of the failure plane?

SI Solution

Draw a Mohr's circle to plot the stresses in two dimensions. The axial stress at failure is the combination of axial and radial loads.

$$\begin{aligned}\sigma_{A,f} &= p_R + p_A \\ &= 145 \text{ kPa} + 520 \text{ kPa} \\ &= 665 \text{ kPa}\end{aligned}$$

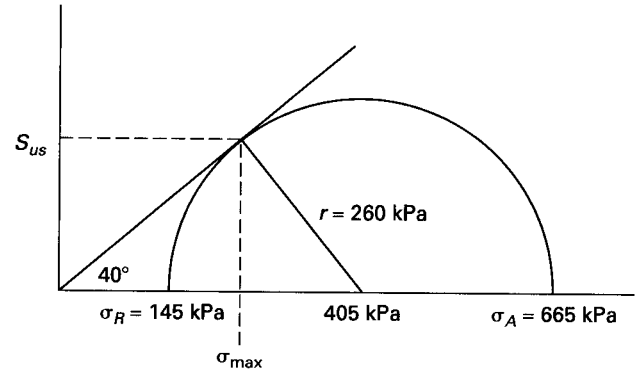
The center of the Mohr's circle is

$$\begin{aligned}\frac{\sigma_R + \sigma_{A,f}}{2} &= \frac{145 \text{ kPa} + 665 \text{ kPa}}{2} \\ &= 405 \text{ kPa}\end{aligned}$$

The radius of the circle is the distance from the center of the circle to the radial stress.

$$405 \text{ kPa} - 145 \text{ kPa} = 260 \text{ kPa}$$

(a) The failure envelope is tangent to the Mohr's circle. (It is assumed that $c = 0$ for dry sand.) From trigonometry,



$$\phi = \arcsin\left(\frac{260 \text{ kPa}}{405 \text{ kPa}}\right) = 40^\circ$$

(b) The angle of the failure plane is given by Eq. 35.41.

$$\alpha = 45^\circ + \tfrac{1}{2}(40^\circ) = 65^\circ$$

[16]The S-test, R-test, and Q-test designations are by the U.S. Army Corps of Engineers. The letter "R" for the R-test was chosen because R is between Q and S in the alphabet.

[17]There is no category for unconsolidated, drained testing. The theoretical justifications for performing Q-tests do not apply to drained testing of unconsolidated specimens.

Customary U.S. Solution

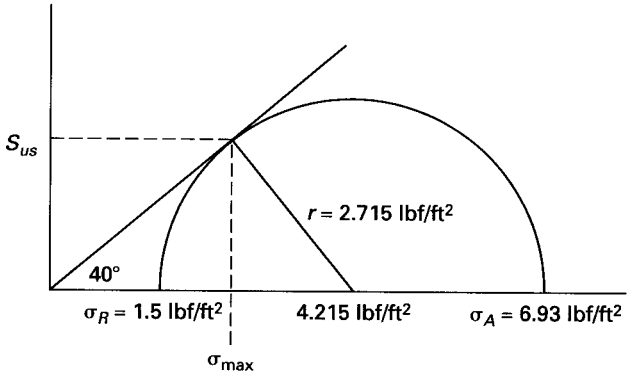
Draw a Mohr's circle to plot the stresses in two dimensions. The axial stress at failure is the combination of axial and radial loads.

$$\begin{aligned}\sigma_{A,f} &= p_R + p_A \\ &= 1.5\ \frac{\text{tons}}{\text{ft}^2} + 5.43\ \frac{\text{tons}}{\text{ft}^2} \\ &= 6.93\ \text{tons/ft}^2\end{aligned}$$

The center of the Mohr's circle is

$$\begin{aligned}\frac{\sigma_R + \sigma_{A,f}}{2} &= \frac{1.5\ \frac{\text{tons}}{\text{ft}^2} + 6.93\ \frac{\text{tons}}{\text{ft}^2}}{2} \\ &= 4.215\ \text{tons/ft}^2\end{aligned}$$

The radius of the circle is the distance from the center of the circle to the radial stress.



$$4.215\ \frac{\text{tons}}{\text{ft}^2} - 1.5\ \frac{\text{tons}}{\text{ft}^2} = 2.715\ \frac{\text{tons}}{\text{ft}^2}$$

(a) The failure envelope is tangent to the Mohr's circle. (It is assumed that $c = 0$ for dry sand.) From trigonometry,

$$\phi = \arcsin\left(\frac{2.715\ \frac{\text{tons}}{\text{ft}^2}}{4.215\ \frac{\text{tons}}{\text{ft}^2}}\right) = 40°$$

(b) The angle of the failure plane is given by Eq. 35.41.

$$\alpha = 45° + \tfrac{1}{2}(40°) = 65°$$

19. VANE-SHEAR TEST

The shear strength of a low-strength, homogeneous cohesive soil (e.g., clay) can be measured in situ by use of a *vane-shear apparatus*, consisting of a four-bladed vane on a vertical shaft. The blades are pushed into the soil and a torque is applied to the shaft until the apparatus rotates. When the soil is stressed to its shear strength, the vanes will rotate in the soil. Since the soil fails along a cylindrical surface, the shearing resistance can be calculated from the vane dimensions and the applied torque.

The sensitivity of the soil can be determined if the test is repeated after turning the sample several times and allowing the soil to remold.

20. UNCONFINED COMPRESSIVE STRENGTH TEST

In an *unconfined compressive strength test*, a cylinder of cohesive soil is loaded axially to compressive failure. Unlike in the triaxial test, there is no radial stress applied before the shearing phase of testing. This test can only be performed on soils that can stand without confinement, usually clays. The unconfined compressive strength test is equivalent to a UU-test (Q-test) in which the chamber pressure is zero.

The unconfined compressive strength is given by Eq. 35.44. The undrained shear strength is calculated as one half of the unconfined compressive strength.

$$S_{uc} = \frac{P}{A} \qquad 35.44$$

$$s_u = \frac{S_{uc}}{2} \qquad 35.45$$

21. SENSITIVITY

Clay will become softer as it is worked, and clay soils can turn into viscous liquids during construction. This tendency, known as *sensitivity*, is determined by measuring the ultimate strength of two samples, one that is undisturbed before testing and the other that has been fully disturbed, usually by mechanically remolding the soil. Although sensitivity is normally determined as the ratio of unconfined compression strengths, the two strength values compared could be from any two identical tests.

$$S_t = \frac{S_{\text{undisturbed}}}{S_{\text{remolded}}} \qquad 35.46$$

Table 35.14 *Sensitivity Classifications*

sensitivity	class
1–4	insensitive clays
4–8	sensitive
8–16	extra sensitive
> 16	quick

22. CALIFORNIA BEARING RATIO TEST

The *California bearing ratio* (CBR) test is used to determine the suitability of a soil for use as a subbase in pavement sections.[18] It is most reliable when used to test cohesive soils. The test measures the relative load required to cause a standard 3 in^2 (19.3 cm^2) plunger to penetrate a water-saturated soil specimen at a specific rate to a specific depth. The word "relative" is used because the actual load is compared to a standard load derived from a sample of crushed stone. The ratio is multiplied by 100, and the result is reported without a percentage symbol.

The resulting data will be in the form of inches of penetration versus load. This data can be plotted as shown in Fig. 35.17. If the plot is concave upward (curve B), the steepest slope is extended downward to the x-axis. This point is taken as the zero penetration point, and all penetration values are adjusted accordingly.

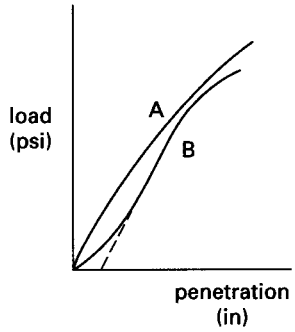


Figure 35.17 *Plotting CBR Test Data*

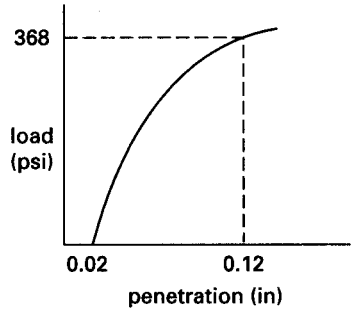
Standard loads for crushed stone are given in Table 35.15. For a plunger of 3 in^2 (19.3 cm^2), the CBR is the ratio of the load for a 0.1 in (2.54 mm) penetration divided by 1000 lbf/in^2 (6900 kPa). The CBR for 0.2 in (5.08 mm) should also be calculated. The test should be repeated if $CBR_{0.2} > CBR_{0.1}$. If the results are similar, $CBR_{0.2}$ should be used.

$$\text{CBR} = \frac{\text{actual load}}{\text{standard load}} \times 100 \qquad 35.47$$

Table 35.15 *Standard CBR Loads*

depth of penetration (in)	standard load lbf/in^2 (MPa)
0.1	1000 (7)
0.2	1500 (10)
0.3	1900 (13)
0.4	2300 (16)
0.5	2600 (18)

(Multiply in by 25.4 to obtain mm.)
(Multiply lbf/in^2 by 0.00689 to obtain MPa.)



[18]California's Department of Transportation (CALTRANS) was the first to make use of the CBR test. However, other states and the Army Corps of Engineers have adopted CBR testing techniques. These states have, generally, retained the California bearing ratio test name for the test.

Table 35.16 *Typical CBR Values*

group symbol	range of CBR values
GW	40–80
GP	30–60
GM	20–60
GC	20–40
SW	20–40
SP	10–40
SM	10–40
SM-SC	5–30
SC	5–20
ML	≤ 15
ML-CL	–
CL	≤ 15
OL	≤ 5
MH	≤ 10
CH	≤ 15
OH	≤ 5

Example 35.9

The following load data are collected for a 3 in^2 plunger test. What is the California bearing ratio?

penetration (in)	load (lbf/in^2)
0.025	20
0.050	130
0.075	230
0.100	320
0.125	350
0.150	470
0.175	530
0.200	600
0.250	700
0.300	830

Solution

After graphing the data, it is apparent that a 0.02 in correction is required. Therefore, the 0.1 in load is read from the graph as a 0.12 in load.

From Eq. 35.47,

$$CBR_{0.1} = \frac{368\ \frac{\text{lbf}}{\text{in}^2}}{1000\ \frac{\text{lbf}}{\text{in}^2}} \times 100$$
$$= 36.8$$

$$CBR_{0.2} = \frac{645\ \frac{\text{lbf}}{\text{in}^2}}{1500\ \frac{\text{lbf}}{\text{in}^2}} \times 100$$
$$= 43.0$$

Since $CBR_{0.2}$ is greater than $CBR_{0.1}$, the test should be repeated.

23. PLATE BEARING VALUE TEST

The *plate bearing value test* is performed on compacted soil in the field and provides an indication of the shear strength of pavement components. A standard diameter round steel plate is set over the soil on a bedding of fine sand or plaster of paris. Smaller diameter plates are placed on top of the bottom plate to ensure rigidity. After the plate is seated by a quick but temporary load, it is loaded to a deflection of about 0.04 in (1 mm). This load is maintained until the deflection rate decreases to 0.001 in/min (0.03 mm/min). The load is then released. The deflection prior to loading, the final deflection, and the deflection each minute are recorded.

The test is repeated 10 times. For each repetition of each load, the endpoint deflection is found for which the deflection rate is exactly 0.001 in/min (0.03 mm/min). The loads are then corrected for dead weights of jacks, plates, and so on.

The corrected load versus the corrected deflection is graphed for the 10th repetition. The bearing value is the interpolated load that would produce a deflection of 0.5 in (12 mm). The *subgrade modulus* (*modulus of subgrade reaction*), k, is the slope of the line (in psi per inch) in the loading range encountered by the soil.

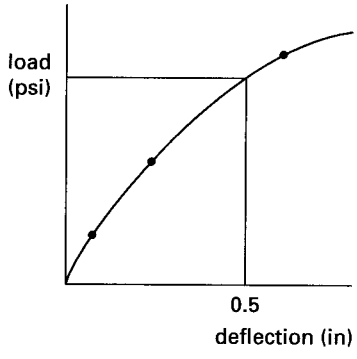


Figure 35.18 *10th Repetition Bearing Load*

Table 35.17 *Typical Values of the Subgrade Modulus*

group symbol	range of subgrade modulus, k, psi/in (kPa/mm)
GW	300–500 (80–140)
GP	250–400 (68–110)
GM	100–400 (27–110)
GC	100–300 (27–80)
SW	200–300 (54–80)
SP	200–300 (54–80)
SM	100–300 (27–80)
SM-SC	100–300 (27–80)
SC	100–300 (27–80)
ML	100–200 (27–54)
ML-CL	–
CL	50–200 (14–54)
OL	50–100 (14–27)
MH	50–100 (14–27)
CH	50–150 (14–41)
OH	25–100 (6.8–27)

(Multiply psi/in by 0.2714 to obtain kPa/mm.)

24. HVEEM'S RESISTANCE VALUE TEST

Hveem's resistance value test is performed to evaluate the suitability of a soil for use in pavement sections. The term "resistance" refers to the ability of a soil to resist lateral deformation when a vertical load acts upon it. When displacement does occur, the soil moves out and away from the applied load.

The *R-value* (*resistance value*) of a soil is measured in a *stabilometer test*. The R-value will range from zero (the resistance of water) to 100 (the approximate resistance of steel). Typical values are clay, 5–15; sandy clay, 10–20; clayey silts, 20–35; sandy silts, 20–55; silty sands, 25–70; sand, 40–75; gravel, 20–80; and good crushed rock, 75–90.

The R-value is determined using soil samples that are compacted as they would be during normal construction. They are tested as near to saturation as possible to give the lowest expected R-value. Thus, the R-value represents the worst possible state the soil might attain during use.

When a compacted soil expands due to the absorption of water, damage such as pavement distortion may result. A determination of expansion pressures is usually performed along with the R-value test.

PRACTICE PROBLEMS

Properties and Classification

1. A clay has the following Atterberg limits: liquid limit = 60, plastic limit = 40, and shrinkage limit = 25. The clay shrinks from 15 cm^3 to 9.57 cm^3 when the

moisture content is decreased from the liquid limit to the shrinkage limit in the Atterberg tests. What is the clay's specific gravity (dry)?

(A) 2.0
(B) 2.3
(C) 2.5
(D) 2.7

The answer is D.

2. A sample of soil has the following characteristics.

% passing #40 screen	95
% passing #200 screen	57
liquid limit	37
plastic limit	18

What are the AASHTO classification and group index number?

(A) A-5(6)
(B) A-5(8)
(C) A-6(8)
(D) A-7(5)

The answer is C.

3. (*Time limit: one hour*) A sample of moist soil was found to have the following characteristics:

volume	0.514 ft^3 (as sampled)
mass	56.74 lbm (as sampled)
	48.72 lbm (after oven drying)
specific gravity of solids	2.69

After drying, the soil was run through a set of sieves with the following percentages passing through each sieve.

sieve	% finer by mass
$\frac{1}{2}$ in	52
#4	37
#10	32
#20	23
#40	11
#60	7
#100	4

(a) What is the density of the in situ soil?

(A) 92 lbm/ft^3
(B) 98 lbm/ft^3
(C) 110 lbm/ft^3
(D) 120 lbm/ft^3

The answer is (C).

(b) What is the unit weight of the in situ soil?

(A) 92 lbf/ft^3
(B) 98 lbf/ft^3
(C) 110 lbf/ft^3
(D) 120 lbf/ft^3

The answer is (C).

(c) What is the void ratio of the in situ soil?

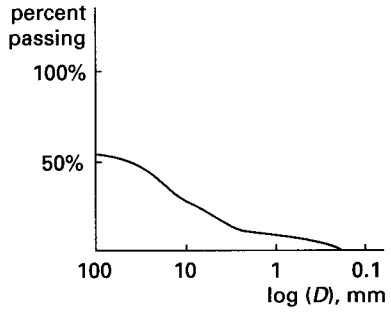
(A) 0.77
(B) 0.80
(C) 1.00
(D) 1.60

The answer is (A).

(d) What is the porosity of the in situ soil?

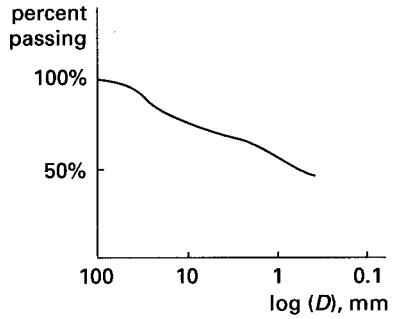
(A) 0.44
(B) 0.57
(C) 0.77
(D) 0.98

The answer is (A).



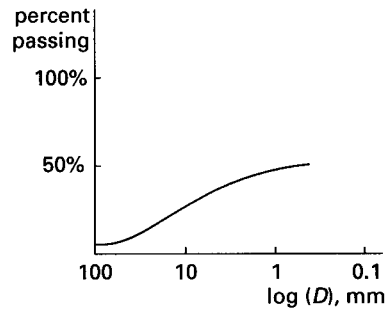
(e) What is the degree of saturation of the in situ soil?

(A) 44%
(B) 57%
(C) 78%
(D) 95%



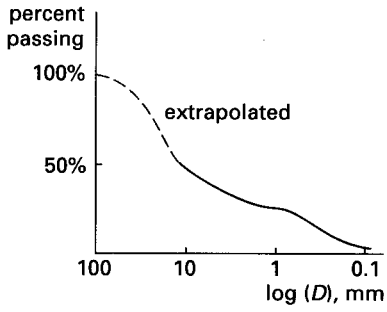
The answer is (B).

(f) Which of the figures represents the particle size distribution of the soil?



(A)

(B)



(C)

Geotechnical

(D)

The answer is (D).

(g) What is the uniformity coefficient?
(A) 35
(B) 40
(C) 43
(D) 57

The answer is (C).

(h) What is the coefficient of curvature?
(A) 0.38
(B) 0.40
(C) 0.51
(D) 0.68

The answer is (A).

(i) What is the USCS classification of the soil?
(A) GW
(B) GP
(C) SW
(D) SM

The answer is (B).

(j) What is the AASHTO classification of the soil?
(A) A-1-a
(B) A-1-b
(C) A-2-4
(D) A-2-7

The answer is (A).

Permeability Test

4. A permeability test is conducted with a sample of soil that is 60 mm in diameter and 120 mm long. The head is kept constant at 225 mm. The flow is 1.5 mL in 6.5 min. What is the coefficient of permeability?
(A) 4.4 m/yr
(B) 12 m/yr
(C) 17 m/yr
(D) 23 m/yr

The answer is (D).

Proctor Test

5. A Proctor test was performed on a soil that has a specific gravity of solids of 2.71. The following results were obtained.

water content (%)	total density (lbf/ft^3)
10	98
13	106
16	119
18	125
20	129
22	128
25	123

(a) Plot the moisture versus dry density curve.

(b) What is the maximum dry specific weight?
(A) 97 lbf/ft^3
(B) 103 lbf/ft^3
(C) 108 lbf/ft^3
(D) 112 lbf/ft^3

The answer is (C).

(c) What is the optimum moisture content?
(A) 12%
(B) 17%
(C) 20%
(D) 24%

The answer is (C).

(d) What range of moisture is permitted if a contractor must achieve 90% compaction?
(A) 12–23%
(B) 14–26%
(C) 18–28%
(D) 20–24%

The answer is (B).

6. For the soil in Prob. 5, what volume of water must be added to obtain 1 yd^3 of soil at the maximum density if the soil is originally at 10% water content (dry basis)?
(A) 6 gal
(B) 14 gal
(C) 18 gal
(D) 31 gal

The answer is (D).

Borrow Soil

7. Specifications on a job require a fill using borrow soil to be compacted to 95% of its standard Proctor maximum dry density. Tests indicate that this maximum is

124.0 lbm/ft^3 when dry. The soil now has 12% moisture. The borrow material has a void ratio of 0.60 and a solid specific gravity of 2.65. What is the minimum volume of borrow soil required per 1.0 ft^3 of fill volume?

(A) 0.90 ft^3
(B) 1.1 ft^3
(C) 1.3 ft^3
(D) 1.5 ft^3

The answer is (B).

8. (*Time limit: one hour*) Two choices for borrow soil are available.

	borrow A	borrow B
density in place	115 lbm/ft^3	120 lbm/ft^3
density in transport		95 lbm/ft^3
void ratio in transport	0.92	
water content in place	25%	20%
cost to excavate	\$0.20/yd^3	\$0.10/yd^3
cost to haul	\$0.30/yd^3	\$0.40/yd^3
SG of solids	2.7	2.7
maximum Proctor dry density	112 lbm/ft^3	110 lbm/ft^3

It will be necessary to fill a 200,000 yd^3 depression, and the fill material must be compacted to 95% of the standard Proctor (maximum) density. A final 10% moisture content (dry basis) is desired in either case.

(a) What would be the volume of borrow from site A?

(A) 4.8×10^6 ft^3
(B) 5.4×10^6 ft^3
(C) 5.6×10^6 ft^3
(D) 6.3×10^6 ft^3

The answer is (D).

(b) What would be the volume of borrow from site B?

(A) 4.8×10^6 ft^3
(B) 5.4×10^6 ft^3
(C) 5.6×10^6 ft^3
(D) 6.3×10^6 ft^3

The answer is (C).

(c) What soil would be cheaper to use?

(A) borrow A by \$6200
(B) borrow A by \$7400
(C) borrow B by \$4500
(D) borrow B by \$19,000

The answer is (B).

Triaxial Shear Test

9. A triaxial shear test is performed on a well-drained sand sample. At failure, the normal stress on the failure plane was 6260 lbf/ft^2 and the shear stress on the failure plane was 4175 lbf/ft^2.

(a) What is the angle of internal friction?

(A) 16°
(B) 28°
(C) 34°
(D) 42°

The answer is (C).

(b) What is the maximum principal stress?

(A) 9000 lbf/in^2
(B) 14,000 lbf/in^2
(C) 16,000 lbf/in^2
(D) 22,000 lbf/in^2

The answer is (B).

10. (*Time limit: one hour*) Two series of triaxial shear tests on a soil were performed with the following results. (All values are in lbf/in^2.)

Undrained series:

confining pressure	total axial stress
0	60
50	110
100	160

Drained series:

confining pressure	total axial stress
50	250
100	400
150	550

(a) What is the angle of internal friction for the undrained series?

(A) 0°
(B) 5°
(C) 12°
(D) 23°

The answer is (A).

(b) What is the angle of internal friction for the drained series?

(A) 10°
(B) 20°
(C) 30°
(D) 40°

The answer is (C).

(c) What is the cohesion for the undrained series?

(A) 30 psi
(B) 90 psi
(C) 180 psi
(D) 280 psi

The answer is (A).

(d) What is the cohesion for the drained series?

(A) 17 psi
(B) 23 psi
(C) 29 psi
(D) 45 psi

The answer is (C).

(e) What is the angle of the failure plane (with respect to the horizontal axis) for the undrained series?

(A) 0
(B) 15°
(C) 30°
(D) 45°

The answer is (D).

(f) What is the angle of the failure plane (with respect to the horizontal axis) for the drained series?

(A) 15°
(B) 39°
(C) 45°
(D) 60°

The answer is (D).

(g) Given a fourth test of the drained sample with a radial confining pressure of 300 lbf/in^2, what is the expected axial load at failure?

(A) 550 lbf/in^2
(B) 1000 lbf/in^2
(C) 1200 lbf/in^2
(D) 1600 lbf/in^2

The answer is (B).

11. (*Time limit: one hour*) A consolidated, undrained (CU) triaxial test was performed on a normally consolidated, saturated clay. The minor principal stress, σ_3, at the start of the test was 100 kPa. The deviator stress, σ_D, at failure was 60 kPa. The excess pore pressure, Δu, was measured during the test, and at failure it was 45 kPa.

(a) What is the undrained strength at failure, S_u?

(A) 15 kPa
(B) 30 kPa
(C) 40 kPa
(D) 60 kPa

The answer is (B).

(b) What is the total minor principal stress at failure, σ_{3f}?

(A) 40 kPa
(B) 55 kPa
(C) 60 kPa
(D) 100 kPa

The answer is (D).

(c) What is the total major principal stress at failure, σ_{1f}?

(A) 30 kPa
(B) 40 kPa
(C) 130 kPa
(D) 160 kPa

The answer is (D).

(d) What is the effective minor principal stress at failure, σ'_{3f}?

(A) 30 kPa
(B) 55 kPa
(C) 60 kPa
(D) 100 kPa

The answer is (B).

(e) What is the effective major principal stress at failure, σ'_{1f}?

(A) 60 kPa
(B) 100 kPa
(C) 120 kPa
(D) 160 kPa

The answer is (C).

(f) What is the effective friction angle, ϕ'?

(A) 21°
(B) 22°
(C) 26°
(D) 31°

The answer is (A).

(g) What is the angle of the failure plane, α?

(A) 37°
(B) 45°
(C) 55°
(D) 61°

The answer is (C).

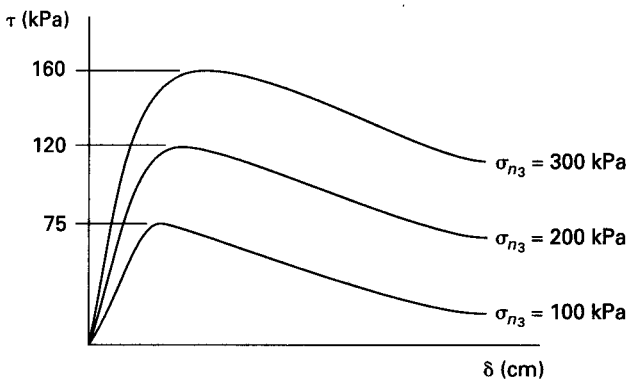
(h) What is the effective normal stress on the failure plane at failure, σ_{nf}?

(A) 66 kPa
(B) 74 kPa
(C) 85 kPa
(D) 130 kPa

The answer is (B).

(i) What is the shear stress on the failure plane at failure, τ_{nf}?

(A) 28 kPa
(B) 30 kPa
(C) 37 kPa
(D) 60 kPa



The answer is (A).

(j) What is another name for this type of test?
(A) S-test
(B) R-test
(C) unconfined compressive test
(D) CBR test

The answer is (B).

Direct Shear Test

12. (*Time limit: one hour*) A sandy clay soil was tested in a direct shear apparatus, with the following results.

(a) What is the friction angle?
(A) 7°
(B) 14°
(C) 23°
(D) 29°

The answer is (C).

(b) What is the cohesion intercept?
(A) 24 kpa
(B) 33 kPa
(C) 57 kPa
(D) 86 kPa

The answer is (B).

Consolidation Test

13. A sample of sand has a relative density of 40% with a solids specific gravity of 2.65. The minimum void ratio is 0.45, and the maximum void ratio is 0.97.

(a) What is the specific weight of the sand in a saturated condition?
(A) 94 lbf/ft^3
(B) 116 lbf/ft^3
(C) 121 lbf/ft^3
(D) 137 lbf/ft^3

The answer is (C).

(b) If the sand is compacted to a relative density of 65%, what will be the decrease in thickness of a layer 4 ft thick?
(A) 0.1 ft
(B) 0.2 ft
(C) 0.3 ft
(D) 0.4 ft

The answer is (C).

14. A consolidation test is performed on a soil with the following results.

pressure (lbf/ft^2)	void ratio, e
250	0.755
520	0.754
1040	0.753
2090	0.750
4180	0.740
8350	0.724
16,700	0.704
33,400	0.684
8350	0.691
250	0.710

(a) Graph the curve of stress versus void ratio on log or semilog paper.

(b) What is the preconsolidation pressure?
(A) 4400 lbf/ft^2
(B) 6200 lbf/ft^2
(C) 8900 lbf/ft^2
(D) 12,000 lbf/ft^2

The answer is (A).

(c) What is the compression index?
(A) 0.0053
(B) 0.090
(C) 0.17
(D) 0.25

The answer is (B).

1. SHALLOW FOUNDATIONS

A *foundation* is the part of an engineered structure that transmits the structure's forces into the soil or rock that supports it. The shape, depth, and materials of the foundation design depend on many factors including the structural loads, the existing ground conditions, and local material availability.

The term *shallow foundation* refers to a foundation system in which the depth of the foundation is shallow relative to its width, usually $D_f/B \leq 1$. This category of foundations includes spread footings, continuous (or wall) footings, and mats.

The main considerations in designing shallow foundations are ensuring against bearing capacity failures and excessive settlements. *Bearing capacity* is the ability of the soil to support the foundation loads without shear failure. *Settlement* is the tendency of soils to deform (densify) under applied loads. Since structures can tolerate only a limited amount of settlement, foundation design will often be controlled by settlement criteria, because soil usually deforms significantly before it fails in shear. Methods of calculating foundation settlements are reviewed in Chap. 40. The most damaging settlements are *differential settlements*—those that are not uniform across the supported area. Excessive settlements may only lead to minor damage such as cracked floors and walls, windows and doors that do not operate correctly, and so on. However, bearing capacity failures have the potential to cause major damage or collapse.

2. SAND VERSUS CLAY

Ordinarily, sand makes a good foundation material. Sand is usually strong, and it drains quickly. It may have an initial, "immediate" settlement upon first loading, but this usually is small and is complete before most architectural elements (drywall, brick, glass), which are rigid and more susceptible to settlement damage, are

constructed. However, it behaves poorly in excavations because it lacks cohesion. When sand is loose and saturated, it can become "quick" (i.e., liquefy), and a major loss in supporting strength occurs.

Clay is generally good in excavations but poor in foundations. Clay strength is usually lower than that of sand. Clays retain water, are relatively impermeable, and do not drain freely. Settlement in clays continues beyond the end of construction, and significant settlement can continue for years or even indefinitely. Large volume changes result from *consolidation*, which is the squeezing out of water from the pores as the soil comes to equilibrium with the applied loads.

A slightly different approach to calculating bearing capacity is used for sands and clays. Clays are not free-draining, so an undrained approach is used as the critical condition. But soils do not always fall into a pure category of "sand" or "clay." Silt, for example, is an intermediate soil type that will behave like a sand or a clay depending on the fraction of clay minerals it possesses. Many soils are a mixture of sand, silt, and clay. It is necessary to use engineering judgment when applying the bearing capacity equations to intermediate soils.

3. GENERAL CONSIDERATIONS FOR FOOTINGS

A *footing* is an enlargement at the base of a load-supporting column that is designed to transmit forces to the soil. The area of the footing will depend on the load and the soil characteristics. Several types of footings are used. A *spread footing* is a footing used to support a single column. This is also known as an *individual column footing* or an *isolated footing*. A *continuous footing*, also known as a *wall footing*, is a long footing supporting a continuous wall. A *combined footing* is a footing carrying more than one column. A *cantilever footing* is a combined footing that supports a column and an exterior wall or column.

Footings should be designed according to the following general considerations.

- The footing should be located below the frost line and below the level affected by seasonal moisture content changes.
- Footings do not need to be any lower than the bottom of the highest inadequate stratum (layer). Inadequate strata include disturbed or compressible soils, uncompacted fills, and soils that are susceptible to erosion or scour.
- The foundation should be safe against overturning, sliding, and uplift. The resultant of the applied load should coincide with the middle third of the footing.
- The allowable soil pressure should not be exceeded.
- Loose sand should be densified prior to putting footings on it. "Loose" is roughly defined as $D_R < 50\%$ for natural sands and RC < 90% (modified Proctor) for compacted sands or fill.
- Footings should be sized to the nearest 3 in (0.075 m) greater than or equal to the theoretical size.

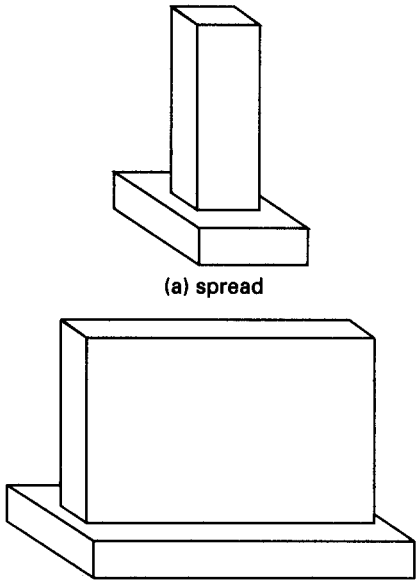

Figure 36.1 *Types of Footings*

4. ALLOWABLE BEARING CAPACITY

The *allowable bearing capacity* (also known as the *net allowable bearing pressure* or *safe bearing pressure*) is the net pressure in excess of the overburden stress that will not cause shear failure or excessive settlements. This is the soil pressure that is used to design the foundation. (The term "allowable" means that a factor of safety has already been applied.) When data from soil tests are unavailable, Table 36.1 can be used for preliminary calculations.

Table 36.1 *Typical Allowable Soil Bearing Capacities*[a]

	allowable pressure	
type of soil	(tons/ft^2)	(kPa)
massive crystalline bedrock	2	200
sedimentary and foliated rock	1	100
sandy gravel and/or gravel (GW and GP)	1	100
sand, silty sand, clayey sand, silty gravel, and clayey gravel (SW, SP, SM, SC, GM, and GC)	0.75	75
clay, sandy clay, silty clay, and clayey silt (CL, ML, MH, and CH)	0.5	50

(Multiply tons/ft^2 by 95.8 to obtain kPa.)
[a]Inclusive of a factor of safety

5. GENERAL BEARING CAPACITY EQUATION

With *general shear failures*, the soil resists an increased load until a sudden failure occurs. *Local shear failure* occurs in looser, more compressible soils and at high bearing pressures. The boundaries between these types of behavior are not distinct, and the methods of calculating general shear failure are commonly used for most soil conditions.

The *ultimate* (or *gross*) *bearing capacity* for a shallow wall footing is given by Eq. 36.1, which is known as the *Terzaghi-Meyerhof equation*. The equation is valid for both sandy and clayey soils. p_q is an additional surface surcharge, if any.

$$q_{\text{ult}} = \tfrac{1}{2}\rho g B N_\gamma + cN_c + (p_q + \rho g D_f)N_q \quad \text{[SI]} \quad \textit{36.1(a)}$$

$$q_{\text{ult}} = \tfrac{1}{2}\gamma B N_\gamma + cN_c + (p_q + \gamma D_f)N_q \quad \text{[U.S.]} \quad \textit{36.1(b)}$$

Various researchers have made improvements on the theory supporting this equation, leading to somewhat different terms and sophistication in evaluating N_γ, N_c, and N_q. The approaches differ in the assumptions made of the shape of the failure zone beneath the footing. However, the general form of the equation is the same in most cases.

Figure 36.2 and Table 36.2 can be used to evaluate the *capacity factors* N_γ, N_c, and N_q in Eq. 36.1. Alternatively, Table 36.3 can be used. The bearing capacity factors in Table 36.2 are based on Terzaghi's 1943 studies. The values in Table 36.3 are based on Meyerhof's 1955 studies and others, and have been widely used. Other values are also in use.

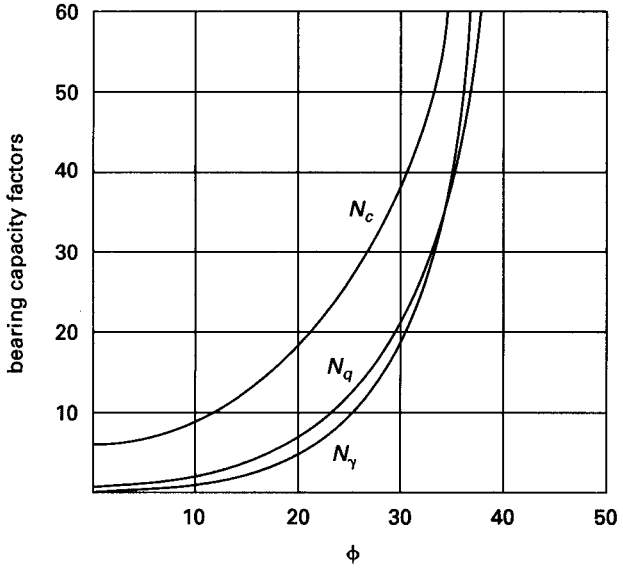

Figure 36.2 *Terzaghi Bearing Capacity Factors*

Table 36.2 *Terzaghi Bearing Capacity Factors for General Shear*

ϕ	N_c	N_q	N_γ
0	5.7	1.0	0.0

[a] As predicted by the Vesic equation, $N_\gamma = 2(N_q + 1)\tan\phi$.

Equation 36.1 is appropriate for a foundation in a continuous wall footing. Corrections for various footing geometries, called *shape factors*, are presented in Tables 36.4 and 36.5 using the parameters identified in Fig. 36.3. The bearing capacity factors N_c and N_γ are multiplied by the appropriate shape factors when they are used in Eq. 36.1.

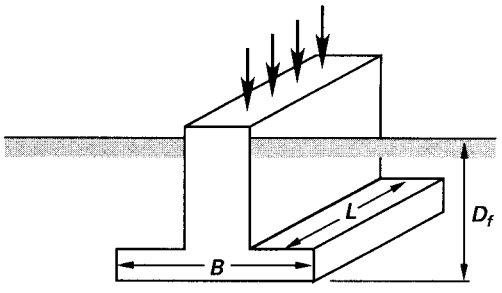

Figure 36.3 *Spread Footing Dimensions*

Geotechnical

1 (circular)	0.70

Several researchers have recommended corrections to N_c to account for footing depth. (Corrections to N_q for footing depth have also been suggested. No corrections to N_γ for footing depth have been suggested.) There is considerable variation in the method of calculating this correction, if it is used at all. A multiplicative correction factor, d_c, which is used most often, has the form

$$d_c = 1 + \frac{KD_f}{B} \qquad 36.2$$

K is a constant for which values of 0.2 and 0.4 have been proposed. The depth factor correction is applied to N_c along with the shape factor correction in Eq. 36.1.

Once the ultimate bearing capacity is determined, it is corrected by the *overburden*, giving the *net bearing capacity*. This is the net pressure the soil can support beyond the pressure applied by the existing overburden.

$$q_{\text{net}} = q_{\text{ult}} - \rho g D_f \quad \text{[SI]} \qquad 36.3(a)$$

$$q_{\text{net}} = q_{\text{ult}} - \gamma D_f \quad \text{[U.S.]} \qquad 36.3(b)$$

The *allowable bearing capacity* is determined by dividing the net capacity by a factor of safety. The safety factor accounts for the uncertainties in evaluating soil properties and anticipated loads, and also on the amount of risk involved in building the structure. A safety factor between 2 and 3 (based on q_{net}) is common for average conditions. Smaller safety factors are sometimes used for transient load conditions such as from wind and seismic forces.

$$q_a = \frac{q_{\text{net}}}{F} \qquad 36.4$$

6. BEARING CAPACITY OF CLAY

Clay is often soft and fairly impermeable. When loads are first applied to saturated clay, the pore pressure increases. For a short time, this pore pressure does not dissipate, and the angle of internal friction should be taken as $\phi = 0°$. This is known as the $\phi = 0°$ case or the *undrained case*, which is the critical condition for saturated clays. As discussed in Chap. 35, the undrained shear strength of clays is equal to the cohesion, which is one-half of the unconfined compressive strength.

$$S_u = c = \frac{S_{\text{uc}}}{2} \qquad 36.5$$

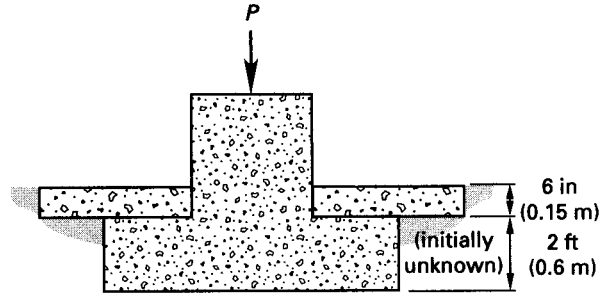
If $\phi = 0°$, then $N_\gamma = 0$ and $N_q = 1$. If there is no surface surcharge (i.e., $p_q = 0$), the ultimate bearing capacity is given by Eq. 36.6.

$$q_{\text{ult}} = cN_c + \rho g D_f \quad \text{[SI]} \qquad 36.6(a)$$

$$q_{\text{ult}} = cN_c + \gamma D_f \quad \text{[U.S.]} \qquad 36.6(b)$$

$$q_{\text{net}} = q_{\text{ult}} - \rho g D_f = cN_c \quad \text{[SI]} \qquad 36.7(a)$$

$$q_{\text{net}} = q_{\text{ult}} - \gamma D_f = cN_c \quad \text{[U.S.]} \qquad 36.7(b)$$



The allowable clay loading is based on a factor of safety, which is typically taken as 3 for clay.

$$q_a = \frac{q_{\text{net}}}{F} \qquad 36.8$$

From Eqs. 36.6 and 36.7, it is evident that the cohesion term dominates the bearing capacity in cohesive soil.

Example 36.1

An individual square column footing carries an 83,800 lbf (370 kN) dead load and a 75,400 lbf (335 kN) live load. The unconfined compressive strength of the supporting clay is 0.84 tons/ft^2 (80 kPa), and its specific weight is $\gamma = 115$ lbf/ft^3 ($\rho = 1840$ kg/m^3). The footing whose upper surface is flush with the original grade is covered by a 6.0 in (0.15 m) thick basement slab. The footing thickness is initially unknown. Neglect depth correction factors. Do not design the structural steel. Specify the footing size and thickness.

SI Solution

The strategy for determining the depth and width of the footing is to calculate the allowable bearing pressure, assume a width and depth that will support the dead load and live load, and then compare the actual

pressures on the footing with the allowable pressures, considering the effect of soil displacement by the concrete footing and slab.

From Eqs. 36.4 and 36.7, the allowable bearing capacity is

$$q_a = \frac{q_{\text{net}}}{F} = \frac{cN_c}{F}$$

From Table 36.2, the bearing capacity factor is $N_c = 5.7$. From Table 36.4, for square footings, the shape factor is 1.25. The cohesion is estimated from the unconfined compressive strength and Eq. 36.5.

$$c = \frac{S_{\text{uc}}}{2} = \frac{80 \text{ kPa}}{2} = 40 \text{ kPa}$$

Using a factor of safety of 3, the allowable pressure is

$$q_a = \frac{cN_c}{F}$$

$$= \frac{(40 \text{ kPa})(5.7)(1.25)}{3} = 94.7 \text{ kPa}$$

The total load on the column is

$$P = \text{DL} + \text{LL} = 370 \text{ kN} + 335 \text{ kN} = 705 \text{ kN}$$

The approximate area required is

$$A = \frac{705 \text{ kN}}{94.7 \text{ kPa}} = 7.44 \text{ m}^2$$

Try a 2.8 m square footing (area = 7.84 m^2). At this point, a footing thickness would be determined based on concrete design considerations, and it is reasonable to assume a 0.6 m footing thickness.

The actual pressure under the footing due to the applied column load is

$$p_{\text{actual}} = \frac{705 \text{ kN}}{7.84 \text{ m}^2} = 89.9 \text{ kPa} < q_a \quad \text{[OK]}$$

This first iteration did not consider the concrete weight. The concrete density is approximately 2400 kg/m^3. Therefore, the pressure surcharge due to 1 m^2 of concrete floor is

$$p_{\text{floor slab}} = (1 \text{ m})(1 \text{ m})(0.15 \text{ m}) \left(2400 \frac{\text{kg}}{\text{m}^3}\right) \left(9.81 \frac{\text{m}}{\text{s}^2}\right)$$

$$= 3.53 \text{ kPa}$$

Similarly, the footing itself has weight. The footing extends 0.6 m down.

$$p_{\text{footing}} = (1 \text{ m})(1 \text{ m})(0.6 \text{ m}) \left(2400 \frac{\text{kg}}{\text{m}^3}\right) \left(9.81 \frac{\text{m}}{\text{s}^2}\right)$$

$$= 14.13 \text{ kPa}$$

Equation 36.3 gives the allowable pressure in excess of the soil surcharge. The footing bottom is 0.75 m below the original grade, so the soil surcharge is

$$p_{\text{soil}} = (0.75 \text{ m}) \left(1840 \frac{\text{kg}}{\text{m}^3}\right) \left(9.81 \frac{\text{m}}{\text{s}^2}\right)$$

$$= 13.54 \text{ kPa}$$

Therefore, the total pressure under the footing is

$$p_{\text{total}} = 89.9 \text{ kPa} + 3.53 \text{ kPa} + 14.13 \text{ kPa} - 13.54 \text{ kPa}$$

$$= 94.02 \text{ kPa}$$

This is the net actual pressure to be compared to the allowable pressure.

$$p_{\text{net,actual}} = 94.02 \text{ kPa}$$

This is essentially the same as q_a (94.7 kPa).

Customary U.S. Solution

The strategy for determining the depth and width of the footing is to calculate the allowable bearing pressure, assume a width and depth that will support the dead load and live load, and then compare the actual pressures on the footing with the allowable pressures, considering the effect of soil displacement by the concrete footing and slab.

From Eqs. 36.4 and 36.7, the allowable bearing capacity is

$$q_a = \frac{q_{\text{net}}}{F} = \frac{cN_c}{F}$$

From Table 36.2, the bearing capacity factor is $N_c = 5.7$. From Table 36.4, for square footings, the shape factor is 1.25. The cohesion is estimated from the unconfined compressive strength and Eq. 36.5.

$$c = \frac{S_{\text{uc}}}{2} = \frac{0.84 \frac{\text{tons}}{\text{ft}^2}}{2}$$

$$= 0.42 \text{ tons/ft}^2$$

Using a factor of safety of 3, the allowable pressure is

$$q_a = \frac{cN_c}{F}$$

$$= \frac{\left(0.42 \frac{\text{tons}}{\text{ft}^2}\right)(5.7)(1.25)}{3} = 0.99 \text{ tons/ft}^2$$

The total load on the column is

$$P = \text{DL} + \text{LL}$$

$$= \frac{83{,}800 \text{ lbf} + 75{,}400 \text{ lbf}}{2000 \frac{\text{lbf}}{\text{ton}}}$$

$$= 79.6 \text{ tons}$$

Geotechnical

The approximate area required is

$$A = \frac{79.6 \text{ tons}}{0.99 \dfrac{\text{tons}}{\text{ft}^2}} = 80.4 \text{ ft}^2$$

Try a 9 ft 3 in square footing (area = 85.6 ft^2).

At this point, a footing thickness would be determined based on concrete design considerations, and it is reasonable to assume a 2 ft footing thickness.

The actual pressure under the footing due to the applied column load is

$$p_{\text{actual}} = \frac{79.6 \text{ tons}}{85.6 \text{ ft}^2}$$

$$= 0.93 \frac{\text{tons}}{\text{ft}^2} < q_a \quad \text{[OK]}$$

This first iteration did not consider the concrete weight. The concrete specific weight is approximately 150 lbf/ft^3. Therefore, the pressure surcharge due to 1 ft^2 of concrete floor slab is

$$p_{\text{floor slab}} = \frac{(1 \text{ ft})(1 \text{ ft})(6 \text{ in})\left(150 \dfrac{\text{lbf}}{\text{ft}^3}\right)}{\left(2000 \dfrac{\text{lbf}}{\text{ton}}\right)\left(12 \dfrac{\text{in}}{\text{ft}}\right)}$$

$$= 0.04 \text{ tons/ft}^2$$

Similarly, the footing itself has weight. The footing extends 2 ft down.

$$p_{\text{footing}} = \frac{(1 \text{ ft})(1 \text{ ft})(2 \text{ ft})\left(150 \dfrac{\text{lbf}}{\text{ft}^3}\right)}{2000 \dfrac{\text{lbf}}{\text{ton}}}$$

$$= 0.15 \text{ tons/ft}^2$$

Equation 36.3 gives the allowable pressure in excess of the soil surcharge. The footing bottom is 2.5 ft below the original grade, so the soil surcharge is

$$p_{\text{soil}} = \frac{(2.5 \text{ ft})\left(115 \dfrac{\text{lbf}}{\text{ft}^3}\right)}{2000 \dfrac{\text{lbf}}{\text{ton}}}$$

$$= 0.14 \text{ tons/ft}^2$$

The total pressure under the footing is

$$p_{\text{total}} = 0.93 \frac{\text{tons}}{\text{ft}^2} + 0.04 \frac{\text{tons}}{\text{ft}^2} + 0.15 \frac{\text{tons}}{\text{ft}^2} - 0.14 \frac{\text{tons}}{\text{ft}^2}$$

$$= 0.98 \text{ tons/ft}^2$$

This is the net actual pressure to be compared to the allowable pressure.

$$p_{\text{net,actual}} = 0.98 \text{ tons/ft}^2$$

This is essentially the same as q_a (0.99 tons/ft^2).

7. BEARING CAPACITY OF SAND

The *cohesion*, c, of ideal sand is zero. The ultimate bearing capacity can be derived from Eq. 36.1 by setting $c = 0$.

$$q_{\text{ult}} = \tfrac{1}{2} B \rho g N_\gamma + (p_q + \rho g D_f) N_q \quad \text{[SI]} \quad \textit{36.9(a)}$$

$$q_{\text{ult}} = \tfrac{1}{2} B \gamma N_\gamma + (p_q + \gamma D_f) N_q \quad \text{[U.S.]} \quad \textit{36.9(b)}$$

The net ultimate bearing capacity when there is no surface surcharge (i.e., $p_q = 0$) is

$$q_{\text{net}} = q_{\text{ult}} - \rho g D_f$$

$$= \tfrac{1}{2} B \rho g N_\gamma + \rho g D_f (N_q - 1) \quad \text{[SI]} \quad \textit{36.10(a)}$$

$$q_{\text{net}} = q_{\text{ult}} - \gamma D_f$$

$$= \tfrac{1}{2} B \gamma N_\gamma + \gamma D_f (N_q - 1) \quad \text{[U.S.]} \quad \textit{36.10(b)}$$

From Eqs. 36.9 and 36.10, it is evident that the depth term $\rho g D_f N_q$ dominates the bearing capacity in cohesionless soil. A small increase in depth increases the bearing capacity substantially.

The allowable bearing capacity is based on a factor of safety, which is typically taken as 2 for sand.

$$q_a = \frac{q_{\text{net}}}{F}$$

$$= \left(\frac{B}{F}\right)\left[\tfrac{1}{2} \rho g N_\gamma + \rho g (N_q - 1)\left(\frac{D_f}{B}\right)\right] \quad \text{[SI]} \quad \textit{36.11(a)}$$

$$q_a = \frac{q_{\text{net}}}{F}$$

$$= \left(\frac{B}{F}\right)\left[\tfrac{1}{2} \gamma N_\gamma + \gamma (N_q - 1)\left(\frac{D_f}{B}\right)\right] \quad \text{[U.S.]} \quad \textit{36.11(b)}$$

For common applications, Eq. 36.11 can be simplified. The quantity in brackets in Eq. 36.11 is constant for specific D_f/B ratios, and the bearing capacity factors depend on ϕ, which can be correlated to the *standard penetration test* (SPT) N-value in blows per foot. Assuming $F = 2$, $\gamma = 100$ lbf/ft^3, and $D_f < B$, Eq. 36.12 can be derived.

$$q_a = 0.11 C_n N \quad \text{[in tons/ft}^2\text{]} \quad \textit{36.12}$$

No correction is usually made to Eq. 36.12 if the density is different from 100 lbf/ft^3. However, the equation assumes that the overburden load (γD_f) is approximately

1 ton/ft^2. This means that the N-values will correspond to data from a depth of 10 to 15 ft below the original surface, not the basement surface. If the footing is to be installed close to the original surface, then a correction factor is required. (The correction is actually a correction for N. If corrected N-values are known, C_n may be neglected.) The potential failure zone extends into the soil below the footing, and it is common practice to evaluate N from the bottom of the footing to a depth B below the footing. The lowest average value of N from this zone is used to calculate the bearing capacity.

Table 36.6 *Overburden Corrections*

overburden (tons/ft^2 (kPa))	C_n
0 (0)	2
0.25 (24)	1.45
0.5 (48)	1.21
1.0 (96)	1.00
1.5 (144)	0.87
2.0 (192)	0.77
2.5 (240)	0.70
3.0 (287)	0.63
3.5 (335)	0.58
4.0 (383)	0.54
4.5 (431)	0.50
5.0 (479)	0.46

(Multiply tons/ft^2 by 95.8 to obtain kPa.)

For a given sand settlement, the soil pressure will be greatest in intermediate-width (B = 2 to 4 ft) footings. This is illustrated in Fig. 36.4. Equation 36.12 should not be used for small-width footings, since bearing pressure governs. For wide footings (i.e., $B > 2$ to 4 ft), settlement governs.

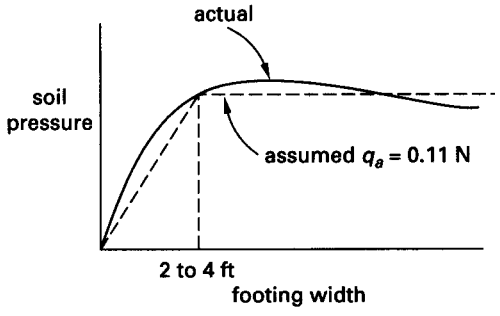


Figure 36.4 *Soil Pressure on Sand (Constant Settlement)*

8. BEARING CAPACITY OF ROCK

If bedrock can be reached by excavation, the allowable pressure is likely to be determined by local codes. A safety factor of 5 based on the unconfined compressive strength is typical. For most rock beds, the design will be based on settlement characteristics, not strength.

9. EFFECTS OF WATER TABLE ON FOOTING DESIGN

The presence of a water table within the soil support zone may or may not affect bearing capacity, according to the following principles.

General Principle 1: For cohesive ($\phi = 0°$) soils (e.g., clay), the location of the water table does not affect the bearing capacity, and the effect of the water table is disregarded. (Strictly speaking, the water table has some effect, but the theory predicts none. If $\phi = 0$, then $N_\gamma = 0$. Also, $N_q = 1$, which is essentially zero. These two terms "zero out" the density terms in Eq. 36.1.)

General Principle 2: For sand, use the *submerged density* $\gamma_b = \gamma_d - 62.4$ lbf/ft^3 (or, $\rho_b = \rho_d - 1000$ kg/m^3) in the equation for bearing capacity, Eq. 36.1. Since the submerged density is approximately half of the dry density, it is commonly stated that the bearing capacity of a footing with the water table at the ground surface is half of the dry bearing capacity, varying linearly to full strength at a distance B below the footing base. However, a more accurate estimate can be obtained from the following cases.

(a) When the water table is at the base of the footing, use the submerged density in the first term of Eq. 36.1 only. The bearing capacity is

$$q_{ult} = \tfrac{1}{2}\rho_b g B N_\gamma + \rho_d g D_f N_q \quad \text{[SI]} \quad \textit{36.13(a)}$$

$$q_{ult} = \tfrac{1}{2}\gamma_b B N_\gamma + \gamma_d D_f N_q \quad \text{[U.S.]} \quad \textit{36.13(b)}$$

(b) When the water table is at the surface, use the submerged density in both the first and third terms of Eq. 36.1.

$$q_{ult} = \tfrac{1}{2}\rho_b g B N_\gamma + \rho_b g D_f N_q \quad \text{[SI]} \quad \textit{36.14(a)}$$

$$q_{ult} = \tfrac{1}{2}\gamma_b B N_\gamma + \gamma_b D_f N_q \quad \text{[U.S.]} \quad \textit{36.14(b)}$$

(c) When the water table is between the base of the footing and the surface, use the submerged density in the first term as in (a) above. Calculate the third term in Eq. 36.1 as

$$\left(p_q + \rho_d g D_w + \left(\rho_d - 1000\ \frac{\text{kg}}{\text{m}^3}\right) g(D_f - D_w)\right) N_q = \left(p_q + \rho_d g D_f + \left(1000\ \frac{\text{kg}}{\text{m}^3}\right) g(D_w - D_f)\right) N_q \quad \text{[SI]} \quad \textit{36.15(a)}$$

$$\left(p_q + \gamma_d D_w + \left(\gamma_d - 62.4\ \frac{\text{lbf}}{\text{ft}^3}\right)(D_f - D_w)\right) N_q = \left(p_q + \gamma D_f + \left(62.4\ \frac{\text{lbf}}{\text{ft}^3}\right)(D_w - D_f)\right) N_q \quad \text{[U.S.]} \quad \textit{36.15(b)}$$

General Principle 3: For sand, if the water table depth, D_w, is greater than $D_f + B$ (i.e., more than a distance B below the base of the footing), the bearing capacity is not affected. Calculate the bearing capacity from Eq. 36.1 as if there was no water table.

$$q_{ult} = \tfrac{1}{2}\rho_d g B N_\gamma + \rho_d g D N_q \quad \text{[SI]} \quad \textit{36.16(a)}$$

$$q_{ult} = \tfrac{1}{2}\gamma_d B N_\gamma + \gamma_d D N_q \quad \text{[U.S.]} \quad \textit{36.16(b)}$$

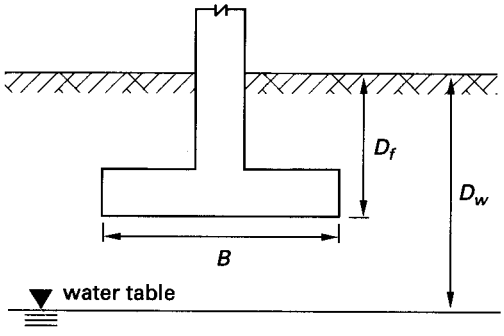

Figure 36.5 *Water Table Beneath a Footing*

10. ECCENTRIC LOADS ON RECTANGULAR FOOTINGS

If a rectangular footing carries a moment in addition to its vertical load, an eccentric loading situation is created. Under these conditions, the footing bearing capacity should be analyzed assuming an area in which the size is reduced by twice the eccentricity.

$$\epsilon_B = \frac{M_B}{P};\ \epsilon_L = \frac{M_L}{P} \qquad \textit{36.17}$$

$$L' = L - 2\epsilon_L;\ B' = B - 2\epsilon_B \qquad \textit{36.18}$$

$$A' = L'B' \qquad \textit{36.19}$$

This area reduction places the equivalent force at the centroid of the reduced area. The equivalent width B' should be used in Eq. 36.1, and both B' and L' should be used in the ratio B'/L' used to determine shape factors. The footing bearing capacity is reduced in two ways. First, a smaller B in Eq. 36.1 results in a smaller q_{ult} and q_a. Second, a smaller q_a results in a smaller allowable load (i.e., $P = q_a B' L'$).

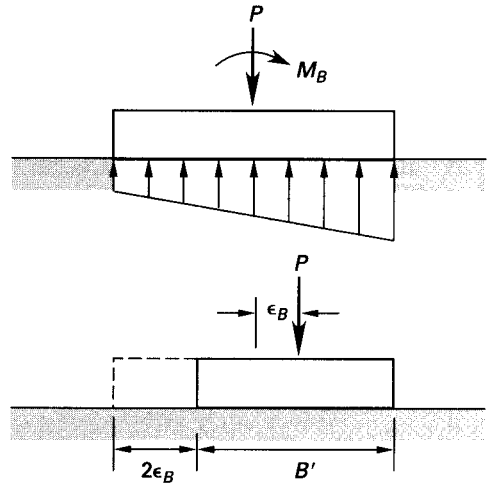

Figure 36.6 *Footing with Overturning Moment*

Although the eccentricity is independent of the footing dimensions, a trial-and-error solution may be necessary when designing footings. Trial and error is not required when analyzing a rectangular footing of known dimensions.

Assuming $M_L = 0$ and $\epsilon_B = \epsilon$ and disregarding the concrete and overburden weights, the actual soil pressure distribution is given by Eq. 36.20. B' and L' should not be used in Eq. 36.20 because these variables place the load at the centroid of the reduced area, assuming a uniform pressure distribution.

$$p_{max},\ p_{min} = \left(\frac{P}{BL}\right)\left(1 \pm \frac{6\epsilon}{B}\right) \qquad \textit{36.20}$$

If the eccentricity, ϵ, is sufficiently large, a negative soil pressure will result. Since soil cannot carry a tensile stress, such stresses are neglected. This results in a reduced area to carry the load.

If the resultant force is within the middle third of the footing, the contact pressures will be distributed over the entire footing. That is, the maximum eccentricity without incurring a reduction in footing contact area will be $B/6$.

11. GENERAL CONSIDERATIONS FOR RAFTS

A *raft* or *mat* foundation is a combined footing slab that usually covers the entire area beneath a building and supports all walls and columns. (The term *pad* is also used.) A raft foundation should be used (at least for economic reasons) any time the individual footings would constitute half or more of the area beneath a building. Rafts are also used to combine foundations with basement floor slabs, to minimize differential settlements over compressible soils, or to provide resistance to uplift.

12. RAFTS ON CLAY

The net or ultimate bearing capacity for rafts on clay is found in the same manner as for shallow footings. Since the size of the raft is usually fixed by the building size (within a few feet), the only method available to increase the loading is to lower the elevation (increase D_f) of the raft.

The factor of safety produced by a raft construction is given by Eq. 36.21, which can also be solved to give the required values of D_f if the factor of safety is known. The factor of safety should be at least 3 for normal loadings, but it may be reduced to 2 during temporary extreme loading.

$$F = \frac{cN_c}{\frac{\text{total load}}{\text{raft area}} - \rho g D_f} \quad \text{[SI]} \quad \textit{36.21(a)}$$

$$F = \frac{cN_c}{\frac{\text{total load}}{\text{raft area}} - \gamma D_f} \quad \text{[U.S.]} \quad \textit{36.21(b)}$$

If the denominator in Eq. 36.21 is small, the factor of safety is very large. If the denominator is zero, the raft is said to be a *fully compensated foundation*. In a fully compensated foundation, the loads imposed on the foundation by the structure are exactly equal to the weight of the soil that is excavated. For D_f less than the fully compensated depth, the raft is said to be a *partially compensated foundation*.

Example 36.2

A raft foundation is to be designed for a 120 ft × 200 ft (36 m × 60 m) building with a total loading of 5.66×10^7 lbf (2.5×10^5 5 kN). The clay specific weight is $\gamma = 115\ \text{lbf/ft}^3$ ($\rho = 1840\ \text{kg/m}^3$), and the clay has an average unconfined compressive strength of 0.3 tons/ft^2 (28 kPa). Neglect depth correction factors. (a) What should be the raft depth, D_f, for full compensation? (b) What should be the raft depth for a factor of safety of 3?

SI Solution

(a) For full compensation, by Eq. 36.21,

$$\frac{\text{total load}}{\text{raft area}} - \rho g D_f = 0$$

$$D_f = \frac{\frac{\text{total load}}{\text{raft area}}}{\rho g}$$

$$= \frac{(2.5 \times 10^5\ \text{kN})\left(1000\ \frac{\text{N}}{\text{kN}}\right)}{\left(1840\ \frac{\text{kg}}{\text{m}^3}\right)\left(9.81\ \frac{\text{m}}{\text{s}^2}\right)(36\ \text{m})(60\ \text{m})}$$

$$= 6.4\ \text{m}$$

(b) From Eq. 36.21,

$$F = \frac{cN_c}{\frac{\text{total load}}{\text{raft area}} - \rho g D_f}$$

From Table 36.2, $N_c = 5.7$. Since $B/L = 36\ \text{m}/60\ \text{m} = 0.6$, use an N_c multiplier of 1.15 from Table 36.4. The cohesion is calculated from Eq. 36.5.

$$c = \frac{S_{uc}}{2} = \frac{28.7\ \text{kPa}}{2} = 14.35\ \text{kPa}$$

$$D_f = \frac{\frac{\text{total load}}{\text{raft area}} - \frac{cN_c}{F}}{\rho g}$$

$$= \frac{\frac{(2.5 \times 10^5\ \text{kN})\left(1000\ \frac{\text{N}}{\text{kN}}\right)}{(36\ \text{m})(60\ \text{m})} - \frac{(14.35\ \text{kPa})\left(1000\ \frac{\text{N}}{\text{kN}}\right)(5.7)(1.15)}{3}}{\left(1840\ \frac{\text{kg}}{\text{m}^3}\right)\left(9.81\ \frac{\text{m}}{\text{s}^2}\right)}$$

$$= 4.7\ \text{m}$$

Customary U.S. Solution

(a) For full compensation, use Eq. 36.21.

$$\frac{\text{total load}}{\text{raft area}} - \gamma D_f = 0$$

$$D_f = \frac{\frac{\text{total load}}{\text{raft area}}}{\gamma}$$

$$= \frac{\frac{5.66 \times 10^7\ \text{lbf}}{(120\ \text{ft})(200\ \text{ft})}}{115\ \frac{\text{lbf}}{\text{ft}^3}}$$

$$= 20.5\ \text{ft}$$

(b) From Eq. 36.21,

$$F = \frac{cN_c}{\frac{\text{total load}}{\text{raft area}} - \gamma D_f}$$

From Table 36.2, $N_c = 5.7$. Since $B/L = 120\ \text{ft}/200\ \text{ft} = 0.6$, use an N_c multiplier of 1.15 from Table 36.4.

Geotechnical

The cohesion is calculated from Eq. 36.5.

$$c = \frac{S_{uc}}{2} = \frac{\left(0.3\ \frac{\text{ton}}{\text{ft}^2}\right)\left(2000\ \frac{\text{lbf}}{\text{ton}}\right)}{2}$$
$$= 300\ \text{lbf/ft}^2$$

$$D_f = \frac{\frac{\text{total load}}{\text{raft area}} - \frac{cN_c}{F}}{\gamma}$$
$$= \frac{\frac{5.66 \times 10^7\ \text{lbf}}{(120\ \text{ft})(200\ \text{ft})} - \frac{\left(300\ \frac{\text{lbf}}{\text{ft}^2}\right)(5.7)(1.15)}{3}}{115\ \frac{\text{lbf}}{\text{ft}^3}}$$
$$= 14.8\ \text{ft}$$

13. RAFTS ON SAND

Rafts on sand are well protected against bearing capacity failure. Therefore, settlement will govern the design. Since differential settlement will be much smaller for various locations on the raft (due to the raft's rigidity), the allowable soil pressure may be doubled.

$$q_a = 0.22C_nN \quad [\text{in tons/ft}^2] \qquad 36.22$$

N should always be at least 5 after correcting for overburden. (Note that the depth of the potential failure zone, $D_f + B$, is very large for a raft foundation.) Otherwise, the sand should be compacted or a pier or pile foundation should be used.

The net bearing capacity should be compared with the actual (net) bearing pressure. The actual (net) bearing pressure is

$$p_{\text{net}} = \frac{\text{total load}}{\text{raft area}} - \rho g D_f \quad [\text{SI}] \qquad 36.23(a)$$

$$p_{\text{net}} = \frac{\text{total load}}{\text{raft area}} - \gamma D_f \quad [\text{U.S.}] \qquad 36.23(b)$$

PRACTICE PROBLEMS

1. A mat foundation is to be used to support a building with dimensions of 80 ft × 40 ft and a total load of 5200 tons. The mat is located at a depth of $D_f = 8$ ft below the ground surface. The soil beneath the mat is a sand with a density of 120 lbf/ft^3 and an average SPT N-value of 18.

(a) What is the allowable bearing capacity of the mat?

(A) 2.2 tons/ft^2
(B) 2.5 tons/ft^2
(C) 2.9 tons/ft^2
(D) 5.4 tons/ft^2

The answer is (B).

(b) What is the factor of safety against bearing capacity failure?

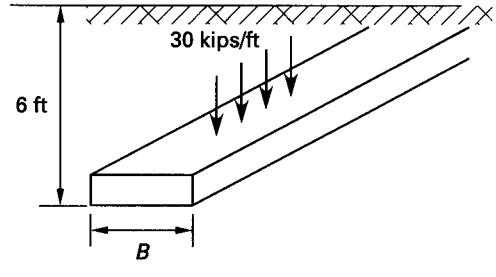
(A) 1.3
(B) 1.9
(C) 2.2
(D) 2.8

The answer is (C).

2. A total force of 1600 kN is to be supported by a square footing. The footing is to rest directly on sand that has a density of 1900 kg/m^3 and an angle of internal friction of 38°.

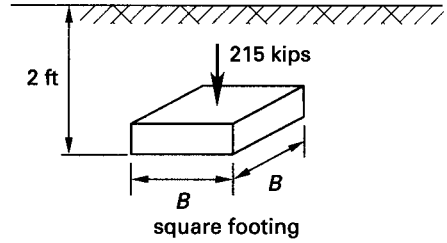
(a) Size the footing.

(A) 1.8 m square
(B) 2.4 m square
(C) 2.7 m square
(D) 3.4 m square



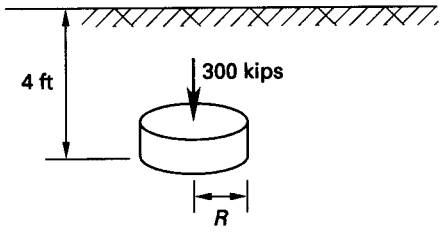
The answer is (A).

(b) Size the footing if it is to be placed 1.5 m below the surface.



(A) 1.0 m square
(B) 1.1 m square
(C) 1.3 m square
(D) 1.8 m square

The answer is (B).



3. (*Time limit: one hour*) The three foundations shown are situated in a sandy clay with the following characteristics: specific weight = 108 lbf/ft^3, angle of internal friction = 25°, and cohesion = 400 lbf/ft^2. The water table is 35 ft below the ground surface. Use a factor of safety of 2.5 where required.

wall footing

square footing

round footing

(a) What is the bearing capacity factor N_c according to the Terzaghi and Meyerhof theories?

(A) 5.7, 5.1
(B) 11, 9.7
(C) 25, 21
(D) 350, 270

The answer is (C).

(b) What is the bearing capacity factor N_q according to the Terzaghi and Meyerhof theories?

(A) 0, 0
(B) 1.0, 1.0
(C) 3.6, 3.2
(D) 13, 11

The answer is (D).

(c) What is the bearing capacity factor N_γ according to the Terzaghi and Meyerhof theories?

(A) 0, 0
(B) 1.0, 1.0
(C) 1.9, 1.9
(D) 9.7, 11

The answer is (D).

(d) What should be the width of the wall footing using the Terzaghi factors? Neglect the weight of the footing.

(A) 2.0 ft
(B) 3.5 ft
(C) 3.8 ft
(D) 4.6 ft

The answer is (C).

(e) What should be the width of the square footing using the Terzaghi factors? Neglect the weight of the footing.

(A) 2.5 ft
(B) 3.2 ft
(C) 4.8 ft
(D) 5.5 ft

The answer is (D).

(f) What should be the radius of the circular footing using the Terzaghi factors? Neglect the weight of the footing.

(A) 3.5 ft
(B) 3.8 ft
(C) 4.2 ft
(D) 5.5 ft

The answer is (A).

(g) What should be the radius of the circular footing using the Meyerhof factors? Neglect the weight of the footing.

(A) 3.5 ft
(B) 3.7 ft
(C) 4.7 ft
(D) 5.8 ft

The answer is (B).

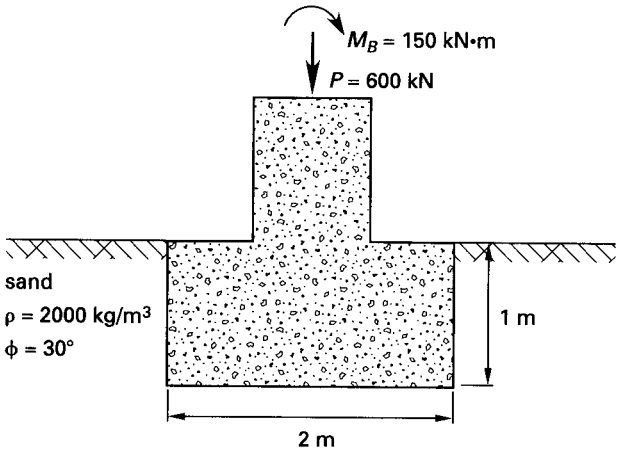
(h) What is the allowable bearing capacity of the square footing assuming a width of 4 ft and assuming that the water table is at 2.0 ft? Use the Meyerhof factors.

(A) 5300 lbf/ft^2
(B) 6300 lbf/ft^2
(C) 7600 lbf/ft^2
(D) 11,000 lbf/ft^2

The answer is (A).

(i) What is the allowable bearing capacity of the square footing assuming a width of 4 ft and assuming that the water table is at 1.0 ft? Use the Meyerhof factors.

(A) 4900 lbf/ft^2
(B) 5100 lbf/ft^2
(C) 6200 lbf/ft^2
(D) 8900 lbf/ft^2



The answer is (B).

(j) What is the allowable bearing capacity of the circular footing assuming a radius of 4 ft and assuming that the water table is at the ground surface? Use the Meyerhof factors.

(A) 5200 lbf/ft^2
(B) 5700 lbf/ft^2
(C) 7600 lbf/ft^2
(D) 9300 lbf/ft^2

The answer is (A).

4. (*Time limit: one hour*) A 2 m × 2 m square spread footing is designed to support an axial column load of 600 kN and a moment of 150 kN·m, as shown. The footing is placed 1 m into a sandy soil with a density of 2000 kg/m^3 and an angle of internal friction of 30°.

(a) What is the eccentricity of the resultant load?
(A) 0.10 m
(B) 0.25 m
(C) 0.50 m
(D) 1.3 m

The answer is (B).

(b) What equivalent width should be used for the footing design?
(A) 1.3 m
(B) 1.5 m
(C) 1.8 m
(D) 2.0 m

The answer is (B).

(c) Using the Meyerhof theory, what is the value of the bearing capacity factor, N_γ, to be used in calculating the bearing capacity?
(A) 16
(B) 22
(C) 27
(D) 35

The answer is (B).

(d) Using the Meyerhof theory, what is the value of the bearing capacity factor, N_q, to be used in calculating the bearing capacity?
(A) 11
(B) 16
(C) 18
(D) 23

The answer is (C).

(e) What is the value of the shape factor for N_γ to be used in calculating the bearing capacity?
(A) 0.85
(B) 0.88
(C) 0.90
(D) 1.00

The answer is (B).

(f) What is the value of the net bearing capacity?
(A) 100 kPa
(B) 340 kPa
(C) 540 kPa
(D) 1300 kPa

The answer is (C).

(g) What is the value of the allowable bearing capacity?
(A) 280 kPa
(B) 340 kPa
(C) 670 kPa
(D) 990 kPa

The answer is (A).

(h) What is the total allowable load on the shallow foundation?
(A) 810 kN
(B) 1100 kN
(C) 1300 kN
(D) 2100 kN

The answer is (A).

(i) What is the maximum soil pressure on the bottom of the footing?
(A) 55 kPa
(B) 90 kPa
(C) 200 kPa
(D) 270 kPa

The answer is (D).

(j) What is the factor of safety against bearing capacity failure for this footing?
(A) 1.9
(B) 2.4
(C) 2.7
(D) 3.0

The answer is (B).

1. TYPES OF RETAINING WALL STRUCTURES

A *gravity wall* is a high-bulk structure that relies on self-weight and the weight of the earth over the heel to resist overturning. *Semi-gravity walls* are similar though less massive. A *buttress wall* depends on compression ribs (*buttresses*) between the stem and the toe to resist flexure and overturning. *Counterfort walls* depend on tension ribs between the stem and the heel to resist flexure and overturning. A *cantilever wall* resists overturning through a combination of the soil weight over the heel and the resisting pressure under the base.

A *cantilever retaining wall* consists of a base, a stem, and an optional key. The stem may have a constant thickness, or it may be tapered. The taper is known as *batter*. The *batter decrement* is the change in stem thickness per unit of vertical distance. Batter is used to "disguise" bending (deflection) that would otherwise make it appear as if the wall were failing. It also reduces the quantity of material needed at the top of the wall where less strength is needed.

Cantilever retaining walls are generally intended to be permanent and are made of cast-in-place poured concrete. However, retaining walls may also be constructed from reinforced masonry block, stacked elements of various types, closely spaced driven members, railroad ties, and heavy lumber.

Gabion walls, consisting of stacked layers of rock-filled wire cages (baskets), may be economical if adequate rock is available nearby. Gabions are applicable to waterway lining, embankment control, spillways, and stilling basins as well as retaining walls. Other stacked-wall structures use interlocking concrete blocks, with and without tension cabling. Geosynthetic fabrics may be needed with gabion and stacked-block walls to prevent the migration of fines.

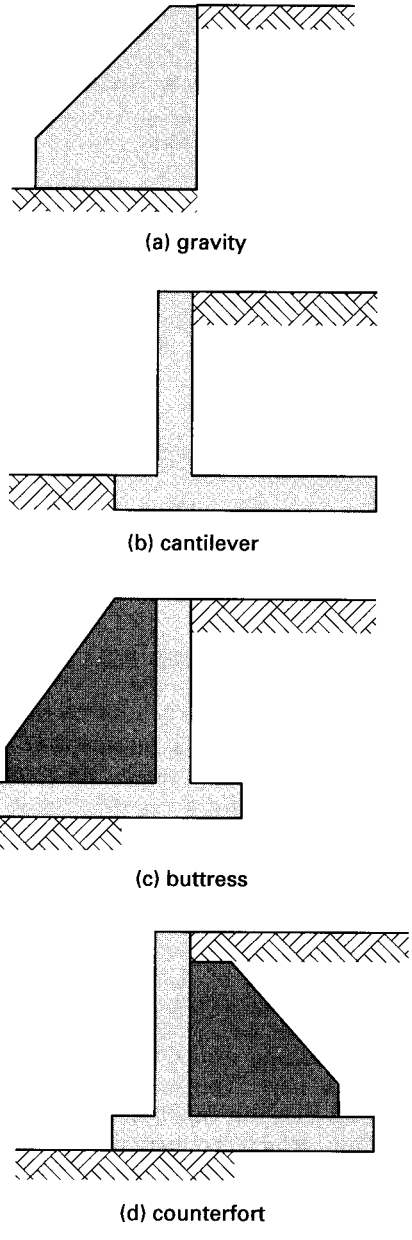

Figure 37.1 *Types of Retaining Walls*

2. COHESIVE AND GRANULAR SOILS

The nature of the backfilled or retained soil greatly affects the design of retaining walls. The two main soil classifications are granular and cohesive soils. *Cohesive soils* are clay-type soils with angles of internal friction, ϕ, of close to zero. *Granular soils* (also referred to as *noncohesive soils* and *cohesionless soils*) are sand- and gravel-type soils with values of cohesion, c, of close to zero. It is understood that granular soils also encompass "moist sands" and "drained sands."

3. EARTH PRESSURE

Earth pressure is the force per unit area exerted by soil on the retaining wall. Generally, the term is understood to mean "horizontal earth pressure." *Active earth pressure* (also known as *tensioned soil pressure* and *forward soil pressure*) is present behind a retaining wall that moves away from and tensions the remaining soil. *Passive earth pressure* (also known as *backward soil pressure* and *compressed soil pressure*) is present in front of a retaining wall that moves toward and compresses the soil.

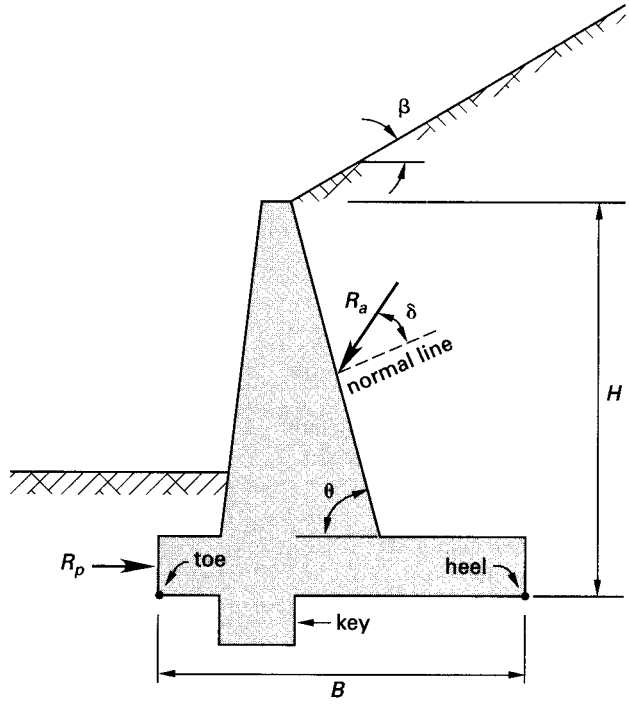

Figure 37.2 *Active and Passive Earth Pressure*

There are three common earth pressure theories. The *Rankine earth pressure theory* assumes that failure occurs along a flat plane behind the wall inclined at an angle α from the horizontal. The area above the failure plane is referred to as the *active zone*. The Rankine theory disregards friction between the wall and the soil.

$$\alpha = 45^\circ + \frac{\phi}{2} \quad \text{[Rankine]} \qquad 37.1$$

The *Coulomb earth pressure theory* also assumes a flat failure plane, but the effect of wall friction is included. Where friction is significant, the Coulomb theory can

predict a lower active pressure than the Rankine theory. The angle of the failure plane depends on both ϕ and δ.

$$\alpha_a = 90^\circ - \phi - \arctan\left(- \tan\phi + \frac{\sqrt{\tan\phi(\tan\phi + \cot\phi)(1 + \tan\delta\cot\phi)}}{1 + \tan\delta(\tan\phi + \cot\phi)} \right)$$

[Coulomb] *37.2*

The *log-spiral theory* assumes that the failure surface will be curved. The sophistication of a log-spiral solution is probably warranted only for the passive case, and even then, only when δ is large (i.e., larger than approximately 15°).

4. VERTICAL SOIL PRESSURE

Vertical soil pressure, p_v, is caused by the soil's own weight and is calculated in the same manner as for a fluid column. H is measured from the bottom of the base.

$$p_v = \rho g H \quad \text{[SI]} \quad \textit{37.3(a)}$$

$$p_v = \gamma H \quad \text{[U.S.]} \quad \textit{37.3(b)}$$

5. ACTIVE EARTH PRESSURE

Equation 37.4 is the equation for horizontal active earth pressure with level backfill for all soil types (i.e., sandy soils and clayey soils). k_a is the *coefficient of active earth pressure* (*active earth pressure coefficient*). Depending on the value of the cohesion, c, p_a can become negative above the wall base.

$$p_a = p_v k_a - 2c\sqrt{k_a} \qquad \textit{37.4}$$

The method of calculating k_a depends on the assumptions made. Equation 37.5 is the most general form of the active Coulomb equation. This form allows for sloping backfill (angle β), inclined active-side wall face (angle θ), and friction between the soil and wall face (angle δ).

$$k_a = \frac{\sin^2(\theta + \phi)}{\sin^2\theta\sin(\theta - \delta)\left(1 + \sqrt{\dfrac{\sin(\phi + \delta)\sin(\phi - \beta)}{\sin(\theta - \delta)\sin(\theta + \beta)}}\right)^2}$$

[Coulomb] *37.5*

Source: *Foundations and Earth Structures*, NAVFAC DM-7.2 (1982), p. 7.2-63, Table 1

Geotechnical

The Rankine theory disregards wall friction. The most general Rankine equation is derived by setting $\delta = 0$ in Eq. 37.5.

$$k_a = \frac{\sin^2(\theta + \phi)}{\sin^3\theta \left(1 + \sqrt{\dfrac{\sin\phi \sin(\phi - \beta)}{\sin\theta \sin(\theta + \beta)}}\right)^2} \quad \text{[Rankine]} \qquad 37.6$$

If the backfill is horizontal ($\beta = 0$) and the wall face is vertical ($\theta = 90$), then

$$k_a = \frac{1}{k_p} = \tan^2\left(45° - \frac{\phi}{2}\right) = \frac{1 - \sin\phi}{1 + \sin\phi} \quad \left[\begin{array}{c}\text{Rankine: horizontal} \\ \text{backfill; vertical face}\end{array}\right] \qquad 37.7$$

For saturated clays, the angle of internal friction, ϕ, is zero. As long as tension cracks do not develop near the top of the retaining wall, $k_a = 1$ and Eq. 37.4 resolves to

$$p_a = p_v - 2c \quad [\phi = 0] \qquad 37.8$$

For granular soils, $c = 0$. In that case, Eq. 37.4 resolves to

$$p_a = k_a p_v \quad [c = 0] \qquad 37.9$$

Since Eq. 37.9 describes a triangular pressure distribution, the *total active resultant* acts $H/3$ above the base and is

$$R_a = \tfrac{1}{2} p_a H = \tfrac{1}{2} k_a \rho g H^2 \quad \text{[SI]} \qquad 37.10(a)$$

$$R_a = \tfrac{1}{2} p_a H = \tfrac{1}{2} k_a \gamma H^2 \quad \text{[U.S.]} \qquad 37.10(b)$$

Since wall friction is disregarded with the Rankine case, the earth pressure resultant is normal to the wall. For the Coulomb case, there is a downward force component, and the earth pressure resultant is directed at the angle δ above the normal, or $90° - \delta$ from the wall.

$$\theta_R = 90° \text{ from the wall} \quad \text{[Rankine]} \qquad 37.11$$

$$\theta_R = 90° - \delta \text{ from the wall} \quad \text{[Coulomb]} \qquad 37.12$$

6. PASSIVE EARTH PRESSURE

Equation 37.13 is the equation for horizontal passive earth pressure with level backfill for all soil types (i.e., sandy soils and clayey soils). k_p is the *coefficient of passive earth pressure* (*passive earth pressure coefficient*).

$$p_p = p_v k_p + 2c\sqrt{k_p} \qquad 37.13$$

The method of calculating k_p depends on the assumptions made. Equation 37.14 is the most general form of the passive Coulomb equation. This form allows for sloping backfill (angle β), inclined active-side wall face (angle θ), and friction between the soil and wall face (angle δ).

$$k_p = \frac{\sin^2(\theta - \phi)}{\sin^2\theta \sin(\theta + \delta) \left(1 - \sqrt{\dfrac{\sin(\phi + \delta)\sin(\phi + \beta)}{\sin(\theta + \delta)\sin(\theta + \beta)}}\right)^2} \quad \text{[Coulomb]} \qquad 37.14$$

The Rankine theory disregards wall friction. The most general Rankine equation is derived by setting $\delta = 0$ in Eq. 37.14.

$$k_p = \frac{\sin^2(\theta - \phi)}{\sin^3\theta \left(1 - \sqrt{\dfrac{\sin\phi \sin(\phi + \beta)}{\sin\theta \sin(\theta + \beta)}}\right)^2} \quad \text{[Rankine]} \qquad 37.15$$

If the backfill is horizontal ($\beta = 0$) and the wall face is vertical ($\theta = 90$), then

$$k_p = \frac{1}{k_a} = \tan^2\left(45° + \frac{\phi}{2}\right) = \frac{1 + \sin\phi}{1 - \sin\phi} \quad \left[\begin{array}{c}\text{Rankine: horizontal} \\ \text{backfill; vertical face}\end{array}\right] \qquad 37.16$$

For saturated clays, the angle of internal friction, ϕ, is zero and $k_p = 1$. Eq. 37.13 resolves to

$$p_p = p_v + 2c \quad [\phi = 0] \qquad 37.17$$

For granular soils, $c = 0$. In that case, Eq. 37.13 resolves to

$$p_p = k_p p_v \quad [c = 0] \qquad 37.18$$

$$R_p = \tfrac{1}{2} p_p H = \tfrac{1}{2} k_p \rho g H^2 \quad \text{[SI]} \qquad 37.19(a)$$

$$R_p = \tfrac{1}{2} p_p H = \tfrac{1}{2} k_p \gamma H^2 \quad \text{[U.S.]} \qquad 37.19(b)$$

Passive earth pressure may not always be present during the life of the wall. When a retaining wall is first backfilled, or when the toe of the wall is excavated for repair or other work, the passive pressure may be absent. Because of this, the restraint from passive pressure is usually disregarded in factor-of-safety calculations.

7. AT-REST SOIL PRESSURE

The active and passive pressures predicted by the Rankine and Coulomb theories assume the wall moves slightly. Lateral movement as little as $H/200$ is sufficient for the active/passive distributions to develop. In some situations, however, the soil is completely confined and cannot move. This "at rest" case is appropriate for soil next to bridge abutments, basement walls restrained at their tops, walls bearing on rock, and walls with soft-clay backfill, as well as for sand deposits of infinite depth and extent.

The horizontal pressure at rest depends on the *coefficient of earth pressure at rest*, k_o, which varies from 0.4 to 0.5 for untamped sand, from 0.5 to 0.7 for normally consolidated clays, and from 1.0 and up for overconsolidated clays.

$$p_o = k_o p_v \tag{37.20}$$

$$k_o \approx 1 - \sin\phi \tag{37.21}$$

$$R_o = \tfrac{1}{2} k_o \rho g H^2 \quad \text{[SI]} \tag{37.22(a)}$$

$$R_o = \tfrac{1}{2} k_o \gamma H^2 \quad \text{[U.S.]} \tag{37.22(b)}$$

Table 37.2 *Typical Range of Earth Pressure Coefficients*

condition	granular soil	cohesive soil
active	0.33–0.22	1–0.5
passive	3–14	1–2
at rest	0.4–0.6	0.4–0.8

8. GRAPHICAL SOLUTIONS

Appendix 37.A provides a convenient graphical method of evaluating the horizontal and vertical earth pressures for various soil types. Since average values of soil density have been incorporated, K_h and K_v have units of lbf/ft^3 (lbf/ft^2 per lineal foot of wall). H is defined as shown: the height of the soil directly above the heel.

$$R_{a,h} = \tfrac{1}{2} K_h H^2 \tag{37.23}$$

$$R_{a,v} = \tfrac{1}{2} K_v H^2 \tag{37.24}$$

$$R_a = \sqrt{R_{a,h}^2 + R_{a,v}^2} \tag{37.25}$$

$$\theta = \arctan\left(\frac{R_v}{R_h}\right) \tag{37.26}$$

Most complications involving irregular and stratified backfill, irregular surcharges, and sloping water tables require more complex calculations. However, App. 37.B provides a way of evaluating retaining walls with *broken slope backfill*.

9. SURCHARGE LOADING

A *surcharge* is an additional force applied at the exposed upper surface of the restrained soil. A surcharge can result from a uniform load, point load, line load, or strip load. (Line and strip loads are parallel to the wall.)

With a *uniform load surcharge* of q (in lbf/ft^2 (N/m^2)) at the surface, there will be an additional active force, R_q. R_q acts horizontally at $H/2$ above the base. This surcharge resultant is in addition to the backfill active force that acts at $H/3$ above the base.

$$p_q = k_a q \tag{37.27}$$

$$R_q = k_a q H \times (\text{wall width}) \tag{37.28}$$

If a vertical *point load surcharge* (e.g., a truck wheel), V_q, in pounds (newtons) is applied a distance x back from the wall face, the approximate distribution of pressure behind the wall can be found from Eq. 37.29 or 37.30. These equations assume elastic soil performance and a Poisson's ratio of 0.5. The coefficients have been adjusted to bring the theoretical results into agreement with observed values.

$$p_q = \frac{1.77 V_q m^2 n^2}{H^2 (m^2 + n^2)^3} \quad [m > 0.4] \tag{37.29}$$

$$p_q = \frac{0.28 V_q n^2}{H^2 (0.16 + n^2)^3} \quad [m \le 0.4] \tag{37.30}$$

$$R_q \approx \frac{0.78 V_q}{H} \quad [m = 0.4] \tag{37.31}$$

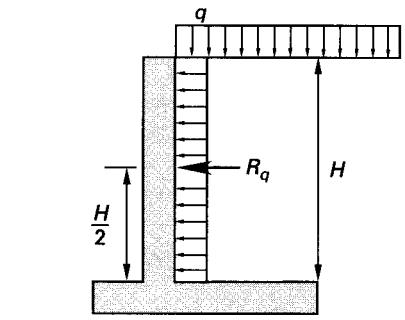
$$R_q \approx \frac{0.60 V_q}{H} \quad [m = 0.5] \tag{37.32}$$

$$R_q \approx \frac{0.46 V_q}{H} \quad [m = 0.6] \tag{37.33}$$

$$m = \frac{x}{H} \tag{37.34}$$

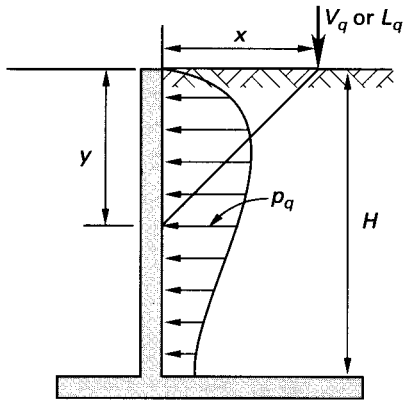
$$n = \frac{y}{H} \tag{37.35}$$

For a *line load surcharge*, L_q (in lbf/ft (N/m)), the distribution of pressure behind the wall is given by Eqs. 37.36 and 37.38.



$$p_q = \frac{4 L_q m^2 n}{\pi H (m^2 + n^2)^2} \quad [m > 0.4] \tag{37.36}$$

$$R_q = \frac{0.64 L_q}{m^2 + 1} \tag{37.37}$$



$$p_q = \frac{0.203 L_q n}{H (0.16 + n^2)^2} \quad [m \le 0.4] \tag{37.38}$$

$$R_q = 0.55 L_q \tag{37.39}$$

Sidewalks, railways, and roadways parallel to the retaining wall are examples of *strip surcharges*. The effect of a strip surcharge, S_q (in lbf/ft^2 (N/m^2)), is covered in most soils textbooks.

(a) uniform

(b) point or line

Figure 37.3 *Surcharges*

10. EFFECTIVE STRESS

Rarely in a properly designed retaining wall is the *groundwater table* (GWT) above the base. However, with submerged construction or when drains become plugged, a significant water table can exist behind the wall. The *pore pressure* (i.e., the *hydrostatic pressure*), μ, behind the wall at a point h below the water table is

$$\mu = \rho_w g h \quad \text{[SI]} \quad \textit{37.40(a)}$$
$$\mu = \gamma_w h \quad \text{[U.S.]} \quad \textit{37.40(b)}$$

The soil pressure behind the wall depends on its saturated density. The saturated soil density can be calculated from the porosity, n, or void ratio, e.

$$\rho_{\text{sat}} = \rho_{\text{dry}} + n\rho_w$$
$$= \rho_{\text{dry}} + \left(\frac{e}{1+e}\right)\rho_w \quad \text{[SI]} \quad \textit{37.41(a)}$$
$$\gamma_{\text{sat}} = \gamma_{\text{dry}} + n\gamma_w$$
$$= \gamma_{\text{dry}} + \left(\frac{e}{1+e}\right)\gamma_w \quad \text{[U.S.]} \quad \textit{37.41(b)}$$

The water provides a buoyant effect, since each sand particle is submerged. The *effective pressure* (generally referred to as the *effective stress*) is the difference between the *total pressure* and the pore pressure.

$$p_v = g(\rho_{\text{sat}} H - \rho_w h) \quad \text{[SI]} \quad \textit{37.42(a)}$$
$$p_v = \gamma_{\text{sat}} H - \gamma_w h \quad \text{[U.S.]} \quad \textit{37.42(b)}$$

The total horizontal pressure from the submerged sand is the sum of the hydrostatic pressure and the lateral earth pressure considering the buoyant effect.

$$p_h = g\rho_w h + k_a(\rho_{\text{sat}} H - \rho_w h)$$
$$= g\big(k_a \rho_{\text{sat}} H + (1-k_a)\rho_w h\big) \quad \text{[SI]} \quad \textit{37.43(a)}$$
$$p_h = \gamma_w h + k_a(\gamma_{\text{sat}} H - \gamma_w h)$$
$$= k_a \gamma_{\text{sat}} H + (1-k_a)\gamma_w h \quad \text{[U.S.]} \quad \textit{37.43(b)}$$

The increase in horizontal pressure above the saturated condition is the *equivalent hydrostatic pressure* (*equivalent fluid pressure*) caused by the *equivalent fluid weight* (*equivalent fluid density*, *equivalent fluid specific weight*, etc.), γ_{eq}. Considering typical values of k_a, the equivalent specific weight of water behind a retaining wall is typically taken as 45 lbf/ft^3 (720 kg/m^3).

$$\rho_{\text{eq}} = (1-k_a)\rho_w \quad \text{[SI]} \quad \textit{37.44(a)}$$
$$\gamma_{\text{eq}} = (1-k_a)\gamma_w \quad \text{[U.S.]} \quad \textit{37.44(b)}$$

The effective pressure can be quite low due to submergence and tension cracking in cohesive clays. However, all retaining walls should be designed for a minimum effective density of 30 lbf/ft^3 (480 kg/m^3).

11. CANTILEVER RETAINING WALLS: ANALYSIS

Retaining walls must have sufficient resistance against overturning and sliding, and they must possess adequate structural strength against bending outward. The maximum soil pressure under the base must be less than the allowable soil pressure. The following procedure can be used to analyze a retaining wall whose dimensions are known.

step 1: Determine the horizontal active earth pressure resultants from the backfill and all surcharges, $R_{a,h,i}$. Determine the points of application and moment arms, $y_{a,h,i}$, above the base.

step 2: Unless it is reasonable to assume that they will always be present, restraint from passive distributions is disregarded. If it is to be considered, however, determine the passive earth pressure.

step 3: Find all of the vertical forces acting at the base. These include the weights of the retaining wall itself, the soil directly above the heel, and the soil directly above the toe. Each of these weights can be evaluated individually by dividing the concrete and soil into areas with simple geometric shapes. The specific weight of concrete is almost always taken as 150 lbf/ft^3 (2400 kg/m^3). Find the

location of the centroid of each shape and the moment arm, x_i. Either the base of the heel or the base of the toe can be chosen as the pivot point. However, it is more consistent to use distances from the toe.

$$W_i = g\rho_i A_i \quad \text{[SI]} \qquad 37.45(a)$$

$$W_i = \gamma_i A_i \quad \text{[U.S.]} \qquad 37.45(b)$$

step 4: Find the moment about the toe from the forces found in steps 1 through 3.

$$M_{\text{toe}} = \sum W_i x_i - R_{a,h} y_a + R_{a,v} x_a \qquad 37.46$$

step 5: Determine the location, x_R, and eccentricity, ϵ, of the vertical force component. The eccentricity is the distance from the center of the base to the vertical force resultant. Eccentricity should be less than $B/6$ for the entire base to be in compression.

$$x_R = \frac{M_{\text{toe}}}{\sum (W_i + R_{a,v})} \qquad 37.47$$

$$\epsilon = \frac{B}{2} - x_R \qquad 37.48$$

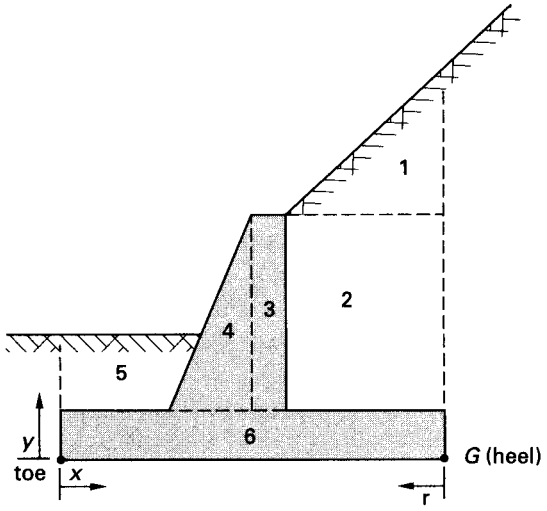
step 6: Check the factor of safety, F, against overturning. The factor of safety generally should be greater than 1.5 for granular soils and 2.0 for cohesive soils.

$$F_{\text{OT}} = \frac{M_{\text{resisting}}}{M_{\text{overturning}}} = \frac{R_{a,h} y_{a,h}}{\sum W_i x_i + R_{a,v} x_{a,v}} \qquad 37.49$$

step 7: Find the maximum pressure (at the toe) and the minimum pressure (at the heel) on the base. The maximum pressure should not exceed the allowable pressure.

$$p_{v,\max},\ p_{v,\min} = \left(\frac{\sum W_i + R_{a,v}}{B}\right) \times \left(1 \pm \left(\frac{6\epsilon}{B}\right)\right) \qquad 37.50$$

step 8: Calculate the resistance against sliding. The active pressure is resisted by friction and adhesion between the base and the soil, and in the case of a keyed base, also by the shear strength of the soil. Equation 37.51 is for use when the wall has a key, and then only for the compressed soil in front of the key. Equation 37.52 is for use with a keyless base and for tensioned soil behind the key.



$$R_{\text{SL}} = (\sum W_i + R_{a,v}) \tan\phi + c_A B \qquad 37.51$$

$$R_{\text{SL}} = (\sum W_i + R_{a,v}) \tan\delta + c_A B \qquad 37.52$$

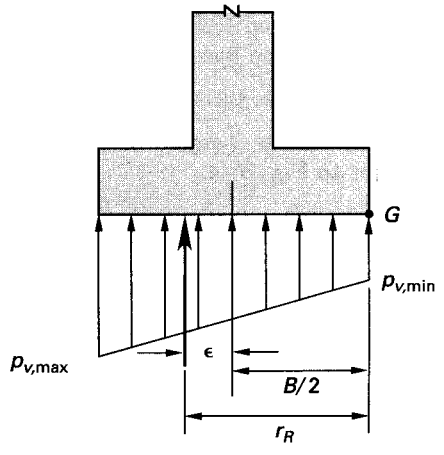
The adhesion, c_A, is zero for granular soil. $\tan\delta$ is referred to as a coefficient of friction and is given the symbol k or f by some authorities. In the absence of more sophisticated information, $\tan\delta$ is approximately 0.60 for rock, 0.55 for sand without silt, 0.45 for sand with silt, 0.35 for silt, and 0.30 for clay.

step 9: Calculate the factor of safety against sliding. A lower factor of safety (which may be referred to as the "minimum" factor of safety), 1.5, is permitted when the passive resultant is disregarded. If the passive resultant is included, the factor of safety (referred to as the "maximum" factor of safety) should be higher (e.g., 2). If the factor of safety is too low, the base length (B) can be increased, or a vertical key can be used.

$$F_{\text{SL}} = \frac{R_{\text{SL}}}{R_{a,h}} \qquad 37.53$$

[a]Some retaining walls may not have all elements.

Figure 37.4 *Elements Contributing to Vertical Force[a] (step 3)*



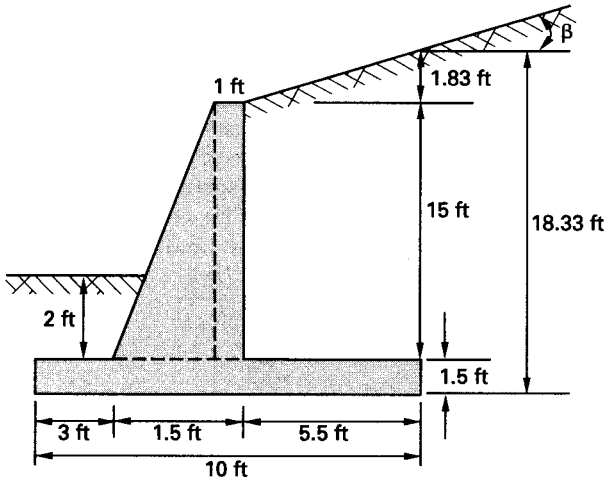


Figure 37.5 *Resultant Distribution on the Base (step 7)*

Example 37.1

The unkeyed retaining wall shown has been designed for a backfill of coarse-grained sand with silt having a weight of 125 lbf/ft^3. The angle of internal friction, ϕ, is 30°, and the angle of external friction, δ, is 17°. The backfill is sloped as shown. The maximum allowable soil pressure is 3000 lbf/ft^2. The adhesion is 950 lbf/ft^2. Check the factor of safety against sliding.

Solution

step 1: $\beta = \arctan\left(\dfrac{1.83 \text{ ft}}{5.5 \text{ ft}}\right) = \arctan\left(\frac{1}{3}\right) = 18.4°$

From App. 37.A with a type-2 fill, k_v = 10 lbf/ft^2 and k_h = 40 lbf/ft^2.

$$R_{a,v} = \tfrac{1}{2}k_v H^2 = \left(\tfrac{1}{2}\right)\left(10 \frac{\text{lbf}}{\text{ft}^2}\right)(18.33 \text{ ft})^2$$
$$= 1680 \text{ lbf}$$

$$R_{a,h} = \tfrac{1}{2}k_h H^2 = \left(\tfrac{1}{2}\right)\left(40 \frac{\text{lbf}}{\text{ft}^2}\right)(18.33 \text{ ft})^2$$
$$= 6720 \text{ lbf}$$

$R_{a,h}$ is located 18.33 ft/3 = 6.11 ft above the bottom of the base.

step 2: Disregard the passive earth pressure.

step 3: Calculate the weights of soil and concrete. Refer to Fig. 37.4.

i	area (ft^2)	γ (lbf/ft^3)	W_i (lbf)	x_i (ft)	M_i (ft-lbf)
1	(0.5)(5.5)(1.83) = 5.03	125	629	8.17	5139
2	(5.5)(15) = 82.5	125	10,313	7.25	74,769
3	(1)(15) = 15	150	2250	4.0	9000
4	(0.5)(0.5)(15) = 3.75	150	563	3.33	1875
5	(2)(3) = 6	125	750	1.5	1125
6	(1.5)(10) = 15	150	2250	5.0	11,250
		totals	16,755		103,158

step 4: Find the moment about the toe. Notice that $R_{a,v}$ goes through the heel and has a moment arm equal to the base length. Use Eq. 37.46.

$$M_{\text{toe}} = \sum W_i x_i - R_{a,h} y_a + R_{a,v} x_a$$
$$= 103{,}158 \text{ ft-lbf} - (6720 \text{ lbf})(6.11 \text{ ft})$$
$$+ (1680 \text{ lbf})(10 \text{ ft})$$
$$= 78{,}899 \text{ ft-lbf}$$

step 5: Use Eq. 37.47.

$$x_R = \frac{M_{\text{toe}}}{\sum(W_i + R_{a,v})}$$
$$= \frac{78{,}899 \text{ ft-lbf}}{16{,}755 \text{ lbf} + 1680 \text{ lbf}}$$
$$= 4.28 \text{ ft}$$

Use Eq. 37.48.

$$\epsilon = \frac{B}{2} - x_R = \frac{10 \text{ ft}}{2} - 4.28 \text{ ft} = 0.72 \text{ ft}$$

Since 0.72 ft < 10 ft/6, the base is in compression everywhere.

step 6: (This step skipped.)

step 7: $p_{v,\max} = \left(\dfrac{\sum W_i + R_{a,v}}{B}\right)\left(1 + \dfrac{6\epsilon}{B}\right)$

$$= \left(\frac{16{,}755 \text{ lbf} + 1680 \text{ lbf}}{10 \text{ ft}}\right)$$
$$\times \left(1 + (6)\left(\frac{0.72 \text{ ft}}{10 \text{ ft}}\right)\right)$$
$$= 2640 \text{ lbf/ft}^2 \quad [< 3000 \text{ lbf/ft}^2, \text{ so OK}]$$

step 8: Use Eq. 37.52.

$$R_{\text{SL}} = (\sum W_i + R_{a,v}) \tan\delta + c_A B$$
$$= (16{,}755 \text{ lbf} + 1680 \text{ lbf})(\tan 17°)$$
$$+ \left(950 \frac{\text{lbf}}{\text{ft}^2}\right)(10 \text{ ft})$$
$$= 15{,}136 \text{ lbf}$$

step 9: $F_{\text{SL}} = \dfrac{R_{\text{SL}}}{R_{a,h}} = \dfrac{15{,}136 \text{ lbf}}{6720 \text{ lbf}}$

$$= 2.25 \quad [> 1.5, \text{ so OK}]$$

12. RETAINING WALLS: DESIGN

A retaining wall is most likely to fail structurally at its base due to the applied moment. In this regard, a retaining wall is similar to a cantilever beam with a

nonuniform load. The following characteristics are typical of retaining walls and can be used as starting points for more detailed designs.

- To prevent frost heaving, the base should be below the frost line. This establishes a minimum wall height, H.
- The heel length, L, can be determined analytically by setting the active soil moment equal to the "resisting moment" due to the weight of the soil above the heel.

$$R_{a,h}\left(\frac{H}{3}\right) \approx (\text{soil weight})\left(\frac{L}{2}\right) \qquad 37.54$$

- The toe should project approximately $B/3$ beyond the stem face.

$$B \approx \tfrac{3}{2}L \qquad 37.55$$

- If an analytical method is not used to determine its size, the base should be proportioned such that

$B = 0.4H$ [granular backfills and nominal surcharges]

$B = 0.5H$ [granular backfills and heavier surcharges]

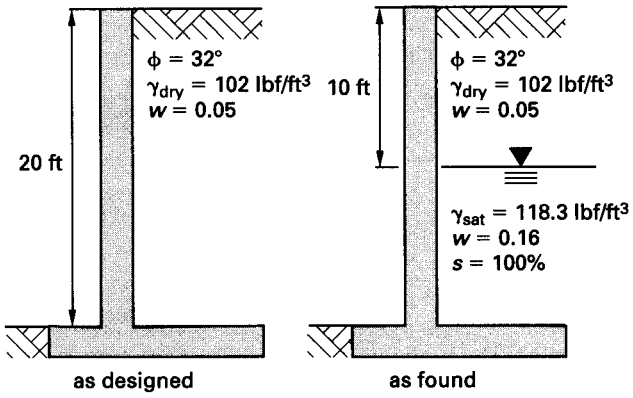
$B = 0.6H$ [cohesive backfills and nominal surcharges]

$B = 0.7H$ [cohesive backfills and heavier surcharges]

- The stem thickness, t_{stem}, should be proportioned such that

$$8 < \frac{H}{t_{\text{stem}}} < 12 \qquad 37.56$$

- The base thickness should be approximately equal to the thickness of the stem at the base, with a minimum of 12 in (300 mm). Alternatively, the base should be proportioned such that



$$10 < \frac{H}{t_{\text{base}}} < 14 \qquad 37.57$$

- The *batter decrement* should be approximately 1/4 in to 1/2 in per vertical foot.
- The minimum stem thickness at the top should be approximately 12 in (300 mm).

PRACTICE PROBLEMS

Retaining Wall Analysis

1. A retaining wall is designed for free-draining granular backfill. After several years of operation, the weepholes become plugged and the water table rises to within 10 ft of the top of the wall. (a) What is the resultant force for the drained case? (b) What is the point of application for the drained case? (c) What is the resultant force for the plugged case? (d) What is the point of application of the resultant force for the plugged case?

Answers: (a) 6576 lbf/ft; (b) 6.67 ft from the bottom; (c) 8910 lbf/ft; (d) 5.79 ft from the bottom

2. *(Time limit: one hour)* A 26 ft high retaining wall holds back sand with a 96 lbf/ft^3 dry specific weight. The water table is 10 ft below the top of the wall. The saturated specific weight is 121 lbf/ft^3. The angle of internal friction is 36°. (a) What is the active earth resultant? (b) What is the location of the active earth pressure resultant? (c) If the water table elevation could be reduced 16 ft to the bottom of the wall, what would be the reduction in overturning moment?

Answers: (a) 15,200 lbf/ft; (b) 7.18 ft from the bottom; (c) 35,900 ft-lbf/ft

Retaining Wall Design

3. *(Time limit: one hour)* A reinforced concrete retaining wall is used to support a 14 ft cut in sandy soil. The backfill is level, but a surcharge of 500 lbf/ft^2 is present for a considerable distance behind the wall. Factors of safety of 1.5 against sliding and overturning are required. Customary and reasonable assumptions regarding the proportions can be made. Passive pressure is to be disregarded. The need for a key must be established.

soil dry specific weight	130 lbf/ft^3
angle of internal friction	35°
coefficient of friction against concrete	0.5
allowable soil pressure	4500 lbf/ft^2
frost line	4 ft below grade

(a) What is the approximate minimum stem height?

(A) 14 ft

(B) 16 ft

(C) 18 ft

(D) 20 ft

The answer is (C).

For parts (b) through (j), assume a base length, B, of 11.5 ft; a base thickness, d, of 1.75 ft; a stem thickness at the base of 1.75 ft; a stem thickness at the top of 1 ft;

Geotechnical

a stem height (above base) of 18 ft; and a heel extension (past the back of the stem) of 6.5 ft.

(b) The surcharge is equivalent to what thickness of backfill soil?

(A) 2 ft
(B) 3 ft
(C) 4 ft
(D) 5 ft

The answer is (C).

(c) What is the horizontal reaction due to the surcharge?

(A) 2400 lbf/ft
(B) 2700 lbf/ft
(C) 3500 lbf/ft
(D) 3900 lbf/ft

The answer is (B).

(d) What is the active soil resultant?

(A) 5700 lbf/ft
(B) 6800 lbf/ft
(C) 7500 lbf/ft
(D) 8300 lbf/ft

The answer is (B).

(e) What is the total overturning moment, taken about the heel, per foot of wall?

(A) 120,000 ft-lbf
(B) 140,000 ft-lbf
(C) 160,000 ft-lbf
(D) 190,000 ft-lbf

The answer is (D).

(f) What is the maximum vertical pressure at the toe?

(A) 4000 lbf/ft^2
(B) 4500 lbf/ft^2
(C) 5000 lbf/ft^2
(D) 5500 lbf/ft^2

The answer is (A).

(g) What is the minimum vertical pressure at the heel?

(A) 600 lbf/ft^2
(B) 1300 lbf/ft^2
(C) 2400 lbf/ft^2
(D) 2700 lbf/ft^2

The answer is (A).

(h) What is the factor of safety against sliding without a key?

(A) 1.3
(B) 1.4
(C) 1.6
(D) 1.8

The answer is (B).

(i) What is the factor of safety if a key, 1.75 ft wide and 1.0 ft deep, is used?

(A) 1.4
(B) 1.6
(C) 1.7
(D) 2.1

The answer is (C).

(j) What is the factor of safety against overturning?

(A) 1.5
(B) 1.8
(C) 2.3
(D) 2.6

The answer is (D).

1. INTRODUCTION

Piles are slender members that are hammered, drilled, or jetted into the ground. They provide strength in soils that would otherwise be too weak to support a foundation. Piles may be constructed of timber, steel, or prestressed reinforced concrete. *Composite piles* include any combination of timber, steel, concrete, and fiberglass (e.g., a concrete-filled steel or concrete-filled fiberglass casing). Other deep foundations include micropiles, auger-cast piles, I-piles, and H-piles (i.e., steel piles with H-shaped cross sections).

Friction piles derive the majority of their loadbearing ability from the skin friction between the soil and the pile. *Point-bearing piles* derive their loadbearing ability from the support of the layer at the tip. (Point-bearing piles are used to transfer loads to rock or firm layers below.) Skin friction capacity and point-bearing capacity are simultaneously present to some degree in all piles. However, one mode is usually dominant.

The capacity of a pile to support static loadings is easily calculated. The capacity of a pile exposed to dynamic loads from earthquakes, explosions, and other vibrations is relevant in many cases, but dynamic capacity is more difficult to determine. All calculations in this chapter are for static capacity.

The *ultimate static bearing capacity*, Q_{ult}, of a single pile is the sum of its point-bearing and skin-friction capacities. For piles supporting a compressive load, the pile weight is balanced by the overburden and is not considered. Other than its effect on the undrained shear strength, the position of the groundwater table has no effect on the ultimate bearing capacity.

$$Q_{ult} = Q_p + Q_f \qquad 38.1$$

The allowable capacity of a pile depends on the factor of safety, which is typically 2 to 3 for both compression and tension piles, the lower value of 2 being used when

Geotechnical

the capacity can be verified by pile loading tests. Even lower values can be specified in unusual and extreme cases.

$$Q_a = \frac{Q_{\text{ult}}}{F} \qquad 38.2$$

Pile capacities do not consider settlement, which might actually be the controlling factor.

2. PILE CAPACITY FROM DRIVING DATA

The *safe load* (*safe bearing value*) can be calculated empirically from installation data using the *Engineer News Record* (*ENR* or *Engineering News*) equations. For a pile driven in by a drop hammer of weight W_{hammer}, falling a distance H, driving a weight of W_{driven} (including the pile weight), and penetrating an average distance S per blow during the last five blows, the maximum allowable vertical load per pile, Q_a, is

$$Q_{a,\text{lbf}} = \frac{2W_{\text{hammer,lbf}}H_{\text{fall,ft}}}{S_{\text{in}} + 1} \quad \text{[drop hammer]} \qquad 38.3$$

$$Q_{a,\text{lbf}} = \frac{2W_{\text{hammer,lbf}}H_{\text{fall,ft}}}{S_{\text{in}} + 0.1} \quad \left[\begin{array}{l}\text{single-acting steam hammer;}\\ \text{driven weight} < \text{striking weight}\end{array}\right] \qquad 38.4$$

$$Q_{a,\text{lbf}} = \frac{2W_{\text{hammer,lbf}}H_{\text{fall,ft}}}{S_{\text{in}} + 0.1\left(\dfrac{W_{\text{driven}}}{W_{\text{hammer}}}\right)} \quad \left[\begin{array}{l}\text{single-acting steam hammer;}\\ \text{driven weight} > \text{striking weight}\end{array}\right] \qquad 38.5$$

For double-acting hammers, the energy, $E_{\text{ft-lbf}}$, transferred to the pile on each stroke replaces the WH potential energy term. Typical values of energy per blow for timber piles are 7500 to 14,000 ft-lbf (10 to 19 kJ) for single-acting hammers and 14,000 ft-lbf (19 kJ) for double-acting hammers. For concrete and steel piles, the typical energy per blow is 15,000 to 20,000 ft-lbf (20 to 27 kJ).

$$Q_{a,\text{lbf}} = \frac{2E_{\text{ft-lbf}}}{S_{\text{in}} + 0.1} \quad \left[\begin{array}{l}\text{double-acting steam hammer;}\\ \text{driven weight} < \text{striking weight}\end{array}\right] \qquad 38.6$$

$$Q_{a,\text{lbf}} = \frac{2E_{\text{ft-lbf}}}{S_{\text{in}} + 0.1\left(\dfrac{W_{\text{driven}}}{W_{\text{hammer}}}\right)} \quad \left[\begin{array}{l}\text{double-acting steam hammer;}\\ \text{driven weight} > \text{striking weight}\end{array}\right] \qquad 38.7$$

Correlations with standard penetration tests (i.e., those that derive the N-value) have also been established and can be used with adequate testing.

3. THEORETICAL POINT-BEARING CAPACITY

The theoretical point-bearing capacity (also known as the *tip resistance* and *point capacity*), Q_p, of a single pile can be calculated in much the same manner as for a footing. Since the pile size, B, is small, the $\frac{1}{2}\gamma BN\gamma$ term is generally omitted.

$$Q_p = A_p\left(\tfrac{1}{2}\rho g B N_\gamma + cN_c + \rho g D_f N_q\right) \quad \text{[SI]} \qquad 38.8(a)$$

$$Q_p = A_p\left(\tfrac{1}{2}\gamma B N_\gamma + cN_c + \gamma D_f N_q\right) \quad \text{[U.S.]} \qquad 38.8(b)$$

For cohesionless (granular) soil, $c = 0$. For sands and silts, the tip capacity increases down to a critical depth, D_c, after which it is essentially constant. For loose sands (i.e., with relative densities less than 30%), the critical depth is taken as $10B$. For dense sands (relative densities above 70%), the critical depth is $20B$. Between relative densities of 30% and 70%, the critical depth can be interpolated between $10B$ and $20B$.

$$Q_p = A_p \rho g D N_q \quad [\text{cohesionless; } D \le D_c] \quad \text{[SI]} \qquad 38.9(a)$$

$$Q_p = A_p \gamma D N_q \quad [\text{cohesionless; } D \le D_c] \quad \text{[U.S.]} \qquad 38.9(b)$$

For cohesive soils with $\phi = 0°$, $N_q = 1$ and the γD_f term is approximately cancelled by the pile weight. $N_c = 9$ for driven piles of virtually all conventional dimensions.

$$Q_p = A_p c N_c \approx 9A_p c \quad \text{[cohesive]} \qquad 38.10$$

Table 38.1 *Meyerhof Values of N_q For Piles*[a]

$\phi°$	20	25	28	30	32	34	36	38	40	42	45
driven	8	12	20	25	35	45	60	80	120	160	230
drilled	4	5	8	12	17	22	30	40	60	80	115

[a]Significant variation in N_q has been reported by various researchers. The actual value is highly dependent on ϕ and the installation method.

Table 38.2 *Values of N_c for Driven Piles*[a] *(square and cylindrical perimeters)*

$\frac{D_f}{B}$	N_c
0	6.3
1	7.8
2	8.5
≥ 4	9

[a]Not for use with drilled piles.

Derived from *Foundations and Earth Structures Design Manual*, NAVFAC, DM 7.2, 1982, Fig. 2, p. 7.2-196.

4. THEORETICAL SKIN-FRICTION CAPACITY

The skin-friction capacity, Q_f (also known as *side resistance, skin resistance,* and *shaft capacity*), is given by Eq. 38.11. L_e is the *effective pile length*, which can be estimated as the pile length less the depth of the *seasonal variation*, if any.

$$Q_f = A_s f_s = p f_s L_e = p f_s (L - \text{seasonal variation}) \quad 38.11$$

For piles passing through two or more layers, the skin friction capacity of each layer is calculated separately, considering only the thickness, L_i, of one layer at a time. Individual layer capacities are summed. Alternatively, a weighted average value of the skin friction coefficient can be calculated by weighting the individual coefficients by the layer thicknesses.

$$Q_f = p \sum f_{s,i} L_{e,i} \quad 38.12$$

The *skin friction coefficient* (*unit shaft friction* or *side friction factor*), f_s, includes both cohesive and adhesive components. The external friction angle, δ, is zero (as is ϕ) for saturated clay, and is generally taken as $^2/_3\phi$ in the absence of specific information. The *adhesion*, c_A, should be obtained from testing, or it can be estimated from the undrained shear strength (cohesion), c. For rough concrete, rusty steel, and corrugated metal, $c_A = c$. For smooth concrete, $0.8c \leq c_A \leq c$. For clean steel, $0.5c \leq c_A \leq 0.9c$.

$$f_s = c_A + \sigma_h \tan\delta \quad 38.13$$

The *α-method* determines the *adhesion factor*, α, as the ratio of the skin friction factor, f_s, to the undrained shear strength (cohesion), c. As in Table 38.4, the values of α are correlated with c.

$$f_s = \alpha c \quad 38.14$$

For sand, the lateral earth pressure, σ_h, depends on the depth, down to a critical depth, D_c, after which it is essentially constant. For loose sands (i.e., relative densities less than 30%), the critical depth is taken as $10B$. For dense sands (relative densities above 70%), the critical depth is $20B$. Between relative densities of 30% and 70%, the critical depth can be interpolated between $10B$ and $20B$.

$$\sigma_h = k_s \sigma_v' = k_s(\rho g D - \mu) \quad \text{[SI]} \quad 38.15(a)$$
$$\sigma_h = k_s \sigma_v' = k_s(\gamma D - \mu) \quad \text{[U.S.]} \quad 38.15(b)$$

For compression piles driven in clay and silt, the *coefficient of lateral earth pressure*, k_s, is 1.0. For piles driven in sand, the coefficient varies from 1.0 to 2.0, with the higher value applicable to the most dense sands. For drilled piles, the coefficients of lateral earth pressure are approximately half of the values for driven piles. For jetted piles, the coefficients are approximately 25% of the driven values.

The *pore pressure*, μ, a distance h below the water table is the hydrostatic pressure at that depth.

$$\mu = \rho_w g h \quad \text{[SI]} \quad 38.16(a)$$
$$\mu = \gamma_w h \quad \text{[U.S.]} \quad 38.16(b)$$

For piles through layers of cohesionless sand, $c = c_A = 0$.

$$Q_f = p k_s \tan\delta \sum L_i \sigma' \quad \text{[cohesionless]} \quad 38.17$$

For piles in clay, $\tan\delta = 0$, $f_s = c_A$, and $k_s = 1$.

$$Q_f = p \sum c_A L_i \quad \text{[cohesive]} \quad 38.18$$

With the *β-method* for cohesive clay, the friction capacity is estimated as a fraction of the average effective vertical stress (as evaluated halfway down the pile). Values of β are correlated with pile length (see Table 38.5). For a pile passing through one layer, the friction capacity is

$$Q_f = p \beta \sigma' L \quad \text{[cohesive]} \quad 38.19$$

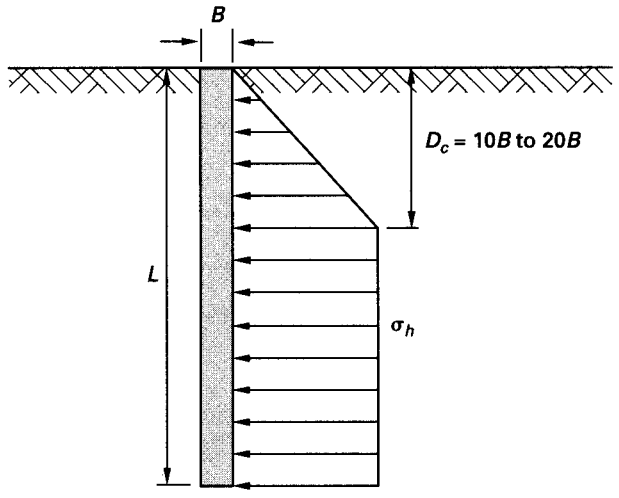

Figure 38.1 *Lateral Earth Pressure Distribution on a Pile in Sand*

5. H-PILES

Analysis of steel H-pile capacity is similar to that of other piles except for the perimeter calculation and friction angle. The area between the flanges is assumed to fill with soil that moves with the pile. In calculating the skin area, A_s, the perimeter should be taken as the block perimeter of the pile. The friction angle should be the average of the soil-on-steel and soil-on-soil cases.

Similarly, the tip capacity should be calculated using the area enclosed by the block perimeter.

Example 38.1

A round concrete pile with a diameter of 11 in is driven 60 ft into wetlands clay. The clay's undrained shear strength and specific weight are 1400 lbf/ft^2 and

Geotechnical

Table 38.3 *Recommended Values of Adhesion (piles in clay)*

pile type	consistency of clay	cohesion, c lbf/ft^2 (GPa)	adhesion, c_A lbf/ft^2 (GPa)

Table 38.4 *Typical Values[a] of the Adhesion Factor, α (for use with Eq. 38.14)*

cohesion, c lbf/ft^2 (GPa)	α range of values	α average
500 (24)	–	1.0
1000 (48)	0.56–0.96	0.83
2000 (96)	0.34–0.83	0.56
3000 (144)	0.26–0.78	0.43

(Multiply lbf/ft^2 by 0.04788 to obtain GPa.)
[a]Reported values vary widely.

120 lbf/ft^3, respectively. At high tide, the water table extends to the ground surface. What is the allowable bearing capacity of the pile?

Solution

$$B = \frac{11 \text{ in}}{12 \frac{\text{in}}{\text{ft}}} = 0.917 \text{ ft}$$

The pile's end and surface areas are

$$A_p = \tfrac{\pi}{4}B^2 = \left(\frac{\pi}{4}\right)(0.917 \text{ ft})^2 = 0.66 \text{ ft}^2$$

$$A_s = \pi BL = \pi(0.917 \text{ ft})(60 \text{ ft}) = 172.9 \text{ ft}^2$$

The tip capacity is given by Eq. 38.10.

$$Q_p = A_p c N_c = 9A_p c$$

$$= \frac{(9)(0.66 \text{ ft}^2)\left(1400 \frac{\text{lbf}}{\text{ft}^2}\right)}{1000 \frac{\text{lbf}}{\text{kip}}}$$

$$= 8.3 \text{ kips}$$

Table 38.5 *Typical Values of β[a] (for use with Eq. 38.19)*

pile length, L ft (m)	skin friction factor, β
0 (0)	0.3
25 (7.5)	0.3
50 (15)	0.3
75 (23)	0.27
100 (30)	0.23
125 (38)	0.20
150 (45)	0.18
175 (53)	0.17
200 (60)	0.16

(Multiply ft by 0.3048 to obtain m.)
[a]For driven piles in soft and medium clays with $c < 2000$ lbf/ft^2 (96 GPa). After Meyerhof.

Estimate $c_A = 0.9c$ for smooth concrete. The friction capacity is given by Eq. 38.11.

$$Q_f = A_s f_s = A_s c_A$$

$$= \frac{(172.9 \text{ ft}^2)(0.9)\left(1400 \frac{\text{lbf}}{\text{ft}^2}\right)}{1000 \frac{\text{lbf}}{\text{kip}}}$$

$$= 217.9 \text{ kips}$$

The total capacity is

$$Q_{\text{ult}} = Q_p + Q_f = 8.3 \text{ kips} + 217.9 \text{ kips} = 226.2 \text{ kips}$$

With a factor of safety of 3, the allowable load is

$$Q_a = \frac{Q_{\text{ult}}}{F} = \frac{226.2 \text{ kips}}{3} = 75.4 \text{ kips}$$

6. TENSILE CAPACITY

Tension piles are intended to resist upward forces. Basements and buried tanks below the water level may require tension piles to prevent "floating away." However, tall buildings subjected to overturning moments also need to resist pile pull-out.

Unlike piles loaded in compression, the *pull-out capacity* of piles does not include the tip capacity. The pullout capacity includes the weight of the pile and the shaft resistance (skin friction). Tensile shaft resistance is calculated similarly to, but not necessarily the same as, compressive shaft resistance. For example, the lateral earth pressure coefficient, k_s, is approximately 50 to 75% of the equivalent values in tension.

7. CAPACITY OF PILE GROUPS

Some piles are installed in groups, spaced approximately 3 to 3.5 times the pile diameter apart. The piles function as a group due to the use of a concrete load-transfer cap encasing all of the pile heads. The weight of the cap subtracts from the gross group capacity. The capacity due to the pile cap resting on the ground (as a spread footing) is disregarded.

For cohesionless (granular) soils, the capacity of a pile group is taken as the sum of the individual capacities, although the actual capacity will be greater. In-situ tests should be used to justify any increases.

For cohesive soils, the group capacity is taken as the smaller of (a) the sum of the individual capacities and (b) the capacity assuming block action. The block action capacity is calculated assuming that the piles form a large pier whose dimensions are the group's perimeter. The block depth, L, is the distance from the surface to the depth of the pile points. The width, w, and length, b, of the pier are the length and width of the pile group as measured from the outsides (not centers) of the outermost piles.

The average undrained shear strength, c_1, along the depth of the piles is used to calculate the skin friction capacity. The undrained shear strength at the pile tips, c_2, is used to calculate the end-bearing capacity. A factor of safety of 3 is used to determine the allowable capacity. Any increase in friction capacity due to lateral soil pressure is disregarded.

$$Q_s = 2(b+w)L_e c_1 \qquad 38.20$$

$$Q_p = 9c_2 bw \qquad 38.21$$

$$Q_{\text{ult}} = Q_s + Q_p \qquad 38.22$$

$$Q_a = \frac{Q_{\text{ult}}}{F} \qquad 38.23$$

The group capacity can be more or less than the sum of the individual pile capacities. The *pile group efficiency*, η_G, is

$$\eta_G = \frac{\text{group capacity}}{\sum \text{individual capacities}} \qquad 38.24$$

For pile groups in clay, the efficiency is typically less than 100% for spacings up to approximately $8B$, above which an efficiency of 100% is maintained for all reasonable pile spacings. For pile groups in sand, efficiencies are similar, although some researchers report efficiencies higher than 100% at very close (e.g., $2B$) spacings. Efficiencies higher than 100% are rarely counted on in designs.

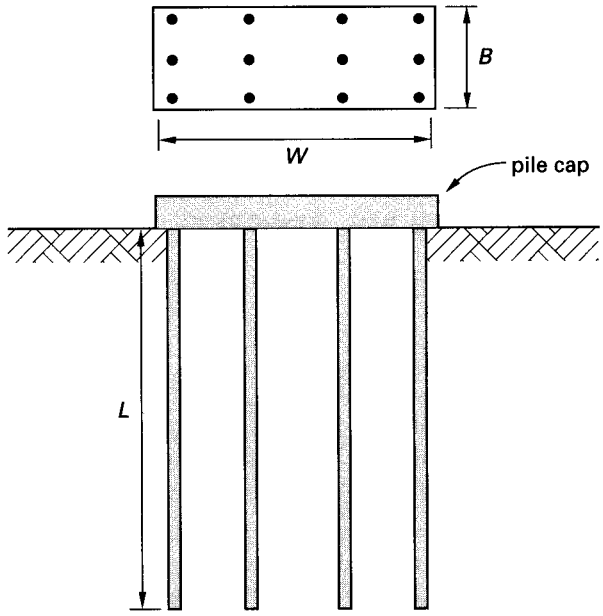

Figure 38.2 *Pile Group*

8. SETTLEMENT OF PILES AND PILE GROUPS

Piles bearing on rock essentially do not settle. Piles in sand experience minimal settlement. There are few theoretical or empirical methods of evaluating settlement of piles in sand.

Piles in clay may experience significant settling. The settlement of a pile group can be estimated by assuming that the support block (used to calculate the group capacity) extends to a depth of only two thirds of the pile length. Settlement above $^2/_3L$ is assumed to be negligible. Below the $^2/_3L$ depth, the pressure distribution spreads out at a vertical:horizontal rate of 2:1 (i.e., at an angle of 60° from the horizontal). The consolidation of the layers encountering the pressure distribution is the pile group settlement. The presence of the lower $L/3$ pile length is disregarded.

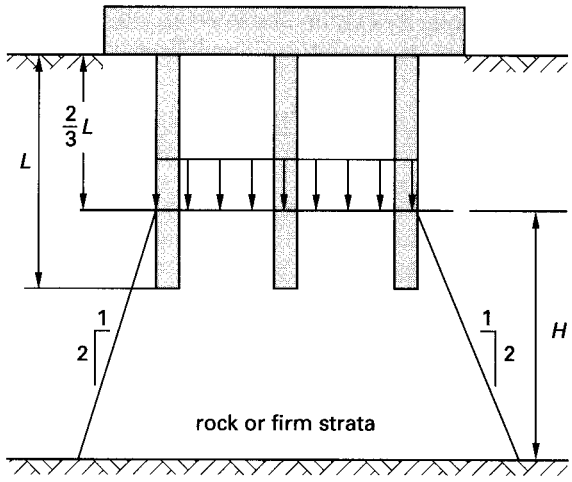

Figure 38.3 *Settlement of Pile Groups*

9. DOWNDRAG AND ADFREEZE FORCES

Downdrag occurs when the skin friction force is in the same direction as the axial load. *Negative skin friction* occurs when the settlement of the surrounding soil exceeds the downward movement of the pile shaft. This can occur when a pile passes through an underconsolidated layer of fill that is consolidating under its own weight, but can also be due to a lowering of the water table or placement of surcharges.

Pile support is also affected by the freeze-thaw process. *Frost jacking* occurs when the frozen ground moves upward (*frost heave*) and takes a pile with it. The forces from this process are known as *adfreeze forces*. When the soil subsequently thaws in the summer, a downdrag force will be experienced. Thus, a pile may experience upward adfreeze forces each winter and downdrag forces each summer. The effects of such forces are particularly pronounced in piles penetrating permafrost.

10. MICROPILES

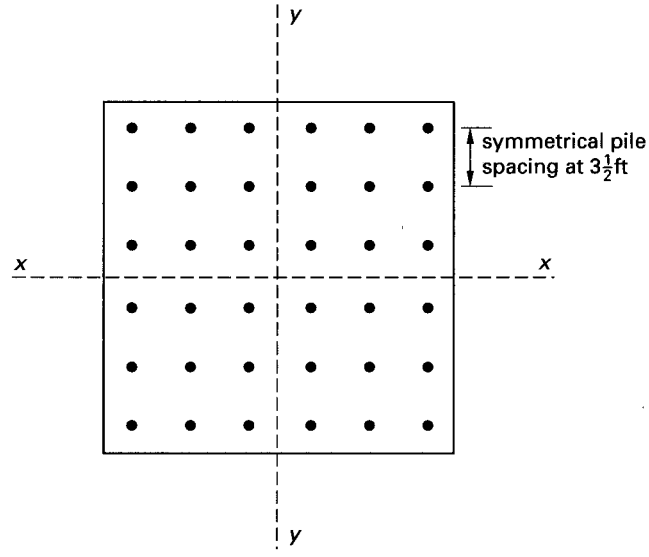
Machine-drilled micropiles (*small-diameter grouted piles, minipiles, pin piles, root piles*, and *needle piles*) are piles with diameters 4 to 10 in (100 to 250 mm) in diameter, 65 to 100 ft (20 to 30 m) long. Significant column strength is obtained from thick wall sections, usually occupying 50% of the cross-sectional area.

Micropiles are installed using rotary drilling techniques. (The micropile can serve as its own drill bit.) After installation, grout is used to fill the interior of the pile, as well as the tip and any annular voiding. Micropiles are used when traditional pile driving is prevented by restricted access. (This is usually the case in urban areas and in seismic retrofits.)

11. PIERS

A *pier* is a deep foundation with a significant cross-sectional area. A pier differs from a pile in its diameter (larger), load-carrying capacity (much larger), and installation method (usually cased within an excavation). In other respects, the analysis of pier foundations is similar to that of piles.

PRACTICE PROBLEMS



Single Piles

1. A 10.75 in diameter steel pile is driven 65 ft into stiff, insensitive clay. The clay has an undrained shear strength of 1300 lbf/ft^2. The clay's specific weight is 115 lbf/ft^3. The water table is at the ground surface. The entire pile length is effective. (a) What is the end-bearing capacity? (b) What is the friction capacity? (c) What is the allowable bearing capacity?

Answers: (a) 7.4 kips; (b) 119 kips; (c) 42 kips

Pile Groups

2. *(Time limit: one hour)* Tests have shown that a single pile would have, by itself, an uplift capacity of 150 tons and a compressive capacity of 500 tons. 36 piles are installed on a grid with a spacing of 3.5 ft. The pile group is capped and connected at the top by a thick concrete slab adding its own axial load of 600 tons. (a) Find the maximum moment that the pile group can take in the x- and y-directions. (b) If the concrete slab is sawed completely through along the y-axis into two separate pieces and then reconnected by a flat steel plate at the slab top to prevent drifting, what will be the maximum moment that the pile group can take about the y-axis?

Answers: (a) 58,360 ft-tons; (b) zero

1. BRACED CUTS

Bracing is used when temporary trenches for water, sanitary, and other lines are opened in soil. A *braced cut* is an excavation in which the active earth pressure from one bulkhead is used to support the facing bulkhead. The *box-shoring* and *close-sheeting* methods of support are shown in Fig. 39.1. (A partial support system known as *skeleton shoring* is not shown.) Deeper braced cuts may be constructed with vertical *soldier piles* (typically steel H-sections) with horizontal timber sheeting members (known as *polings*) between the soldiers.

(a) box shoring

(b) close sheeting

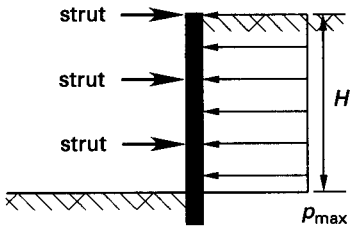
Figure 39.1 *Shoring of Braced Cuts*

Geotechnical

The load is transferred to the struts at various points, so the triangular active pressure distribution does not develop. Since struts are installed as the excavation goes down, the upper part of the wall deflects very little due to the strut restraint. The pressure on the upper part of the wall is considerably higher than is predicted by the active earth pressure equations. Failure in soils above the water table generally occurs by wale (stringer) crippling followed by strut buckling.

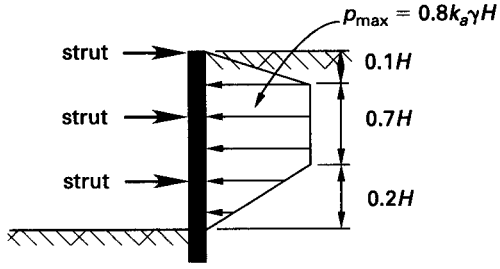
The soil removed from the excavation is known as the *spoils*. Spoils should be placed far enough from the edge of the cut so that they do not produce a surcharge lateral loading.

The bottom of the excavation is referred to as the *base of the cut*, *mud line* (or *mudline*), *dredge line*, and *toe of the excavation*.



Excavations below the water table should be dewatered prior to cutting.

2. BRACED CUTS IN SAND



The analysis of braced cuts is approximate due to the extensive bending of the sheeting. For drained sand, the pressure distribution is approximately uniform with depth. (The *Tschebotarioff trapezoidal pressure distribution*, Fig. 39.2(b), has also been proposed for sand.) The maximum lateral pressure is

$$p_{\max} = 0.65 k_a \rho g H \quad \text{[SI]} \quad 39.1(a)$$

$$p_{\max} = 0.65 k_a \gamma H \quad \text{[U.S.]} \quad 39.1(b)$$

(a) typical

(b) Tschebotarioff

Figure 39.2 *Cuts in Sand*

3. BRACED CUTS IN STIFF CLAY

For undrained clay (typical of cuts made rapidly in comparison to drainage times), $\phi = 0°$. In this case, the lateral pressure distribution depends on the average undrained shear strength (cohesion) of the clay. If $\gamma H/c \leq 4$, the clay is stiff and the pressure distribution is as given in Fig. 39.3. (The quantity $\gamma H/c$ is known as the *stability number* and is sometimes given the symbol N_o.) The value of $p_{\max}$ is affected by many variables. Use the lower range of values of $p_{\max}$ in Eq. 39.2 when movement is minimal or when the construction period is short.

$$0.2\rho g H \leq p_{\max} \leq 0.4\rho g H \quad \text{[SI]} \quad 39.2(a)$$

$$0.2\gamma H \leq p_{\max} \leq 0.4\gamma H \quad \text{[U.S.]} \quad 39.2(b)$$

Except when the cut is underlain by deep, soft, normally consolidated clay, the maximum pressure can be estimated as

$$p_{\max} = k_a \rho g H \quad \text{[SI]} \quad 39.3(a)$$

$$p_{\max} = k_a \gamma H \quad \text{[U.S.]} \quad 39.3(b)$$

$$k_a = 1 - \frac{4c}{\rho g H} \quad \text{[SI]} \quad 39.4(a)$$

$$k_a = 1 - \frac{4c}{\gamma H} \quad \text{[U.S.]} \quad 39.4(b)$$

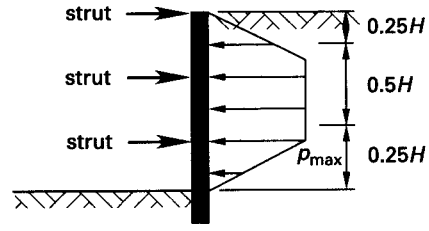


Figure 39.3 *Cuts in Stiff Clay*

4. BRACED CUTS IN SOFT CLAY

If $\gamma H/c \geq 6$, the clay is soft and the lateral pressure distribution will be as shown in Fig. 39.4. Except for cuts underlain by deep, soft, normally consolidated clays, the maximum pressure is

$$p_{\max} = \rho g H - 4c \quad \text{[SI]} \quad 39.5(a)$$

$$p_{\max} = \gamma H - 4c \quad \text{[U.S.]} \quad 39.5(b)$$

If $6 \leq \gamma H/c \leq 8$, the bearing capacity of the soil is probably sufficient to prevent shearing and upward heave. Simple braced cuts should not be attempted if $\gamma H/c > 8$.

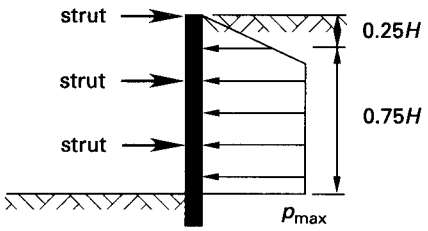

Figure 39.4 *Cuts in Soft Clay*

5. BRACED CUTS IN MEDIUM CLAY

If $4 < \gamma H/c < 6$, the soft and stiff clay cases should both be evaluated. The case that results in the greater pressure should be used when designing the bracing.

6. ANALYSIS/DESIGN OF BRACED EXCAVATIONS

Since braced excavations with more than one strut are statically indeterminate, strut forces and sheet piling moments may be evaluated by assuming continuous beam action or hinged beam action (i.e., with hinges at the strut points). In the absence of a true indeterminate analysis, the axial strut compression can be determined by making several strategic assumptions.

A hinge (point of zero moment) is assumed to exist at the second (from the top) strut support point. If moments above that point are taken, a force in the first strut will be derived. Next, a hinge is assumed at the third (from the top) strut support point and moments are taken about that point (including moments from the top strut, now known), giving the force in the second strut. The process is repeated for all lower struts, finishing by assuming the existence of a fictitious support at the base of the cut in order to determine the force in the last real strut. The pressure distribution on any embedment below the base of the cut is disregarded.

The required section modulus of the sheet piling is given by Eq. 39.6. Typical values of F_b are given in Table 39.2.

$$S = \frac{M_{\text{max,sheet piling}}}{F_b} \qquad 39.6$$

Struts are selected as column members in order to support the axial loads with acceptable slenderness ratios. Wales are selected as uniform-loaded beams, although cofferdam wales are simultaneously loaded in compression and are designed as beam-columns.

7. STABILITY OF BRACED EXCAVATIONS IN CLAY

Heave may occur at the bottom of cuts in soft clay. The depth of excavation at which a heaving failure can be expected to occur is referred to as the *critical height of excavation*, H_c. B is the width of the excavation. In Eqs. 39.7 and 39.8, it is assumed that there is sufficient distance between the base of the cut and any hard stratum below to allow the heave failure surface to fully form. Friction and adhesion on the back of the sheeting are disregarded.

$$H_c = \frac{5.7c}{\rho g - \sqrt{2}\left(\frac{c}{B}\right)} \quad [H < B] \quad \text{[SI]} \qquad 39.7(a)$$

$$H_c = \frac{5.7c}{\gamma - \sqrt{2}\left(\frac{c}{B}\right)} \quad [H < B] \quad \text{[U.S.]} \qquad 39.7(b)$$

$$H_c = \frac{N_c c}{\rho g} \quad [H > B] \quad \text{[SI]} \qquad 39.8(a)$$

$$H_c = \frac{N_c c}{\gamma} \quad [H > B] \quad \text{[U.S.]} \qquad 39.8(b)$$

Approximate values of N_c for infinitely long trenches are given in Table 39.1. Different values are necessary for circular, square, and rectangular cofferdam-like excavations that are sheeted on all sides.

It is common to apply a factor of safety of 1.5 to the undrained shear strength (cohesion), c. (If the factor of safety is less than 1.5, the sheeting must be carried down below the base of the cut until a factor of safety of 1.5 is achieved.) For the common case where $H > B$, where sheeting terminates at the base of the cut, and where there is a surface surcharge loading, q, the factor of safety is

$$F = \frac{N_c c}{\rho g H + q} \quad \text{[SI]} \qquad 39.9(a)$$

$$F = \frac{N_c c}{\gamma H + q} \quad \text{[U.S.]} \qquad 39.9(b)$$

If the factor of safety is less than 1.5, the sheeting must be carried to a depth approximately $B/2$ below the base of the cut.

Table 39.1 *Approximate Skempton Values of N_c for Infinitely Long Trenches (for use in Eqs. 39.8 and 39.9)*

H/B	N_c
0	5.1
1	6.3
2	7.0
3	7.3
≥ 4	7.5

8. STABILITY OF BRACED EXCAVATIONS IN SAND

For braced excavations in sand, the stability is independent of H and B. However, stability does depend on density, friction angle, and seepage conditions. When the water table is at least a distance of B below the

Geotechnical

base of the cut and the drained (dry, moist, etc.) sand density below the cut is the same as behind the cut, the factor of safety is

$$F = 2N_\gamma k_a \tan \phi \qquad 39.10$$

If the water table is stationary (i.e., not rising or falling) at the base of the cut,

$$F = 2N_\gamma \left(\frac{\rho_{\text{submerged}}}{\rho_{\text{drained}}}\right) k_a \tan \phi \quad \text{[SI]} \qquad 39.11(a)$$

$$F = 2N_\gamma \left(\frac{\gamma_{\text{submerged}}}{\gamma_{\text{drained}}}\right) k_a \tan \phi \quad \text{[U.S.]} \qquad 39.11(b)$$

If there is continual upward seepage through the base of the cut, the uplift pressure must also be evaluated.

9. SHEET PILING

Steel *sheet piles* (also known as *trench sheets*) are blade-like rolled steel sections that are driven into the ground to provide lateral support. Sheet piles are placed side by side and generally have interlocking edges ("clutches") that enable the individual sheet piles to act as a continuous wall. Sheet piles are driven into the unexcavated ground ahead of the trenching operation.

Sheet piling is selected according to its geometry (i.e., flat, waffle, Z-, etc.) and the required section modulus. ASTM A572 is a typical steel, with the grade indicating the minimum yield point in ksi. The allowable design stress, F_b, is usually taken as 65% of the minimum yield stress, with some increases for temporary overstresses typically being allowed.

Table 39.2 *Suggested Allowable Design Stress in Sheet Piling*

	minimum yield point		allowable design stress[a]	
steel grade	ksi	MPa	ksi	MPa
A572 grade 55	55	380	35	240
A572 grade 50	50	345	32	220
A572 grade 45	45	310	29	200
A328 regular carbon	38.5	265	25	170

(Multiply ksi by 6.9 to obtain MPa.)
[a]65% of the minimum yield stress

10. ANALYSIS/DESIGN OF FLEXIBLE BULKHEADS

There are two types of flexible bulkheads: untied and tied (i.e., anchored). If the bulkhead is untied, it is designed as a cantilever beam. This is known as a *cantilever wall.*

The first step in the design of flexible bulkheads is determining the lateral pressure distribution due to the restrained soil and surcharges. Below the base of the cut, the passive pressure distribution opposes the active pressure distribution. The point at which the net pressure distribution (i.e., the shear) is zero is taken as the *hinge point* (or *pivot point, inflection point,* or *point of counterflexure*). This corresponds to the point of maximum moment.

The theoretical depth of embedment, D, is chosen such that the sum of moments (taken about any convenient point) is zero. Thus, the pivot point must simultaneously satisfy both force and moment equilibrium conditions. Figure 39.5 illustrates the pressure distributions for cohesionless sand. The solution procedure for cohesive clay is more complex since the pressure distribution depends on the backfill material and changes with time.

$$y = \frac{k_p D^2 - k_a (H + D)^2}{(k_p - k_a)(H + 2D)} \qquad 39.12$$

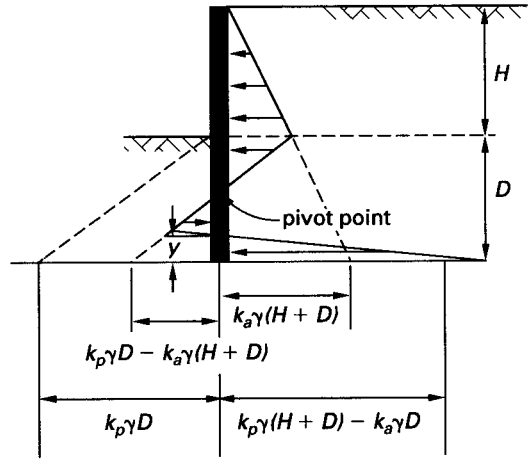

Figure 39.5 *Cantilever Wall in Uniform Granular Soil*

11. ANCHORED BULKHEADS

An *anchored bulkhead* is supported at its base by its embedment. The bulkhead is anchored near the top by *tie rods* (*tendons, ties, tie backs*, etc.) projecting back into the soil. These rods can terminate at deadmen, vertical piles, walls, beams, or various other types of anchors. To be effective, the anchors must be located outside of the failure zone (i.e., behind the slip plane).

Anchored bulkheads can fail in several ways. (a) The soil's base layer can heave (i.e., fail due to inadequate bearing capacity). The soil will shear along a circular arc passing under the bulkhead. (b) The anchorage can fail. (c) The toe embedment at the base of the cut can fail. This is referred to as *toe kick-out* and *toe wash-out* (d) Rarely, the sheeting can fail.

12. ANALYSIS/DESIGN OF TIED BULKHEADS

The *anchor pull* (tension in the tie) is found by setting to zero the sum of all horizontal loads on the bulkhead, including the passive loads on the embedded portion.

If the dimensions are known, the factor of safety against toe failure is found by taking moments about the anchor point on the bulkhead. (Alternatively, if the dimensions are not known, the depth of embedment can be found by taking moments about the anchor point.)

The maximum bending moment in the bulkhead sheeting is found by taking moments about the hinge point, where the shear is zero. If the dimensions are not known, the location of this point must be initially assumed. For firm and dense embedment soils, the hinge point is assumed to be at the base of the cut. For loose and weak soils, it is 1 to 2 ft below the base of the cut. For a soft layer over a hard layer, it is at the depth of the hard layer. The stress in the bulkhead is

$$f = \frac{M}{S} \qquad 39.13$$

If the dimensions are not known, the required section modulus is

$$S = \frac{M}{F_b} \qquad 39.14$$

With multiple ties, the strut forces are statically indeterminate. Although exact methods (e.g., moment distribution) could be used, it is more expedient to assign portions of the active distribution to the struts based on the tributary areas. The area tributary to strut is bounded by imaginary lines running midway between it and an adjacent strut, in all four directions.

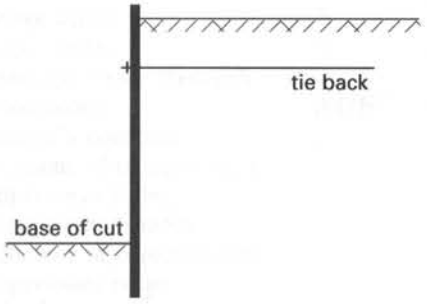

Figure 39.6 *Anchored Bulkhead*

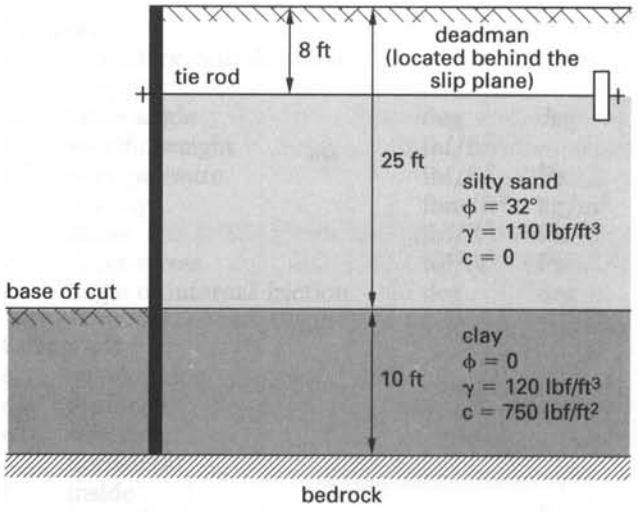
PRACTICE PROBLEMS



Braced Cuts

1. A 30 ft deep, 40 ft square excavation in sand is being designed. The sand will be dewatered before excavation. The angle of internal friction is 40°, and the specific weight is 121 lbf/ft^3. Bracing consists of horizontal lagging supported by 8 in soldier piles separated horizontally by 8 ft. (a) What is the approximate shape of the pressure diagram on the lagging? (b) What is the bending moment on the lagging?

Answers: (a) rectangular; (b) 4100 ft-lbf

Flexible Bulkheads

2. *(Time limit: one hour)* A 35 ft long sheet pile is driven through 10 ft of clay to bedrock below. The sheet pile supports a 25 ft vertical cut through drained sand. A tie rod is located 8 ft below the surface, terminating at a deadman behind the failure plane. There is no significant water table. Soil parameters are shown in the accompanying illustration. (a) What is the tensile force in the tie rod, disregarding the passive pressure distribution? (b) What is the tensile force in the tie rod, considering only the passive pressure distribution only above the inflection point?

Answer: (a) 6060 lbf; (b) 5990 lbf

1. PRESSURE FROM APPLIED LOADS: BOUSSINESQ'S EQUATION

The increase in vertical pressure (stress), Δp_v, caused by an application of a point load, P, at the surface can be found from *Boussinesq's equation*. This equation assumes that the footing width, B, is small compared to the depth, h, and that the soil is semi-infinite, elastic,

isotropic, and homogeneous. It is sometimes convenient to solve Eq. 40.1 by using specially prepared *Boussinesq contour charts* included as Apps. 40.A and 40.B.

$$\Delta p_v = \frac{3h^3P}{2\pi z^5}$$

$$= \left(\frac{3P}{2\pi h^2}\right)\left(\frac{1}{1+\left(\frac{r}{h}\right)^2}\right)^{\frac{5}{2}} \quad [h > 2B] \qquad 40.1$$

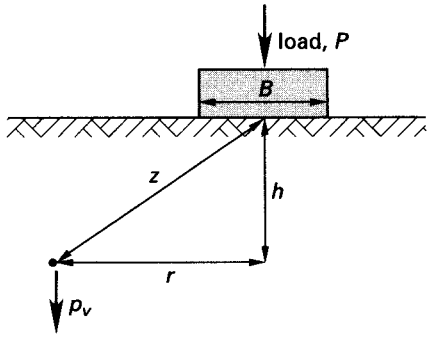

Figure 40.1 *Pressure at a Point*

Not all situations are adequately described by the Boussinesq theory. The *Westergaard case* applies to layered materials as they exist in multilayered highway pavement sections. The effect of such layering is to reduce the stresses substantially below those predicted by the Boussinesq theory.

2. PRESSURE FROM APPLIED LOADS: ZONE OF INFLUENCE

The approximate stress at a depth can be determined by assuming the geometry of the affected area (i.e., the *zone of influence*). Approximate methods can be reasonably accurate in nonlayered homogeneous soils when $1.5 < h/B < 5$.

The zone of influence is defined by the angle of the *influence cone*. This angle is typically assumed to be 51° for point loads and 60° from the horizontal for uniformly loaded circular and rectangular footings. (Accordingly, this method is sometimes referred to as the *60° method*.) Alternatively, since 60° is an approximation anyway, for ease of computation, the angle is taken as 63.4°, corresponding to a 2:1 (vertical:horizontal) influence cone angle.

For any depth, the area of the cone of influence is the area of the horizontal plane enclosed by the influence boundaries, as determined geometrically. For a rectangular footing with the 60° method, the area of influence at depth h is

$$A = \big(B + 2(h \cot 60°)\big)\big(L + 2(h \cot 60°)\big) \qquad 40.2$$

For a rectangular footing assuming a 2:1 influence, the area of influence is

$$A = (B + h)(L + h) \qquad 40.3$$

The increase in pressure at that location is

$$\Delta p_v = \frac{P}{A} \qquad 40.4$$

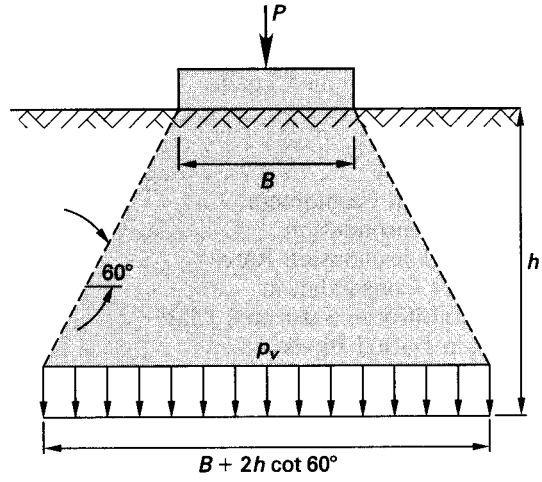

Figure 40.2 *Zone of Influence*

3. PRESSURE FROM APPLIED LOADS: INFLUENCE CHART

If a footing or mat foundation is large compared to the depth where the unknown pressure is wanted, the vertical pressure at a point can be estimated by using an *influence chart* (*Newmark chart*). A Newmark influence chart is a graphical solution to the Boussinesq case. Each influence chart has an indicated scale (the "key") and an influence value that is equal to the reciprocal of the number of squares in the chart.

To use the influence chart, the implied scale is determined by making the indicated distance A-B equal to the depth at which the pressure is wanted. Using this scale, a plan view of the footing or mat foundation is drawn on a piece of tracing paper. The tracing paper is placed over the influence chart such that the center of the chart coincides with the location under the footing where the pressure is wanted. Then, the number of squares under the footing drawing is counted. Partial squares are counted as fractions. The pie-shaped areas in the center circle are counted as complete squares. The *influence value* is read from the influence chart, and Eq. 40.5 is used to calculate the pressure.

$$\Delta p_v = (\text{influence value})(\text{no. of squares}) \times (\text{applied pressure}) \qquad 40.5$$

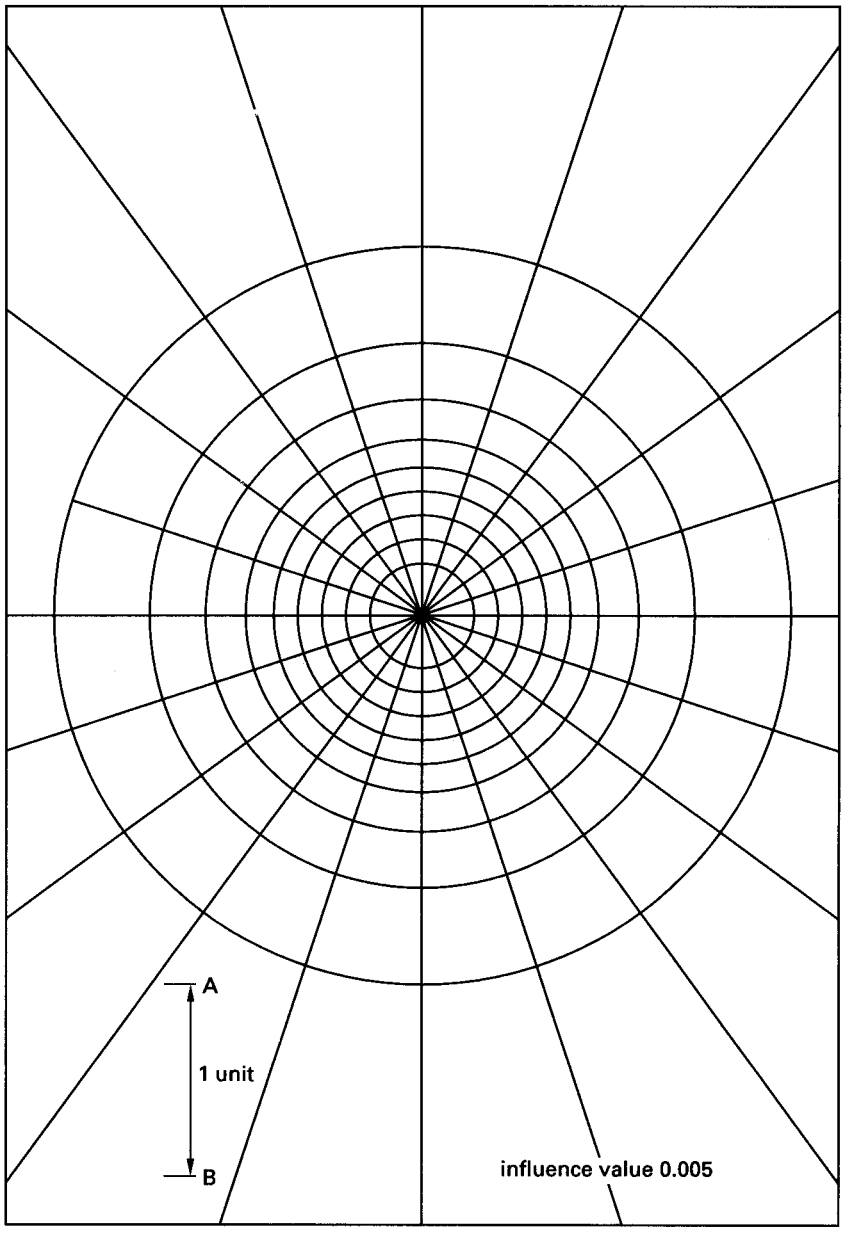

Figure 40.3 *Influence Chart*

4. SETTLING

Settling is generally due to *consolidation* (i.e., a decrease in void fraction) of the supporting soil. There are three distinct periods of consolidation. (a) *Immediate settling*, also known as *elastic settling*, occurs immediately after the structure is constructed. Immediate settling is the major settling component in sandy soils. (b) In clayey soils, *primary consolidation* occurs gradually due to the extrusion of water from the void spaces. (c) *Secondary consolidation* occurs in clayey soils at a much slower rate after the primary consolidation has finished. Since plastic readjustment of the soil grains (including progressive fracture of the grains themselves) is the primary mechanism, the magnitude of secondary consolidation is considerably less than primary consolidation.

Since settling is greater for higher foundation pressures, specific settlement limits (e.g., 1 in) are directly related to the maximum allowable pressures. This, in turn, can be used to size footings and other foundations.

5. CLAY CONDITION

For clays, the method used to calculate consolidation depends on the clay condition. Figure 40.4 shows a typical *consolidation curve* showing void ratio, e,

versus applied effective pressure, p' (or effective stress, σ'), for a previously consolidated clayey soil, graphed on an e-log p curve. The curve shows a *recompression segment* (*preconsolidated* or *overconsolidated segment*) and the *virgin compression branch* (*normally consolidated segment*).

If the pressure is increased from p_1 to p_2, the consolidation will be in the recompression zone, which has the lower slope, C_r. C_r is typically one fifth to one tenth of C_c. If the pressure is increased above p_2, consolidation is more dramatic as the slope C_c is higher. If the pressure is increased from p_1 to p_3, the two consolidations are added together to obtain the total settlement.

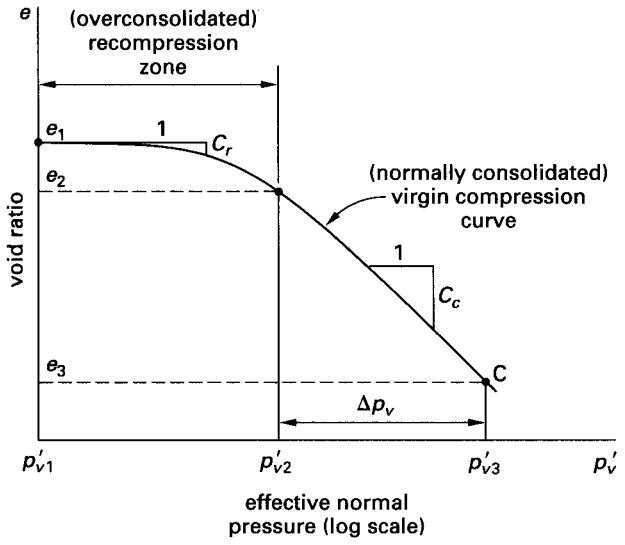

Figure 40.4 *Consolidation Curve for Clay*

6. CONSOLIDATION PARAMETERS

Along the recompression line, the *recompression index*, C_r, is the logarithmic slope of the recompression segment.

$$C_r = \frac{-(e_1 - e_2)}{\log_{10}\left(\frac{p_1}{p_2}\right)} \qquad 40.6$$

The *compression index* is the logarithmic slope of the primary consolidation curve. $p_2 + \Delta p_v$ is the total pressure after the load has been applied (or removed).

$$\begin{aligned} C_c &= \frac{-(e_2 - e_3)}{\log_{10}\left(\frac{p_2}{p_3}\right)} \\ &= \frac{\Delta e}{\log_{10}\left(\frac{p_2}{p_2 + \Delta p_v}\right)} \end{aligned} \qquad 40.7$$

If necessary, the compression index can be estimated from other soil parameters, although these correlations are not highly accurate. For clays, a general expression is given by Eq. 40.8. The term e_o represents the "original" void ratio of the clay, often used as an estimate of the average void ratio over the range of interest. Referring to Fig. 40.4, e_o will either be e_1 or e_2, depending on whether the clay is originally overconsolidated or normally consolidated, respectively.

$$C_c \approx 1.15(e_o - 0.35) \quad \text{[clays]} \qquad 40.8$$

For inorganic soils (overconsolidated clays) with sensitivities less than 4,

$$C_c \approx 0.009(\text{LL} - 10) \qquad 40.9$$

For organic soils (e.g., peat), the compression index depends on the natural moisture content.

$$C_c \approx 0.0155w \qquad 40.10$$

For *varved clays* (i.e., clays that are layered with fine and coarse varieties),

$$C_c \approx (1 + e_o)\big(0.1 + 0.006(w_n - 25)\big) \qquad 40.11$$

Some authorities define the *compression ratio*, CR (not to be confused with C_r), and the *recompression ratio*, RR (also known as the *swelling index*), as follows.

$$\text{CR} = \frac{C_c}{1 + e_o} \qquad 40.12$$

$$\text{RR} = \frac{C_r}{1 + e_o} \qquad 40.13$$

For saturated soils, the voids ratio, e, can be calculated from the water content.

$$e = w(\text{SG}) \quad \text{[saturated]} \qquad 40.14$$

7. PRIMARY CONSOLIDATION

When clay layers are loaded to a higher pressure, water is "squeezed" from the voids. Water is lost over a long period of time, though the rate of loss decreases with time. The loss of water results in a consolidation of the clay layer and a settlement of the soil surface. The long-term consolidation due to water loss is the *primary consolidation*, S_{primary}. For an overconsolidated clay layer of thickness H, the consolidation is

$$\begin{aligned} S_{\text{primary}} &= \frac{H\Delta e}{1 + e_o} \\ &= \frac{HC_r \log_{10}\left(\frac{p'_o + \Delta p'_v}{p'_o}\right)}{1 + e_o} \\ &= H(\text{RR}) \log_{10}\left(\frac{p'_o + \Delta p'_v}{p'_o}\right) \quad \text{[overconsolidated]} \end{aligned} \qquad 40.15$$

The primary consolidation in a normally consolidated clay layer of thickness H is

$$S_{\text{primary}} = \frac{H\Delta e}{1+e_o} = \frac{HC_c \log_{10}\left(\frac{p'_o + \Delta p'_v}{p'_o}\right)}{1+e_o} = H(\text{CR})\log_{10}\left(\frac{p'_o + \Delta p'_v}{p'_o}\right) \quad \left[\begin{array}{c}\text{normally}\\ \text{consolidated}\end{array}\right] \qquad 40.16$$

$\Delta p'_v$ is the increase in effective vertical pressure. Boussinesq's equation, stress contour charts, or influence charts can be used to determine Δp_v.

p'_o is the original *effective pressure* (*effective stress*) at the midpoint of the clay layer and directly below the foundation. The average effective pressure is the sum of the following items, depending on whether the layer is above or below the *ground water table* (GWT). H is the layer thickness. Notice that in Eq. 40.16, p' is the effective pressure, exclusive of the pore pressure. Only the effective pressure causes consolidation.

$$p_v = \gamma_{\text{layer}} H \quad \text{[above GWT]} \qquad 40.17$$

$$p'_v = \gamma_{\text{layer}} H - \gamma_{\text{water}} h = p_v - \mu \quad \text{[below GWT]} \qquad 40.18$$

$$\mu = \gamma_{\text{water}} h \qquad 40.19$$

The *pore pressure*, μ, can be determined in a number of ways, including piezometer readings (i.e., the height of water in a standpipe).

8. PRIMARY CONSOLIDATION RATE

Consolidation of clay is a continuous process, though the rate decreases with time. The time for a single layer to reach a specific consolidation is given by Eq. 40.20. H_d is the full layer thickness if drainage is from one surface only (i.e., *single drainage* or *one-way drainage*). If drainage is through both the top and bottom surfaces (i.e., *double drainage* or *two-way drainage*), H_d is half the layer's thickness. The units of t will depend on the units of C_v.

$$t = \frac{T_v H_d^2}{C_v} \qquad 40.20$$

The *coefficient of consolidation*, C_v, with typical units of ft^2/day (m^2/day), is assumed to remain constant over small variations in the void ratio, e.

$$C_v = \frac{K(1+e_o)}{a_v \gamma_{\text{water}}} \qquad 40.21$$

The *coefficient of compressibility*, a_v, can be found from the void ratio and the effective pressure (stress) for any two different loadings. The coefficient of compressibility is not really constant—it decreases with increasing stress. However, it is assumed constant over small variations.

$$a_v = \frac{-(e_2 - e_1)}{p'_2 - p'_1} \qquad 40.22$$

T_v is a dimensionless *time factor* that depends on the *degree of consolidation*, U_z. U_z is the fraction of the total consolidation that is expected. For values of U_z larger than 0.60, Table 40.1 can be used.

$$T_v = \tfrac{1}{4}\pi U_z^2 \quad [U_z < 0.60] \qquad 40.23$$

Table 40.1 *Approximate Time Factors*[a]

U_z	T_v
0.10	0.008
0.20	0.031
0.30	0.071

$$T_v = 1.781 - 0.933\log\bigl(100\,(1-U_z)\bigr) \quad [U_z > 0.60]$$

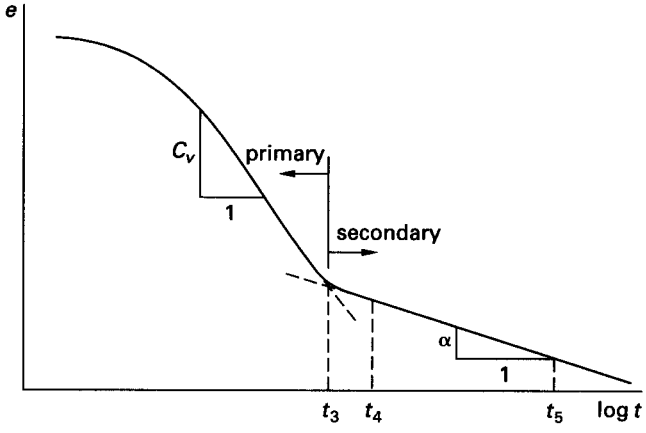

Figure 40.5 *Consolidation Parameters*

9. SECONDARY CONSOLIDATION

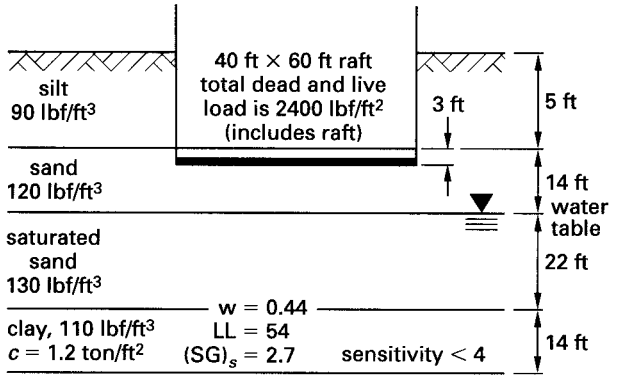
Following the completion of primary consolidation (at $T_v = 1$), the rate of consolidation decreases markedly. The continued consolidation is known as *secondary consolidation*. Secondary consolidation is a gradual continuation of consolidation that continues long after the cessation of primary consolidation. Secondary consolidation may not occur at all, as is the case in granular soils. Secondary consolidation may be a major factor for inorganic clays and silts, as well as for highly organic soils.

Secondary consolidation can be identified on a chart of void ratio (or settlement) versus logarithmic time. The region of secondary consolidation is characterized by a distinct slope reduction. The plot can be used to obtain important parameters necessary to calculate the magnitude and rate of secondary consolidation.

The final void ratio, e_3, at the end of the primary consolidation period is read directly from the chart. The logarithmic slope of the secondary compression line is the *secondary compression index*, α, which generally varies from 0 to 0.03, seldom exceeding 0.04.

$$\alpha = \frac{-(e_5 - e_4)}{\log\left(\frac{t_5}{t_4}\right)} \qquad 40.24$$

The *coefficient of secondary consolidation*, C_α, is given by Eq. 40.25. e_o is the "original" void ratio, often used as an approximation of the average void ratio over the range of interest.



$$C_\alpha = \frac{\alpha}{1 + e_o} \qquad 40.25$$

The secondary consolidation during the period t_4 to t_5 is

$$S_{\text{secondary}} = C_\alpha H \log_{10}\left(\frac{t_5}{t_4}\right) \qquad 40.26$$

Example 40.1

A 40 ft × 60 ft raft foundation on sand is constructed and loaded as shown. The sand has already settled. (a) What long-term primary settlement can be expected at the center of the raft? (b) What long-term primary settlement can be expected at the corner of the raft?

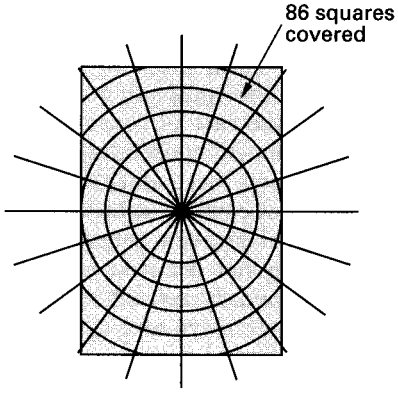
Solution

step 1: Only the clay will contribute to long-term settlement. Calculate the original pressure at the center of the clay layer. The pressure consists of components from the various layers above it.

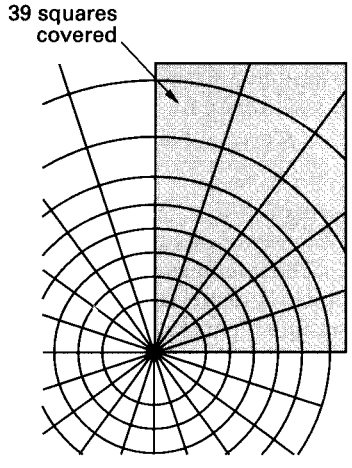
$$\text{silt layer: } (5\text{ ft})\left(90\ \frac{\text{lbf}}{\text{ft}^3}\right) = 450\ \text{lbf/ft}^2$$

$$\text{drained sand layer: } (14\text{ ft})\left(120\ \frac{\text{lbf}}{\text{ft}^3}\right) = 1680\ \text{lbf/ft}^2$$

$$\text{submerged sand layer: } (22\text{ ft})\left(130\ \frac{\text{lbf}}{\text{ft}^3} - 62.4\ \frac{\text{lbf}}{\text{ft}^3}\right) = 1487\ \text{lbf/ft}^2$$



$$\text{clay layer: } \left(\tfrac{1}{2}\right)(14\text{ ft})\left(110\ \frac{\text{lbf}}{\text{ft}^3} - 62.4\ \frac{\text{lbf}}{\text{ft}^3}\right) = 333\ \text{lbf/ft}^2$$



$$\text{total: } p_o = 3950\ \text{lbf/ft}^2$$

step 2: The applied pressure at the base of the raft is the load and live loading less the overburden due to the excavated sand and silt.

$$p_{\text{net,center}} = 2400\ \frac{\text{lbf}}{\text{ft}^2} - (5\text{ ft})\left(90\ \frac{\text{lbf}}{\text{ft}^3}\right) - (3\text{ ft})\left(120\ \frac{\text{lbf}}{\text{ft}^3}\right) = 1590\ \text{lbf/ft}^2$$

Use Fig. 40.3 to calculate the pressure increase due to the loading. The distance from the bottom of the raft to the midpoint of the clay layer is 36 ft − 3 ft + 7 ft = 40 ft. Using a scale of 1 in:40 ft, the raft is 1 in × 1½ in. When the raft is centered over the influence chart, 86 squares are covered. When the raft's corner is placed over the center of the chart, 39 squares are covered.

The midlayer pressure increases are given by Eq. 40.5.

$$\begin{aligned} p_{v,\text{center}} &= (\text{influence value}) \\ &\quad \times (\text{no. of squares}) \\ &\quad \times (\text{applied pressure}) \\ &= (0.005)(86)\left(1590\ \frac{\text{lbf}}{\text{ft}^2}\right) \\ &= 680\ \text{lbf/ft}^2 \end{aligned}$$

$$\begin{aligned} p_{v,\text{corner}} &= (0.005)(39)\left(1590\ \frac{\text{lbf}}{\text{ft}^2}\right) \\ &= 310\ \text{lbf/ft}^2 \end{aligned}$$

step 3: Estimate the original void content of the clay. Use Eq. 40.14.

$$e_o \approx w(\text{SG}) = (0.44)(2.7) = 1.188$$

step 4: Estimate the compression index. Use Eq. 40.9.

$$\begin{aligned} C_c &\approx 0.009(\text{LL} - 10) \\ &= (0.009)(54 - 10) = 0.396 \end{aligned}$$

step 5: The settlements are given by Eq. 40.16.

$$S_{\text{center}} = \frac{HC_c\left(\log_{10}\left(\frac{p_o + p_v}{p_o}\right)\right)}{1 + e_o}$$

$$= \frac{(14\ \text{ft})(0.396)\left(\log_{10}\left(\frac{3950\ \frac{\text{lbf}}{\text{ft}^2} + 680\ \frac{\text{lbf}}{\text{ft}^2}}{3950\ \frac{\text{lbf}}{\text{ft}^2}}\right)\right)}{1 + 1.118}$$

$$= 0.181\ \text{ft}$$

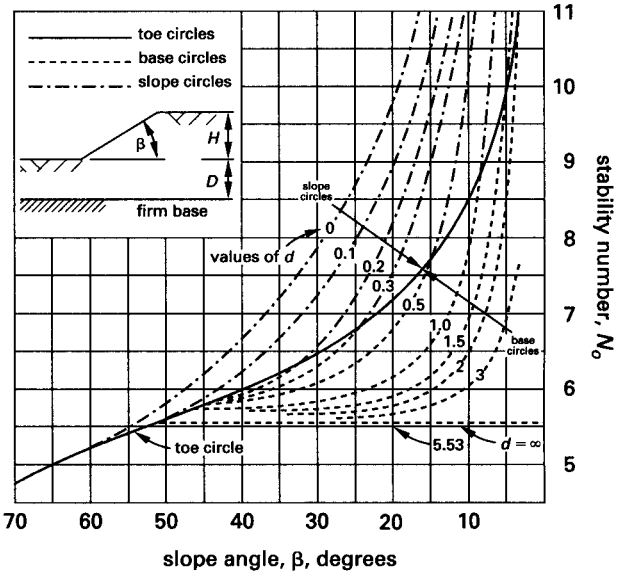
$$S_{\text{corner}} = \frac{(14\ \text{ft})(0.396)\left(\log_{10}\left(\frac{3950\ \frac{\text{lbf}}{\text{ft}^2} + 310\ \frac{\text{lbf}}{\text{ft}^2}}{3950\ \frac{\text{lbf}}{\text{ft}^2}}\right)\right)}{1 + 1.118}$$

$$= 0.086\ \text{ft}$$

10. SLOPE STABILITY IN SATURATED CLAY

The maximum slope for cuts in cohesionless (i.e., drained) sand is the *angle of internal friction*, ϕ, also known as the *angle of repose*. However, the maximum slope for cuts in cohesive soils is more difficult to determine. For saturated clay with $\phi = 0°$, the *Taylor slope stability chart* can be used to determine the factor of safety against slope failure. The Taylor chart makes the following assumptions: (a) There is no open water outside of the slope. (b) There are no surcharges or tension cracks. (c) Shear strength is derived from cohesion only and is constant with depth. (d) Failure takes place as rotation on a circular arc.

The Taylor chart relates a dimensionless depth factor, d, to a dimensionless stability number, N_o. The depth factor, d, is the quotient of the vertical distance from the toe of the slope to the firm base below the clay layer, D, and the slope height, H (the depth of the cut).



$$d = \frac{D}{H} \qquad 40.27$$

Equation 40.28 gives the relationship between the *stability number* and the cohesive factor of safety. The effective specific weight is used when the clay is submerged. The minimum acceptable factor of safety is approximately 1.3 to 1.5.

$$F_{\text{cohesive}} = \frac{N_o c}{\gamma_{\text{eff}} H} \qquad 40.28$$

$$\gamma_{\text{eff}} = \gamma_{\text{saturated}} - \gamma_{\text{water}} \qquad 40.29$$

The Taylor chart shows that toe circle failures occur in slopes steeper than 53°. For slopes of less than 53°, *slope circle failure, toe circle failure*, or *base circle failure* may occur.

Source: *Soil Mechanics*, NAVFAC Design Manual DM-7.1, May 1982

Figure 40.6 *Taylor Slope Stability ($\phi = 0°$)*

Geotechnical

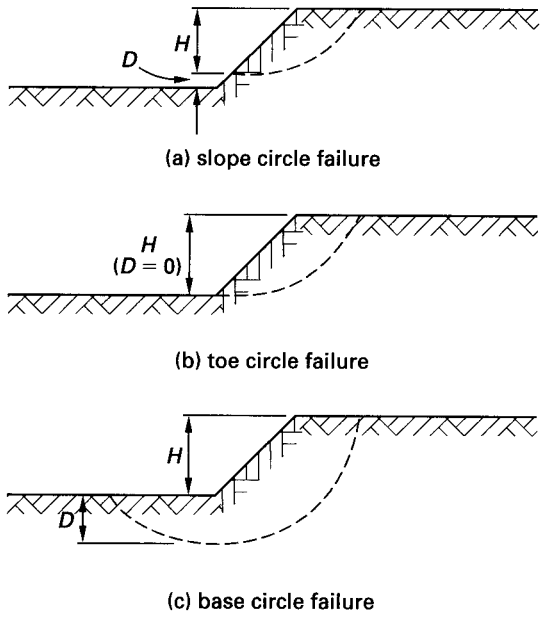


Figure 40.7 *Types of Slope Failures*

Example 40.2

A submerged trench is excavated in a layer of soft mud. The trench walls are sloped at a vertical:horizontal ratio of 1.5:1. The mud has a saturated density of 100 lbf/ft^3 and a cohesion of 400 lbf/ft^2. A factor of safety against cohesive slope failure of 1.5 is required. (a) What type of failure will occur? (b) What depth of cut can be made?

Solution

(a) The cut angle is

$$\beta = \arctan\left(\frac{1.5}{1}\right) = 56^\circ$$

Since this is greater than 53°, the failure will be toe circle.

(b) From Fig. 40.6, the stability number for $\beta = 56^\circ$ is approximately 5.4. Since the clay is submerged, use the effective unit weight.

$$\begin{aligned}\gamma_{\text{eff}} &= \gamma_{\text{saturated}} - \gamma_{\text{water}} \\ &= 100\ \frac{\text{lbf}}{\text{ft}^3} - 62.4\ \frac{\text{lbf}}{\text{ft}^3} = 37.6\ \text{lbf/ft}^3\end{aligned}$$

Solve Eq. 40.28 for depth of cut.

$$\begin{aligned}H &= \frac{N_o c}{F\gamma_{\text{eff}}} \\ &= \frac{(5.4)\left(400\ \frac{\text{lbf}}{\text{ft}^2}\right)}{(1.5)\left(37.6\ \frac{\text{lbf}}{\text{ft}^3}\right)} \\ &= 38.3\ \text{ft}\end{aligned}$$

11. LOADS ON BURIED PIPES

If a pipe is placed in an excavated trench and subsequently backfilled, the pipe must be strong enough to support the vertical soil load in addition to any loads from surface surcharges. The magnitude of the load supported depends on the amount of backfill, type of soil, and pipe stiffness. For rigid pipes (e.g., concrete, cast iron, ductile iron, and older clay types) that cannot deform and that are placed in narrow trenches (e.g., 2 to 3 pipe diameters), the approximate dead load per unit length can be calculated from *Marston's formula*, Eq. 40.30. Typical values of C and γ are given in Table 40.2. B is the trench width at the top of the pipe.

$$w = C\rho g B^2 \quad \text{[SI]} \quad 40.30(a)$$

$$w = C\gamma B^2 \quad \text{[U.S.]} \quad 40.30(b)$$

The *dead load pressure* is the dead load divided by the trench width.

$$p = \frac{w}{B} \quad 40.31$$

Flexible pipes (e.g., steel, plastic, and copper) are able to develop a horizontal restraining pressure equal to the vertical pressure if the backfill is well compacted. There is evidence that flexible pipes shrink away from the soil under high compressive loads, thus reducing the soil pressure significantly.

$$w = C\rho g B D \quad \text{[SI]} \quad 40.32(a)$$

$$w = C\gamma B D \quad \text{[U.S.]} \quad 40.32(b)$$

If a pipe is placed on undisturbed ground and covered with fill (*broad fill* or *embankment fill*), the load is given by Eq. 40.33. Values of C_p are given in Table 40.3.

$$w = C_p \rho g D^2 \quad \text{[SI]} \quad 40.33(a)$$

$$w = C_p \gamma D^2 \quad \text{[U.S.]} \quad 40.33(b)$$

Equation 40.30 shows that the trench width is an important factor in determining whether or not the pipe has sufficient capacity. There is a depth, however, beyond which no additional load is carried by a pipe, regardless of trench width. The maximum load that a pipe will carry can never exceed the value calculated by Eq. 40.33. The limiting trench width, known as the *transition trench width*, is found by setting Eqs. 40.30 and 40.33 to each other.

$$B_{\text{transition}} = D\sqrt{\frac{C_p}{C}} \quad 40.34$$

Boussinesq's equation can be used to calculate the live load on a pipe due to an external loading at the surface. For traffic loads, or if the surface loading is sudden, and if there is less than 3 ft of cover on the pipe, the calculated load should be increased by a multiplicative *impact factor*.

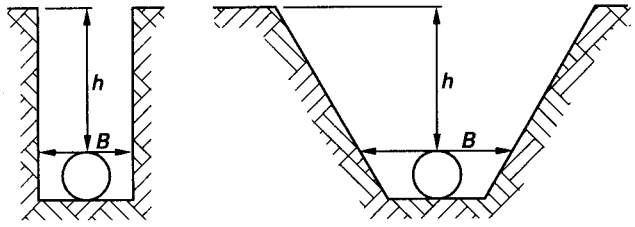

Figure 40.8 *Pipes in Backfilled Trenches*

airfield taxiway, apron	1.50

12. ALLOWABLE PIPE LOADS

The loadbearing ability of concrete pipes is determined in three-edge bearing tests. The *D-load strength*, reported in pounds per foot of pipe length per foot of inside diameter, is the crushing load that causes a 0.01 in (0.25 mm) wide crack. The *crushing strength* (*laboratory strength, cracking strength*, or *ultimate strength*) per unit length of pipe is calculated by multiplying the crushing load by the pipe's inside diameter.

$$\text{crushing strength} = (\text{D-load strength})D_i \qquad 40.35$$

The allowable pipe load is obtained by dividing the crushing strength by a factor of safety and multiplying by a bedding load factor. The factor of safety, F, varies from 1.25 for flexible pipe to 1.50 for rigid (including reinforced concrete) pipe.

$$w_{\text{allowable}} = (\text{crushing strength})\left(\frac{\text{LF}}{F}\right) \qquad 40.36$$

The *bedding load factor*, LF, depends on the bedding method. Class A bedding uses a concrete cradle. Class B bedding is compacted granular fill to half of the pipe's diameter. Class C is compacted granular fill or densely compacted backfill less than half the pipe's diameter. With class D, there is no bedding. The pipe is placed on a flat subgrade and backfilled.

13. SLURRY TRENCHES AND WALLS

Slurry trenches are nonstructural barriers created by chemically solidifying soils and are used to dewater construction sites, contain hazardous groundwater contaminants, and hydraulically isolate holding ponds and lagoons. *Slurry walls* are reinforced semistructural walls used where more seepage control is needed than can be provided by H-pile or sheet-pile construction. The terms *cut-off wall* and *containment wall* are ambiguous and could refer to either slurry trenches or slurry walls.

Large trenches are opened with a backhoe or other conventional equipment. Trenches 4 to 12 in (10 to 39 cm) wide can be opened hydraulically. A slurry trenching fluid containing 1 to 6% *bentonite* (a naturally occurring clay) by weight fills the trench during excavation. The trench is backfilled, often with a mixture of bentonite and previously excavated soil. If the backfill is

soil, the term *soil bentonite (SB) slurry trench* is used. The backfill displaces the trenching fluid, and the trench is extended in a continuous operation. If the trench is filled with only bentonite slurry, the term *cement bentonite slurry trench* is used. Trenches are "keyed" at the bottom by trenching some distance into an impermeable layer (i.e., an *aquiclude*) below.

Bentonite is not very chemically resistant, particularly when it is fully hydrated. Furthermore, its permeability is on the order of 10^{-7} to 10^{-8} cm/s, so a synthetic liner is required to contain hazardous waste.

Slurry walls are constructed by excavating a trench, supporting the open trench with bentonite slurry to prevent ground collapse, inserting a prefabricated rebar cage, and displacing the slurry with cast-in-place *tremie concrete*.

14. COFFERDAMS AND CAISSONS

A *cofferdam* is a temporary structure built to enclose a construction site. Cofferdams may be built to exclude both soil and water from the worksite. Single-walled types are used inland to restrain soil, and double-walled types are used on rivers.

A *caisson* is a permanent structure built in place for the purpose of supporting a bridge or building. A caisson becomes an integral part of the foundation. Some caissons are prebuilt and sunk into place, while others are built in place underwater.

15. GEOTEXTILES

Geotextiles (also known as *filter cloth, reinforcing fabric,* and *support membrane*) are fabrics used to stabilize and retain soil. (*Geosynthetics* is a term more appropriately applied to the synthetic sheets used as impermeable barriers.) Geotextiles are synthetic fabrics made from wood pulp (rayon and acetate), silica (fiberglass), and petroleum (nylon-polyamide, polyolefin, polyester, and polystyrene). Polyolefin includes polyethylene and polypropylene. There are both woven and nonwoven varieties. Modern geotextiles are not subject to biological and chemical degradation. Commercial geotextiles have weights of 4 to 22 oz/yd^2 (140 to 750 g/m^2).

Geotextiles are used to prevent the mixing of dissimilar materials (e.g., an aggregate base and soil), which would reduce the support strength. Geotextiles provide a filtering function, allowing free passage of water while restraining soil movement. Other uses include pavement support, subgrade reinforcement, drainage, erosion control, and silt containment.

A significant fraction of all geotextiles is used in highway repair. A layer of geotextile spread at the base of a new roadway may reduce the amount of sand and gravel required while helping to control drainage. Geotextiles can also be used to prevent the infiltration of fine clays into underdrains. In another application, geotextiles strengthen flexible pavements when placed directly under the surface layer. An innovative use of geotextiles is to retard the onset of reflective cracking in flexible pavements.

Nonwoven fabrics appear to hold asphalt better than woven varieties. The mechanical properties of nonwoven fabrics are uniform in all directions. Nonwovens also have higher permeabilities. (Fabrics should have minimum permeabilities equal to the adjacent soil, and preferably at least ten times the soil's permeability.) However, *woven fabrics* are lower in cost and are often used for subgrade separation. Wovens have higher tensile strength, higher moduli, and lower elongation than nonwovens.

There is significant debate on the merits of woven versus nonwoven varieties. Most departments of transportation sidestep the woven-nonwoven issue by specifying minimum performance specifications and allowing contractors to make the selection.

Table 40.6 *Typical DOT Minimum Geotextile Specifications (woven and nonwoven)*

	application			
property	subsurface drainage	stabilization	riprap filter	erosion control
grab tensile strength, lbf	100	200	250	120–200
elongation (minimum/maximum), %	20/100	20/70	20/70	15/30

puncture time, min	40–60	75	115	40–80
trapezoidal tear time, min	35–50	50	50	50–100
seam strength, lbf	100	200	250	120
permeability, cm/s	0.01–0.02	0.001	0.02	–

(Multiply lbf by 4.45 to obtain N.)
(Multiply cm/s by 0.0328 to obtain ft/sec.)

16. SOIL NAILING

Soil nailing is a slope-stabilization method that involves installing closely spaced "nails" in the soil/rock face to increase its overall shear strength. Nails are actually straight lengths of 60 ksi rebar, typically no. 8 to no. 14, with a length of 75 to 100% of the cut height. The nails are passive in that they are not pretensioned when they are installed. The nails become tensioned only when the soil deflects laterally. Nails are typically inclined upward at 10 to 20° from the horizontal.

In practice, a structural concrete facing (e.g., *shotcrete*) is first placed on the face over a wire mesh support grid. This facing connects the nails and supports the soil between them. Then holes are drilled through the concrete facing and soil/rock behind on a 4 to 5 ft (1.2 to 1.5 m) grid. Nails are inserted and grouted using a portland cement grout to bond the nails to the surrounding soil.

17. TRENCHLESS METHODS

Open-cut methods of pipeline installation and replacement may be the least expensive methods, particularly when lines are close to the surface. Trenchless methods can be used to create and extend existing pipelines, primarily sewer lines, in other situations and where the disruption of trenching is not acceptable. Trenchless installation options include pipe jacking, microtunneling, auger boring, and impact ramming. Renovation options include sliplining, inversion lining, and bursting methods. One problem common to all forms of piping system renovation is that, in providing new lines, connections get sealed off and must be reopened with robotic cutters. Another problem with relining is a reduction in capacity, though some improvement may result from improved hydraulic properties of the lining.

18. LIQUEFACTION

Liquefaction is a sudden drop in shear strength that can occur in soils of saturated cohesionless particles such as sand. The lower shear strength is manifested as a drop in bearing capacity. Continued cycles of reversed shear in a saturated sand layer can cause pore pressures to increase, which in turn decreases the effective stress and shear strength. When the shear strength drops to zero, the sand liquefies. In effect, the soil turns into a liquid, allowing everything it previously supported to sink.

Conditions most likely to contribute to or indicate a potential for liquefaction include (a) a lightly loaded sand layer within 50 to 65 ft (15 to 20 m) of the surface, (b) uniform particles of medium size, (c) saturated conditions below the water table, and (d) a low-penetration test value (i.e., a low N-value).

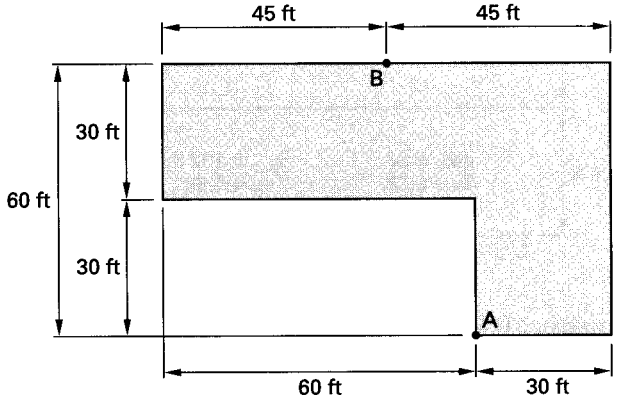
The *cyclic stress ratio* is a numerical rating of the potential for liquefaction in sands with depths up to 40 ft (12 m). This is the ratio of the average cyclic shear stress, τ_h, developed on the horizontal surfaces of the sand as a result of the earthquake loading to the initial vertical effective stress, σ'_o, acting on the sand layer before the earthquake forces were applied. $a_{\max}$ is the maximum (effective peak) acceleration at the ground surface. σ_o is the total overburden pressure on the sand under consolidation. σ'_o is the initial effective overburden pressure. r_d is a stress reduction factor that varies from 1 at the ground surface to about 0.9 at a depth of 30 ft (9 m).

$$\frac{\tau_{h,\text{ave}}}{\sigma'_o} \approx 0.65 \left(\frac{a_{\max}}{g}\right) \left(\frac{\sigma_o}{\sigma'_o}\right) r_d \qquad 40.37$$

The critical value of $\tau_{h,\text{ave}}/\sigma'_o$ that causes liquefaction must be determined from field or laboratory testing. A factor of safety of 1.3 to 1.5 is typical.

PRACTICE PROBLEMS

Pressure at Depths



1. A concentrated vertical load of 6000 lbf is applied at the ground surface. What is the increase in vertical pressure 3.5 ft below the surface and 4 ft from the line of action of the force?

Answer: 29 lbf/ft^2

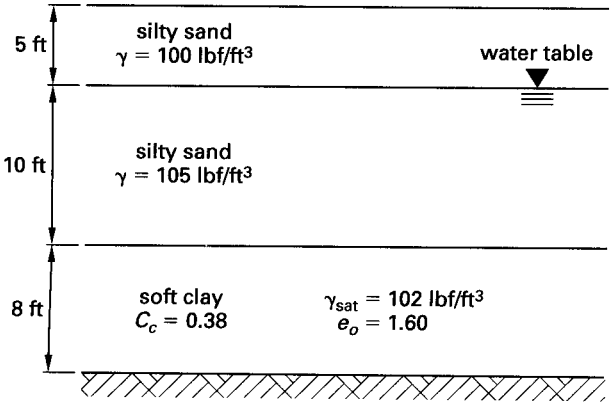
2. A 10 ft × 10 ft footing exerts a pressure of 3000 lbf/ft^2 on the soil below it. What is the increase in vertical soil stress 10 ft below and 8 ft from the center of the footing?

Answer: 300 to 400 lbf/ft^2, depending on the evaluation method used

3. A building weighing 20 tons is placed on the L-shaped slab shown. The soil below the basement is a 100 ft thick layer of dense sand. (a) What is the increase in vertical soil pressure at a depth of 30 ft below point A? (b) What is the increase in vertical soil pressure at a depth of 45 ft below point B?

Answers: (a) 2.6 lbf/ft^2; (b) 3.5 lbf/ft^2

Consolidation



4. A large manufacturing plant with a uniform floor loading of 500 lbf/ft^2 is supported by a large mat foundation. A 38 ft thick layer of silty soil is underlain by sand and gravel. The plant was constructed on the silty soil 10 ft above the water table. After a number of years and after all settlement of the building had stopped, a series of wells were drilled, which dropped the water table from 10 ft below the surface to 18 ft below the surface. The unit weight of the soil above the water table is 100 lbf/ft^3. It is 120 lbf/ft^3 below the water table. The silt compression index is 0.02. The void ratio before the water table was lowered was 0.6. How much more will the building settle?

Answer: 0.018 ft

5. The compression index of a normally loaded 16 ft thick clay soil is 0.31. The clay is bounded above and below by layers of sand. When the effective stress on the soil is 2600 lbf/ft^2, the void ratio is 1.04 and the permeability is 4×10^{-7} mm/s. The stress is increased gradually to 3900 lbf/ft^2. (a) What is the change in the void ratio? (b) What is the settlement in the clay layer? (c) How much time is required for settlement to reach 75%?

Answers: (a) −0.055; (b) −0.43 ft; (c) 352 days

6. At a building site, a rock layer is covered by 8 ft of soft clay. The clay is covered with 15 ft of silty sand. The water table is 18 ft above the rock layer. Properties of the layers are shown on the illustration. A construction firm wants to consolidate the clay layer by surcharging the site with 10 more ft of sandy fill (with a specific weight of 110 lbf/ft^3) and by lowering the water table 5 ft. What consolidation will be achieved by this process?

Answer: 0.42 ft

Stresses on Buried Pipes

7. A 12 in sewer pipe is to be installed under a backfill of 11 ft of saturated topsoil with a specific weight of 120 lbf/ft^3. The trench width is 2 ft. The pipe strength is 1500 lbf/ft. There are no live loads. A factor of safety of 1.5 is required. Specify the bedding design.

Answer: class C or better

Slope Stability

8. A 2:1 (horizontal:vertical) sloped cut is made in homogeneous saturated clay. The clay's specific weight is 112 lbf/ft^3, and its ultimate shear strength is 1100 lbf/ft^2. The cut is 43 ft deep. The clay extends 15 ft below the toe of the cut to a rock layer. What is the cohesive factor of safety of this cut?

Answer: 1.48

9. *(Time limit: one hour)* A 2 in PVC pipe is to be buried in a trench 18 in wide and 3½ ft deep. The angle of internal friction of the cohesive soil is 18°. The cohesion is 200 lbf/ft^2. The moisture content is 20%. The dry specific weight of the soil is 115 lbf/ft^3. (a) Will the soil stand or slide during trenching if the spoils are placed directly alongside the trench sides? (b) How far away from the trench must the spoils be placed to satisfy OSHA? (c) When the spoils are spread evenly for a distance of 2 ft from the trench, will the soil remain stable? (d) Recommend initial bedding and backfill materials. (e) What additional precautions would you recommend to protect any workers who enter the trench?

Answers: (a) no; (b) 2 ft; (c) yes; (d) no special bedding required

1. INTRODUCTION TO STATICS

Statics is a part of the subject known as *engineering mechanics.*[1] It is the study of rigid bodies that are stationary. To be stationary, a rigid body must be in static equilibrium. In the language of statics, a stationary rigid body has no *unbalanced forces* acting on it.

[1]Engineering mechanics also includes the subject of dynamics. Interestingly, the subject of mechanics of materials (i.e., strength of materials) is not part of engineering mechanics.

Structural

2. INTERNAL AND EXTERNAL FORCES

An *external force* is a force on a rigid body caused by other bodies. The applied force can be due to physical contact (i.e., pushing) or close proximity (e.g., gravitational, magnetic, or electrostatic forces). If unbalanced, an external force will cause motion of the body.

An *internal force* is one that holds parts of the rigid body together. Internal forces are the tensile and compressive forces within parts of the body as found from the product of stress and area. Although internal forces can cause deformation of a body, motion is never caused by internal forces.

3. UNIT VECTORS

A *unit vector* is a vector of unit length directed along a coordinate axis.[2] In the rectangular coordinate system, there are three unit vectors, **i**, **j**, and **k**, corresponding to the three coordinate axes, x, y, and z, respectively.[3] Unit vectors are used in vector equations to indicate direction without affecting magnitude. For example, the vector representation of a 97 N force in the negative x-direction would be written as $\mathbf{F} = -97\mathbf{i}$.

4. CONCENTRATED FORCES

A *force* is a push or pull that one body exerts on another. A *concentrated force*, also known as a *point force*, is a vector having magnitude, direction, and location (i.e., point of application) in three-dimensional space. In this chapter, the symbols **F** and F will be used to represent the vector and its magnitude, respectively.[4]

The vector representation of a three-dimensional force is given by Eq. 41.1. Of course, vector addition is required.

$$\mathbf{F} = F_x\mathbf{i} + F_y\mathbf{j} + F_z\mathbf{k} \qquad 41.1$$

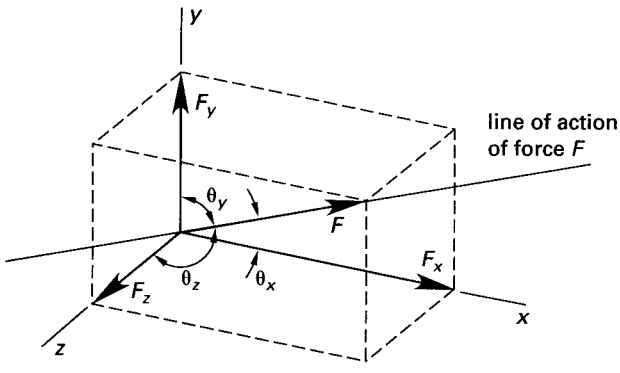

Figure 41.1 *Components and Direction Angles of a Force*

[2]Although polar, cylindrical, and spherical coordinate systems can have unit vectors also, this chapter is concerned only with the rectangular coordinate system.

[3]There are other methods of representing vectors, in addition to bold letters. For example, the unit vector **i** is represented in other sources as $\bar{i}$ and $\hat{i}$.

[4]As with the unit vectors, the symbols **F**, $\overline{F}$, and $\hat{F}$ are used in other sources interchangeably to represent the same vector.

If **u** is a *unit vector* in the direction of the force, the force can be represented as

$$\mathbf{F} = F\mathbf{u} \qquad 41.2$$

The components of the force can be found from the *direction cosines*, the cosines of the true angles made by the force vector with the x-, y-, and z-axes.

$$F_x = F\cos\theta_x \qquad 41.3$$

$$F_y = F\cos\theta_y \qquad 41.4$$

$$F_z = F\cos\theta_z \qquad 41.5$$

$$F = \sqrt{F_x^2 + F_y^2 + F_z^2} \qquad 41.6$$

The *line of action* of a force is the line in the direction of the force extended forward and backward. The force, **F**, and its unit vector, **u**, are along the line of action.

5. MOMENTS

Moment is the name given to the tendency of a force to rotate, turn, or twist a rigid body about an actual or assumed pivot point. (Another name for moment is *torque*, although torque is used mainly with shafts and other power-transmitting machines.) When acted upon by a moment, unrestrained bodies rotate. However, rotation is not required for the moment to exist. When a restrained body is acted upon by a moment, there is no rotation.

An object experiences a moment whenever a force is applied to it.[5] Only when the line of action of the force passes through the center of rotation (i.e., the actual or assumed pivot point) will the moment be zero.

Moments have primary dimensions of length × force. Typical units are foot-pounds, inch-pounds, and newton-meters.[6]

6. MOMENT OF A FORCE ABOUT A POINT

Moments are vectors. The moment vector, $\mathbf{M}_O$, for a force about point O is the *cross product* of the force, **F**, and the vector from point O to the point of application of the force, known as the *position vector*, **r**. The scalar product $|\mathbf{r}|\sin\phi$ is known as the *moment arm*, d.

$$\mathbf{M}_O = \mathbf{r} \times \mathbf{F} \qquad 41.7$$

$$M_O = |\mathbf{M}_O| = |\mathbf{r}|\,|\mathbf{F}|\sin\theta = d|\mathbf{F}| \quad [\theta \le 180^\circ] \qquad 41.8$$

[5]The moment may be zero, as when the moment arm length is zero, but there is a (trivial) moment nevertheless.

[6]Units of kilogram-force-meter have also been used in metric countries.

Foot-pounds and newton-meters are also the units of energy. To distinguish between moment and energy, some authors reverse the order of the units. Therefore, pound-feet and meter-newtons become the units of moment. This convention is not universal and is unnecessary since the context is adequate to distinguish between the two.

The line of action of the moment vector is normal to the plane containing the force vector and the position vector. The sense (i.e., the direction) of the moment is determined from the *right-hand rule.*

Right-hand rule: Place the position and force vectors tail to tail. Close your right hand and position it over the pivot point. Rotate the position vector into the force vector, and position your hand such that your fingers curl in the same direction as the position vector rotates. Your extended thumb will coincide with the direction of the moment.[7]

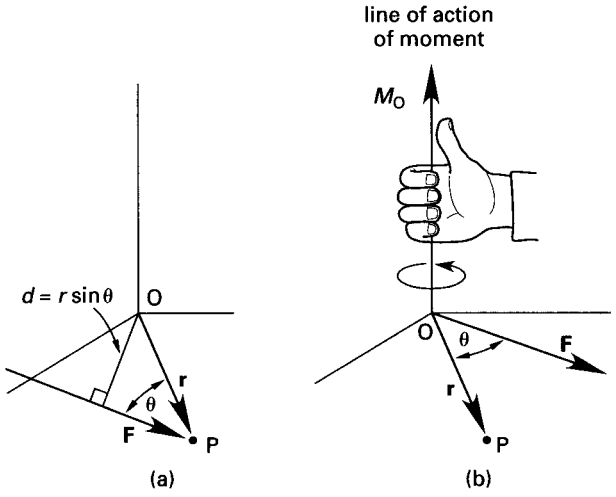

Figure 41.2 *Right-Hand Rule*

7. VARIGNON'S THEOREM

Varignon's theorem is a statement of how the total moment is derived from a number of forces acting simultaneously at a point.

Varignon's theorem: The sum of individual moments about a point caused by multiple concurrent forces is equal to the moment of the resultant force about the same point.

$$(\mathbf{r}\times\mathbf{F}_1)+(\mathbf{r}\times\mathbf{F}_2)+\cdots=\mathbf{r}\times(\mathbf{F}_1+\mathbf{F}_2+\cdots) \qquad 41.9$$

8. MOMENT OF A FORCE ABOUT A LINE

Most rotating machines (motors, pumps, flywheels, etc.) have a fixed rotational axis. That is, the machines turn around a line, not around a point. The moment of a force about the rotational axis is not the same as the moment of the force about a point. In particular, the moment about a line is a scalar.[8]

[7]The direction of a moment also corresponds to the direction a right-hand screw would progress if it was turned in the direction that rotates **r** into **F**.

[8]Some sources say that the moment of a force about a line can be interpreted as a moment directed along the line. However, this interpretation does not follow from vector operations.

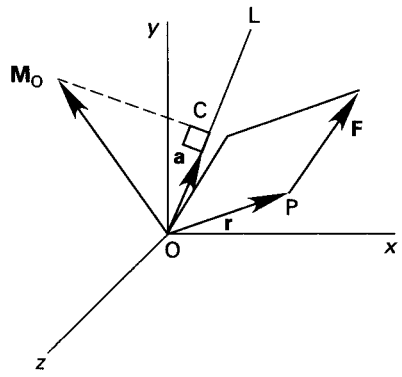

Figure 41.3 *Moment of a Force About a Line*

The moment M_{OL} of a force **F** about a line OL is the projection OC of the moment $\mathbf{M}_O$ onto the line. Equation 41.10 gives the moment of a force about a line. **a** is the unit vector directed along the line, and a_x, a_y, and a_z are the direction cosines of the axis OL. Notice that Eq. 41.10 is a dot product (i.e., a scalar).

$$M_{OL}=\mathbf{a}\cdot\mathbf{M}_O=\mathbf{a}\cdot(\mathbf{r}\times\mathbf{F})$$
$$=\begin{vmatrix} a_x & a_y & a_z \\ x_P-x_O & y_P-y_O & z_P-z_O \\ F_x & F_y & F_z \end{vmatrix} \qquad 41.10$$

If point O is the origin, then Eq. 41.10 reduces to Eq. 41.11.

$$M_{OL}=\begin{vmatrix} a_x & a_y & a_z \\ x & y & z \\ F_x & F_y & F_z \end{vmatrix} \qquad 41.11$$

9. COMPONENTS OF A MOMENT

The direction cosines of a force can be used to determine the components of the moment about the coordinate axes.

$$M_x=M\cos\theta_x \qquad 41.12$$

$$M_y=M\cos\theta_y \qquad 41.13$$

$$M_z=M\cos\theta_z \qquad 41.14$$

Alternatively, the following three equations can be used to determine the components of the moment from a force applied at point (x, y, z) referenced to an origin at $(0, 0, 0)$.

$$M_x=yF_z-zF_y \qquad 41.15$$

$$M_y=zF_x-xF_z \qquad 41.16$$

$$M_z=xF_y-yF_x \qquad 41.17$$

The resultant moment magnitude can be reconstituted from its components.

$$M=\sqrt{M_x^2+M_y^2+M_z^2} \qquad 41.18$$

Structural

10. COUPLES

Any pair of equal, opposite, and parallel forces constitutes a *couple*. A couple is equivalent to a single moment vector. Since the two forces are opposite in sign, the x-, y-, and z-components of the forces cancel out. Therefore, a body is induced to rotate without translation. A couple can be counteracted only by another couple. A couple can be moved to any location without affecting the equilibrium requirements.

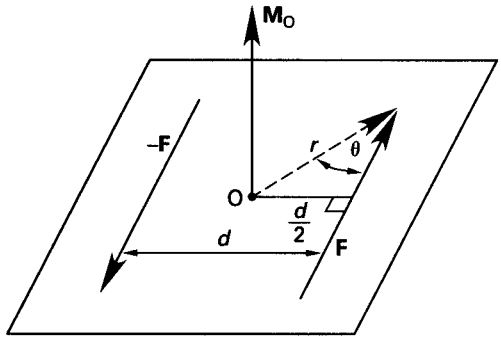

Figure 41.4 *Couple*

In Fig. 41.4, the equal but opposite forces produce a moment vector $\mathbf{M}_O$ of magnitude Fd. The two forces can be replaced by this moment vector, which can be moved to any location on a body. (Such a moment is known as a *free moment*, *moment of a couple*, or *coupling moment*.)

$$M_O = 2rF \sin\theta = Fd \qquad 41.19$$

11. EQUIVALENCE OF FORCES AND FORCE-COUPLE SYSTEMS

If a force, F, is moved a distance d from the original point of application, a couple, M, equal to Fd must be added to counteract the induced couple. The combination of the moved force and the couple is known as a *force-couple system*. Alternatively, a force-couple system can be replaced by a single force located a distance $d = M/F$ away.

12. RESULTANT FORCE-COUPLE SYSTEMS

The equivalence described in the previous section can be extended to three dimensions and multiple forces. Any collection of forces and moments in three-dimensional space is statically equivalent to a single resultant force vector plus a single resultant moment vector. (Either or both of these resultants can be zero.)

The x-, y-, and z-components of the resultant force are the sums of the x-, y-, and z-components of the individual forces, respectively.

$$F_{R,x} = \sum_i (F\cos\theta_x)_i \qquad 41.20$$

$$F_{R,y} = \sum_i (F\cos\theta_y)_i \qquad 41.21$$

$$F_{R,z} = \sum_i (F\cos\theta_z)_i \qquad 41.22$$

The resultant moment vector is more complex. It includes the moments of all system forces around the reference axes plus the components of all system moments.

$$M_{R,x} = \sum_i (yF_z - zF_y)_i + \sum_i (M\cos\theta_x)_i \qquad 41.23$$

$$M_{R,y} = \sum_i (zF_x - xF_z)_i + \sum_i (M\cos\theta_y)_i \qquad 41.24$$

$$M_{R,z} = \sum_i (xF_y - yF_x)_i + \sum_i (M\cos\theta_z)_i \qquad 41.25$$

13. LINEAR FORCE SYSTEMS

A *linear force system* is one in which all forces are parallel and applied along a straight line. A straight beam loaded by several concentrated forces is an example of a linear force system.

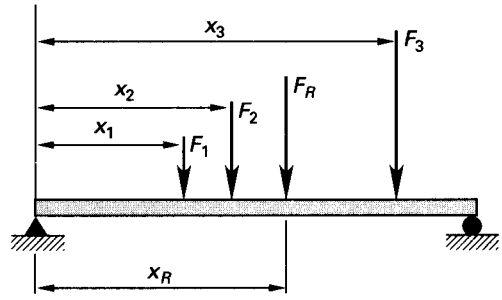

Figure 41.5 *Linear Force System*

For the purposes of statics, all of the forces in a linear force system can be replaced by an *equivalent resultant force*, F_R, equal to the sum of the individual forces. The location of the equivalent force coincides with the location of the centroid of the force group.

$$F_R = \sum_i F_i \qquad 41.26$$

$$x_R = \frac{\sum_i F_i x_i}{\sum_i F_i} \qquad 41.27$$

14. DISTRIBUTED LOADS

If an object is continuously loaded over a portion of its length, it is subject to a *distributed load*. Distributed loads result from *dead load* (i.e., self-weight), hydrostatic pressure, and materials distributed over the object.

If the load per unit length at some point x is $w(x)$, the statically equivalent concentrated load, F_R, can be found from Eq. 41.28. The equivalent load is the area under the loading curve.

$$F_R = \int_{x=0}^{x=L} w(x)\,dx \qquad 41.28$$

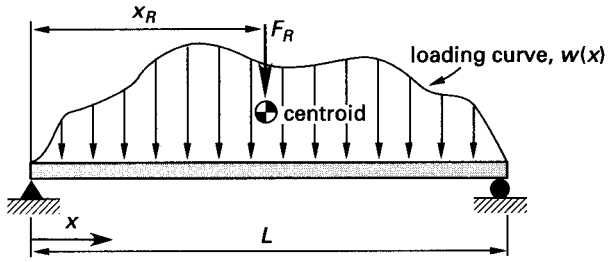

Figure 41.6 *Distributed Loads on a Beam*

The location, x_R, of the equivalent load is calculated from Eq. 41.29. The location coincides with the centroid of the area under the loading curve and is referred to in some problems as the *center of pressure*.

$$x_R = \frac{\int_{x=0}^{x=L} x\,w(x)\,dx}{F_R} \qquad 41.29$$

For a straight beam of length L under a uniform transverse loading of w pounds per foot (newtons per meter),

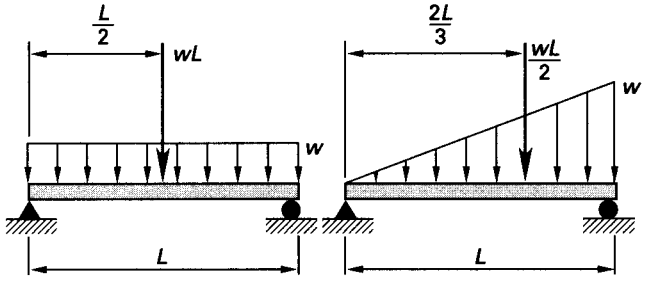
$$F_R = wL \qquad 41.30$$

$$x_R = \frac{L}{2} \qquad 41.31$$

For a straight beam of length L under a triangular distribution that increases from zero (at $x = 0$) to w (at $x = L$),

$$F_R = \frac{wL}{2} \qquad 41.32$$

$$x_R = \frac{2L}{3} \qquad 41.33$$



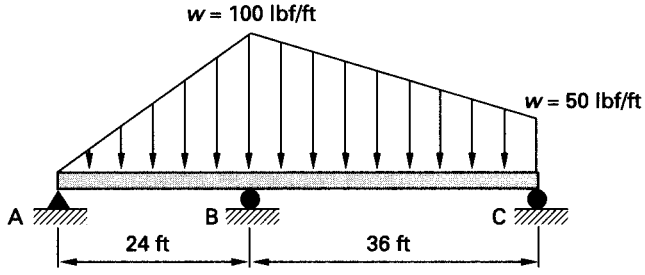


Figure 41.7 *Special Cases of Distributed Loading*

Example 41.1

Find the magnitude and location of the two equivalent forces on the two spans of the beam.

Solution

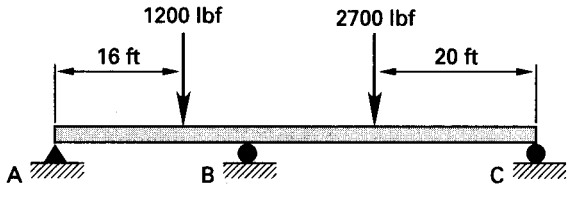
Span A–B

The area under the triangular loading curve is

$$A = \tfrac{1}{2}bh = \left(\tfrac{1}{2}\right)(24\text{ ft})\left(100\ \frac{\text{lbf}}{\text{ft}}\right)$$
$$= 1200\text{ lbf}$$

The centroid of the loading triangle is located at

$$x_{R,\text{A–B}} = \tfrac{2}{3}b = \left(\tfrac{2}{3}\right)(24\text{ ft})$$
$$= 16\text{ ft}$$



Span B–C

The area under the loading curve consists of a uniform load of 50 lbf/ft over the entire span B–C, plus a triangular load that starts at zero at point C and increases to 50 lbf/ft at point B. The area under the loading curve is

$$A = wL + \tfrac{1}{2}bh$$
$$= \left(50\ \frac{\text{lbf}}{\text{ft}}\right)(36\text{ ft}) + \left(\tfrac{1}{2}\right)(36\text{ ft})\left(50\ \frac{\text{lbf}}{\text{ft}}\right)$$
$$= 2700\text{ lbf}$$

The centroid of the trapezoidal loading curve[9] is located at

$$x_{R,\text{B–C}} = \left(\frac{h}{3}\right)\left(\frac{b+2t}{b+t}\right)$$
$$= \left(\frac{36\text{ ft}}{3}\right)\left(\frac{50\text{ ft} + (2)(100\text{ ft})}{50\text{ ft} + 100\text{ ft}}\right) = 20\text{ ft}$$

[9]The formula for the location of a centroid in a trapezoidal area is found in App. 42.A.

Structural

15. MOMENT FROM A DISTRIBUTED LOAD

The total force from a uniformly distributed load w over a distance x is wx. For the purposes of statics, the uniform load can be replaced by a concentrated force of wx located at the centroid of the distributed load, that is, at the midpoint, $x/2$, of the load. Therefore, the moment taken about one end of the distributed load is

$$\begin{aligned} M_{\text{distributed load}} &= \text{force} \times \text{distance} \\ &= wx\left(\frac{x}{2}\right) = \tfrac{1}{2}wx^2 \end{aligned} \qquad 41.34$$

In general, the moment of a distributed load, uniform or otherwise, is the product of the total force and the distance to the centroid of the distributed load.

16. TYPES OF FORCE SYSTEMS

The complexity of methods used to analyze a statics problem depends on the configuration and orientation of the forces. Force systems can be divided into the following categories.

- *concurrent force system:* All of the forces act at the same point.
- *collinear force system:* All of the forces share the same line of action.
- *parallel force system:* All of the forces are parallel (though not necessarily in the same direction).
- *coplanar force system:* All of the forces are in a plane.
- *general three-dimensional system:* This category includes all other combinations of nonconcurrent, nonparallel, and noncoplanar forces.

17. CONDITIONS OF EQUILIBRIUM

An object is static when it is stationary. To be stationary, all of the forces on the object must be in equilibrium.[10] For an object to be in equilibrium, the resultant force and moment vectors must both be zero.

$$\mathbf{F}_R = \sum \mathbf{F} = 0 \qquad 41.35$$

$$F_R = \sqrt{F_{R,x}^2 + F_{R,y}^2 + F_{R,z}^2} = 0 \qquad 41.36$$

$$\mathbf{M}_R = \sum \mathbf{M} = 0 \qquad 41.37$$

$$M_R = \sqrt{M_{R,x}^2 + M_{R,y}^2 + M_{R,z}^2} = 0 \qquad 41.38$$

Since the square of any nonzero quantity is positive, Eqs. 41.39 through 41.44 follow directly from Eqs. 41.36 and 41.38.

$$F_{R,x} = 0 \qquad 41.39$$

$$F_{R,y} = 0 \qquad 41.40$$

$$F_{R,z} = 0 \qquad 41.41$$

$$M_{R,x} = 0 \qquad 41.42$$

$$M_{R,y} = 0 \qquad 41.43$$

$$M_{R,z} = 0 \qquad 41.44$$

Equations 41.39 through 41.44 seem to imply that six simultaneous equations must be solved in order to determine whether a system is in equilibrium. While this is true for general three-dimensional systems, fewer equations are necessary with most problems. Table 41.1 can be used as a guide to determine which equations are most helpful in solving different categories of problems.

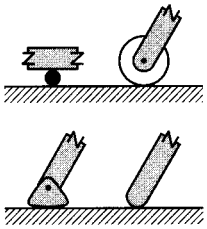
Table 41.1 *Number of Equilibrium Conditions Required to Solve Different Force Systems*

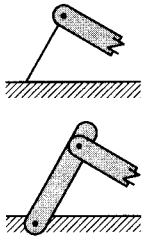
type of force system	two-dimensional	three-dimensional
general	4	6
coplanar	3	3
concurrent	2	3
parallel	2	3
coplanar, parallel	2	2
coplanar, concurrent	2	2
collinear	1	1

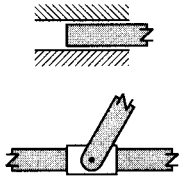
18. TWO- AND THREE-FORCE MEMBERS

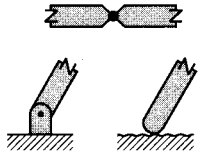
Members limited to loading by two or three forces are special cases of equilibrium. A *two-force member* can be in equilibrium only if the two forces have the same line of action (i.e., are collinear) and are equal but opposite. In most cases, two-force members are loaded axially, and the line of action coincides with the member's longitudinal axis. By choosing the coordinate system so that one axis coincides with the line of action, only one equilibrium equation is needed.

A *three-force member* can be in equilibrium only if the three forces are concurrent or parallel. Stated another way, the force polygon of a three-force member in equilibrium must close on itself.









19. REACTIONS

The first step in solving most statics problems is to determine the reaction forces (i.e., the *reactions*) supporting the body. The manner in which a body is supported determines the type, location, and direction of the reactions. Conventional symbols are often used to define the type of support (such as pinned, roller, etc.). Examples of the symbols are shown in Table 41.2.

For beams, the two most common types of supports are the roller support and the pinned support. The *roller support*, shown as a cylinder supporting the beam, supports vertical forces only. Rather than support a horizontal force, a roller support simply rolls into a new equilibrium position. Only one equilibrium equation

[10] Thus the term *static equilibrium*, though widely used, is redundant.

Table 41.2 *Types of Two-Dimensional Supports*

type of support	reactions and moments	number of unknowns[a]
simple, roller, rocker, ball, or frictionless surface 	reaction normal to surface, no moment	1
cable in tension, or link 	reaction in line with cable or link, no moment	1
frictionless guide or collar 	reaction normal to rail, no moment	1
built-in, fixed support 	two reaction components, one moment	3
frictionless hinge, pin connection, or rough surface 	reaction in any direction, no moment	2

[a]The number of unknowns is valid for two-dimensional problems only.

(i.e., the sum of vertical forces) is needed at a roller support. Generally, the terms *simple support* and *simply supported* refer to a roller support.

The *pinned support*, shown as a pin and clevis, supports both vertical and horizontal forces. Two equilibrium equations are needed.

Generally, there will be vertical and horizontal components of a reaction when one body touches another. However, when a body is in contact with a *frictionless surface*, there is no frictional force component parallel to the surface. Therefore, the reaction is normal to the contact surfaces. The assumption of frictionless contact is particularly useful when dealing with systems of spheres and cylinders in contact with rigid supports. Frictionless contact is also assumed for roller and rocker supports.[11]

20. DETERMINACY

When the equations of equilibrium are independent, a rigid body force system is said to be *statically determinate*. A statically determinate system can be solved for all unknowns, which are usually reactions supporting the body.

When the body has more supports than are necessary for equilibrium, the force system is said to be *statically indeterminate*. In a statically indeterminate system, one or more of the supports or members can be removed or reduced in restraint without affecting the equilibrium position.[12] Those supports and members are known as *redundant members*. The number of redundant members is known as the *degree of indeterminacy*. Figure 41.8 illustrates several common indeterminate structures.

A statically indeterminate body requires additional equations to supplement the equilibrium equations. The additional equations typically involve deflections and depend on mechanical properties of the body.

21. TYPES OF DETERMINATE BEAMS

Figure 41.9 illustrates the terms used to describe determinate beam types.

22. FREE-BODY DIAGRAMS

A *free-body diagram* is a representation of a body in equilibrium. It shows all applied forces, moments, and reactions. Free-body diagrams do not consider the internal structure or construction of the body, as Fig. 41.10 illustrates.

[11]Frictionless surface contact, which requires only one equilibrium equation, should not be confused with a frictionless pin connection, which requires two equilibrium equations. A pin connection with friction introduces a moment at the connection, increasing the number of required equilibrium equations to three.

[12]An example of a support reduced in restraint is a pinned joint replaced by a roller joint. The pinned joint restrains the body vertically and horizontally, requiring two equations of equilibrium. The roller joint restrains the body vertically only and requires one equilibrium equation.

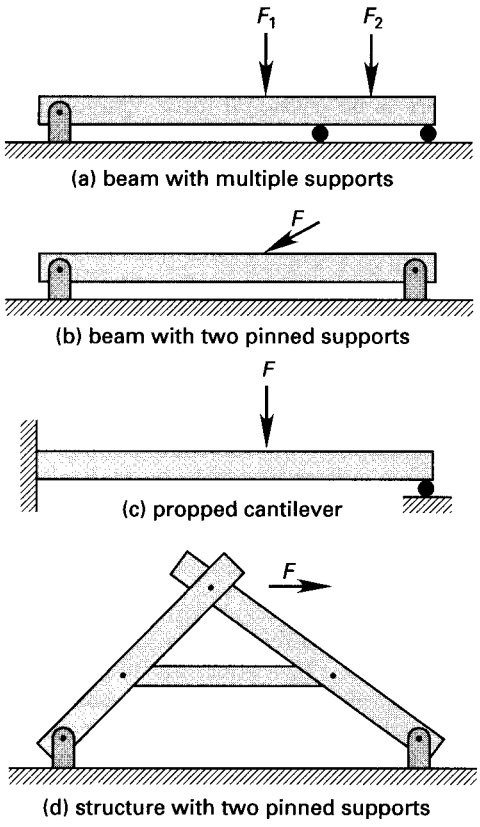


Figure 41.8 *Examples of Indeterminate Systems*

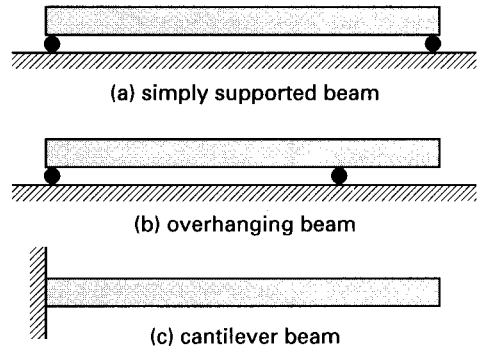

Figure 41.9 *Types of Determinate Beams*

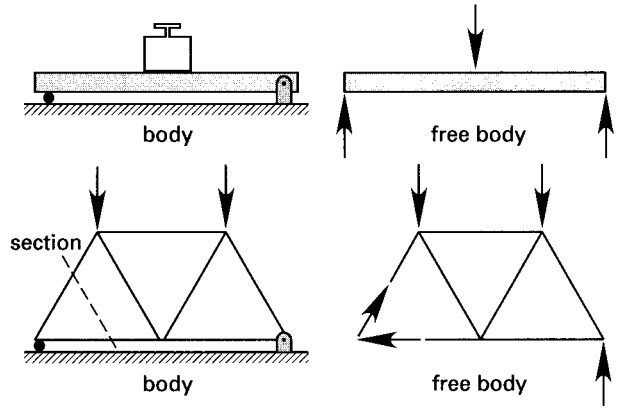

Figure 41.10 *Bodies and Free Bodies*

Since the body is in equilibrium, the resultants of all forces and moments on the free body are zero. In order to maintain equilibrium, any portions of the body that are removed must be replaced by the forces and moments those portions impart to the body. Typically, the body is isolated from its physical supports in order to help evaluate the reaction forces. In other cases, the body may be sectioned (i.e., cut) in order to determine the forces at the section.

23. FINDING REACTIONS IN TWO DIMENSIONS

The procedure for finding determinate reactions in two-dimensional problems is straightforward. Determinate structures will have either a roller support and a pinned support or two roller supports.

step 1: Establish a convenient set of coordinate axes. (To simplify the analysis, one of the coordinate directions should coincide with the direction of the forces and reactions.)

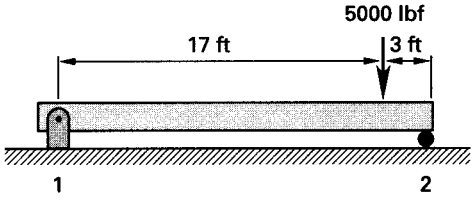
step 2: Draw the free-body diagram.

step 3: Resolve the reaction at the pinned support (if any) into components normal and parallel to the coordinate axes.

step 4: Establish a positive direction of rotation (e.g., clockwise) for purposes of taking moments.

step 5: Write the equilibrium equation for moments about the pinned connection. (By choosing the pinned connection as the point about which to take moments, the pinned connection reactions do not enter into the equation.) This will usually determine the vertical reaction at the roller support.

step 6: Write the equilibrium equation for the forces in the vertical direction. Usually, this equation will have two unknown vertical reactions.

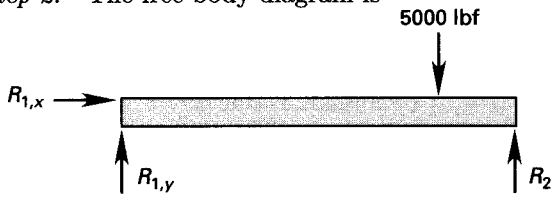


step 7: Substitute the known vertical reaction from step 5 into the equilibrium equation from step 6. This will determine the second vertical reaction.

step 8: Write the equilibrium equation for the forces in the horizontal direction. Since there is a maximum of one unknown reaction component in the horizontal direction, this step will determine that component.

step 9: If necessary, combine the vertical and horizontal force components at the pinned connection into a resultant reaction.

Example 41.2



Determine the reactions, R_1 and R_2, on the following beam.

Solution

step 1: The x- and y-axes are established parallel and perpendicular to the beam.

step 2: The free-body diagram is

step 3: R_1 is a pinned support. Therefore, it has two components, $R_{1,x}$ and $R_{1,y}$.

step 4: Assume clockwise moments are positive.

step 5: Take moments about the left end and set them equal to zero. Use Eq. 41.37.

$$\begin{aligned}\sum M_{\text{left end}} &= (5000 \text{ lbf})(17 \text{ ft}) - R_2(20 \text{ ft}) \\ &= 0 \\ R_2 &= 4250 \text{ lbf}\end{aligned}$$

step 6: The equilibrium equation for the vertical direction is given by Eq. 41.43.

$$\begin{aligned}\sum F_y &= R_{1,y} + R_2 - 5000 \text{ lbf} \\ &= 0\end{aligned}$$

step 7: Substituting R_2 into the vertical equilibrium equation,

$$\begin{aligned}R_{1,y} + 4250 \text{ lbf} - 5000 \text{ lbf} &= 0 \\ R_{1,y} &= 750 \text{ lbf}\end{aligned}$$

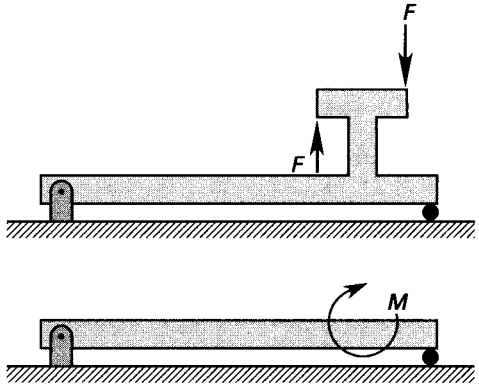
step 8: There are no applied forces in the horizontal direction. Therefore, the equilibrium equation is given by Eq. 41.39.

$$\begin{aligned}\sum F_x &= R_{1,x} + 0 \\ &= 0 \\ R_{1,x} &= 0\end{aligned}$$

24. COUPLES AND FREE MOMENTS

Once a couple on a body is known, the derivation and source of the couple are irrelevant. When the moment on a body is 80 N·m, it does not make any difference whether the force is 40 N with a lever arm of 2 m, or 20 N with a lever arm of 4 m, and so on. Therefore, the point of application of a couple is disregarded when writing the moment equilibrium equation. For this reason, the term *free moment* is used synonymously with *couple*.

Figure 41.11 illustrates two diagrammatic methods of indicating the application of a free moment.



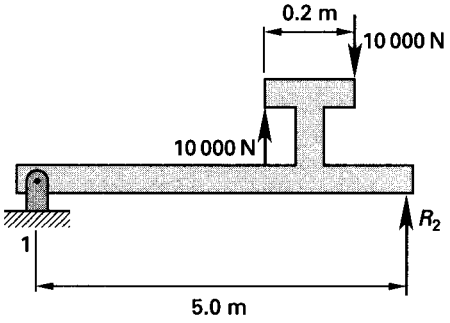


Figure 41.11 *Free Moments*

Example 41.3

What is the reaction R_2 for the beam shown?

Solution

The two couple forces are equal and cancel each other as they come down the stem of the tee bracket. Therefore, there are no applied vertical forces.

The couple has a value given by Eq. 41.7.

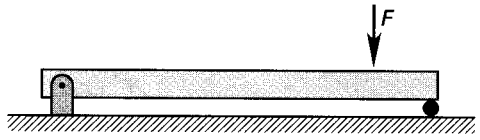
$$M = (10\,000 \text{ N})(0.2 \text{ m}) = 2000 \text{ N·m} \quad \text{[clockwise]}$$

Choose clockwise as the direction for positive moments. Taking moments about the pinned connection and using Eq. 41.37,

$$\begin{aligned}\sum M &= 2000 \text{ N·m} - R_2(5 \text{ m}) \\ &= 0 \\ R_2 &= 400 \text{ N}\end{aligned}$$

Structural

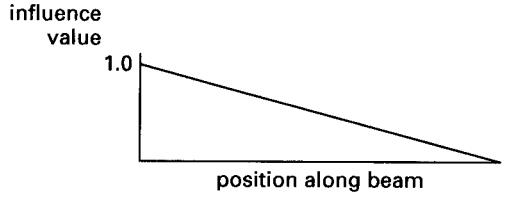
25. INFLUENCE LINES FOR REACTIONS



An *influence line* (also known as an *influence graph* and *influence diagram*) is a graph of the magnitude of a reaction as a function of the load placement.[13] The x-axis of the graph corresponds to the location on the body (along the length of a beam). The y-axis corresponds to the magnitude of the reaction.

By convention (and to generalize the graph for use with any load), the load is taken as one force unit. Therefore, for an actual load of F units, the actual reaction, R, is the product of the actual load and the influence line ordinate.

$$R = F \times \text{influence line ordinate} \qquad 41.45$$

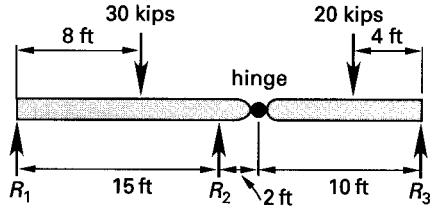


Example 41.4

Draw the influence line for the left reaction for the beam shown.

Solution

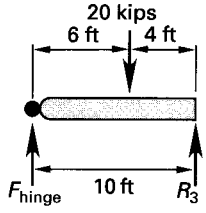
If the unit load is at the left end, the left reaction will be 1.0. If the unit load is at the right end, it will be supported entirely by the right reaction, so the left reaction will be zero. The influence line for the left reaction varies linearly for intermediate load placement.



26. HINGES

Hinges are added to structures to prevent translation while permitting rotation. A frictionless hinge can support a force, but it cannot transmit a moment. Since the moment is zero at a hinge, a structure can be sectioned at the hinge and the remainder of the structure can be replaced by only a force.

Example 41.5



Calculate the reaction R_3 and the hinge force on the two-span beam shown.

[13]Influence diagrams can also be drawn for moments, shears, and deflections.

Solution

At first, this beam may appear to be statically indeterminate since it has three supports. However, the moment is known to be zero at the hinge. Therefore, the hinged portion of the span can be isolated.

Reaction R_3 is found by taking moments about the hinge. Assume clockwise moments are positive.

$$\sum M_{\text{hinge}} = (20{,}000 \text{ lbf})(6 \text{ ft}) - R_3(10 \text{ ft}) = 0$$

$$R_3 = 12{,}000 \text{ lbf}$$

The hinge force is found by summing vertical forces on the isolated section.

$$\sum F_y = F_{\text{hinge}} + 12{,}000 \text{ lbf} - 20{,}000 \text{ lbf} = 0$$

$$F_{\text{hinge}} = 8000 \text{ lbf}$$

27. LEVERS

A *lever* is a simple mechanical machine with the ability to increase an applied force. The ratio of the load-bearing force to applied force (i.e., the *effort*) is known as the *mechanical advantage* or *force amplification*. As Fig. 41.12 shows, the mechanical advantage is equal to the ratio of lever arms.

$$\begin{aligned}\text{mechanical advantage} &= \frac{F_{\text{load}}}{F_{\text{applied}}} = \frac{\text{applied force lever arm}}{\text{load lever arm}} \\ &= \frac{\text{distance moved by applied force}}{\text{distance moved by load}}\end{aligned} \qquad 41.46$$

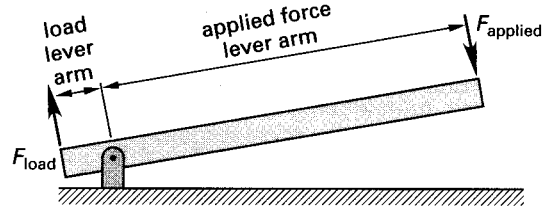


Figure 41.12 Lever

28. PULLEYS

A *pulley* (also known as a *sheave*) is used to change the direction of an applied tensile force. A series of pulleys working together (known as a *block and tackle*) can also provide *pulley advantage* (i.e., mechanical advantage). A *hoist* is any device used to raise or lower an object. A hoist may contain one or more pulleys.

If the pulley is attached by a bracket or cable to a fixed location, it is said to be a *fixed pulley*. If the pulley is attached to a load, or if the pulley is free to move, it is known as a *free pulley*.

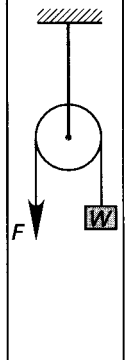
Most simple problems disregard friction and assume that all ropes are parallel.[14] In such cases, the pulley advantage is equal to the number of ropes coming to and going from the load-carrying pulley. The diameters of the pulleys are not factors in calculating the pulley advantage.

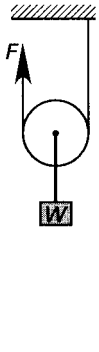
In other cases, a *loss factor*, ϵ, is used to account for rope rigidity. For most wire ropes and chains with 180° contact, the loss factor at low speeds varies between 1.03 and 1.06. The loss factor is the reciprocal of the *pulley efficiency*, η.

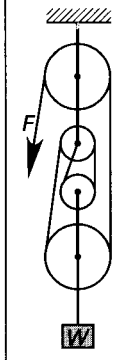
$$\epsilon = \frac{\text{applied force}}{\text{load}} = \frac{1}{\eta} \qquad 41.47$$

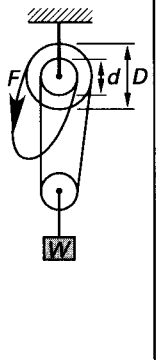
29. AXIAL MEMBERS

An *axial member* is capable of supporting axial forces only and is loaded only at its joints (i.e., ends). This type of performance can be achieved through the use of frictionless bearings or smooth pins at the ends. Since the ends are assumed to be pinned (i.e., rotation-free), an axial member cannot support moments. The weight of the member is disregarded or is included in the joint loading.









An axial member can be in either tension or compression. It is common practice to label forces in axial members as (T) or (C) for tension or compression, respectively. Alternatively, tensile forces can be written as positive numbers, while compressive forces are written as negative numbers.

The members in simple trusses are assumed to be axial members. Each member is identified by its endpoints, and the force in a member is designated by the symbol for the two endpoints. For example, the axial force in a member connecting points C and D will be written as **CD**. Similarly, $\mathbf{EF}_y$ is the y-component of the force in the member connecting points E and F.

For equilibrium, the resultant forces at the two joints must be equal, opposite, and collinear. This applies to the total (resultant) force as well as to the x- and y-components at those joints.

[14] Although the term *rope* is used here, the principles apply equally well to wire rope, cables, chains, belts, etc.

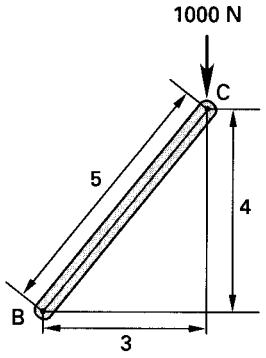
Table 41.3 *Mechanical Advantages of Rope-Operated Machines*

	fixed sheave	free sheave	ordinary pulley block (n sheaves)	differential pulley block
				
F_{ideal}	W	$\frac{W}{2}$	$\frac{W}{n}$	$\left(\frac{W}{2}\right)\left(1-\frac{d}{D}\right)$
F to raise load	ϵW	$\frac{\epsilon W}{1+\epsilon}$	$\frac{\epsilon^n(\epsilon-1)W}{\epsilon^n-1}$	$\frac{\left(\epsilon^2-\frac{d}{D}\right)W}{1+\epsilon}$
F to lower load	$\frac{W}{\epsilon}$	$\frac{W}{1+\epsilon}$	$\frac{\left(\frac{1}{\epsilon}-1\right)W}{1-\epsilon^n}$	$\left(\frac{\epsilon W}{1+\epsilon}\right)\left(\frac{1}{\epsilon^2}-\frac{d}{D}\right)$
ratio of distance of force to distance of load	1	2	n	$\frac{2D}{D-d}$

30. FORCES IN AXIAL MEMBERS

The line of action of a force in an axial member coincides with the longitudinal axis of the member. Depending on the orientation of the coordinate axis system, the direction of the longitudinal axis will have both x- and y-components. Therefore, the force in an axial member will generally have both x- and y-components.

The following four general principles are helpful in determining the force in an axial member.



- A horizontal member carries only horizontal loads. It cannot carry vertical loads.
- A vertical member carries only vertical loads. It cannot carry horizontal loads.
- The vertical component of an axial member's force is equal to the vertical component of the load applied to the member.
- The total and component forces in an inclined member are proportional to the sides of the triangle outlined by the member and the coordinate axes.[15]

[15] This is an application of the principle of similar triangles.

Structural

Example 41.6

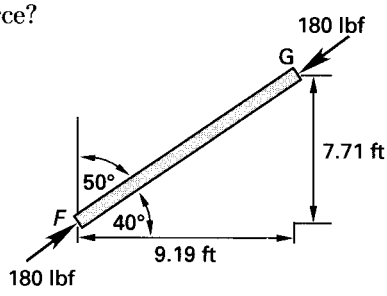
Member BC is an inclined axial member oriented as shown. A vertical 1000 N force is applied to the top end. What are the x- and y-components of the force in member BC? What is the total force in the member?

Solution

From the third principle,

$$\mathbf{BC}_y = 1000 \text{ N}$$

From the fourth principle,



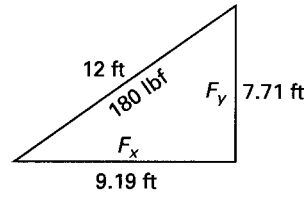
$$\begin{aligned}\mathbf{BC}_x &= \left(\frac{3}{4}\right)\mathbf{BC}_y \\ &= \left(\frac{3}{4}\right)(1000 \text{ N}) \\ &= 750 \text{ N}\end{aligned}$$

The total resultant force in member BC can be calculated from the Pythagorean theorem. However, it is easier to use the fourth principle.

$$\begin{aligned}\mathbf{BC} &= \left(\frac{5}{4}\right)\mathbf{BC}_y \\ &= \left(\frac{5}{4}\right)(1000 \text{ N}) \\ &= 1250 \text{ N}\end{aligned}$$

Example 41.7

The 12 ft long axial member FG supports an axial force of 180 lbf. What are the x- and y-components of the applied force?



Solution

method 1: direction cosines

The x- and y-direction angles are 40° and 90° − 40° = 50°, respectively.

$$\mathbf{FG}_x = (180 \text{ lbf}) \cos 40^\circ = 137.9 \text{ lbf}$$
$$\mathbf{FG}_y = (180 \text{ lbf}) \cos 50^\circ = 115.7 \text{ lbf}$$

method 2: similar triangles

$$\mathbf{FG}_x = \left(\frac{9.19 \text{ ft}}{12 \text{ ft}}\right)(180 \text{ lbf}) = 137.9 \text{ lbf}$$
$$\mathbf{FG}_y = \left(\frac{7.71 \text{ ft}}{12 \text{ ft}}\right)(180 \text{ lbf}) = 115.7 \text{ lbf}$$

31. TRUSSES

A *truss* or *frame* is a set of pin-connected axial *members* (i.e., *two-force members*). The connection points are known as *joints*. Member weights are disregarded, and truss loads are applied only at joints. A *structural cell* consists of all members in a closed loop of members. For the truss to be stable (i.e., to be a *rigid truss*), all of the structural cells must be triangles. Figure 41.13 identifies *chords, end posts, panels*, and other elements of a typical *bridge truss*.

A *trestle* is a braced structure spanning a ravine, gorge, or other land depression in order to support a road or rail line. Trestles are usually indeterminate, have multiple earth contact points, and are more difficult to evaluate than simple trusses.

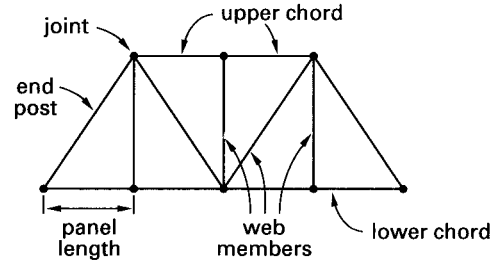


Figure 41.13 *Parts of a Bridge Truss*

Several types of trusses have been given specific names. Some of the more common types of named trusses are shown in Fig. 41.14.

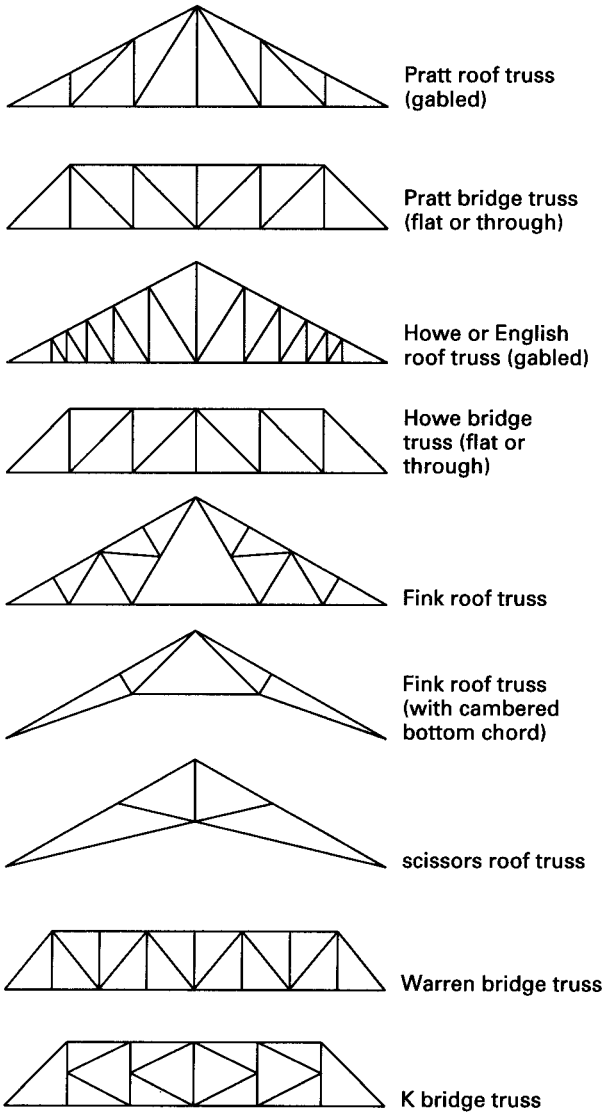

Figure 41.14 *Special Types of Trusses*

Truss loads are considered to act only in the plane of a truss. Therefore, trusses are analyzed as two-dimensional structures. Forces in truss members hold the various truss parts together and are known as *internal forces*. The internal forces are found by drawing free-body diagrams.

Although free-body diagrams of truss members can be drawn, this is not usually done. Instead, free-body diagrams of the pins (i.e., the joints) are drawn. A pin in compression will be shown with force arrows pointing toward the pin, away from the member. (Similarly, a pin in tension will be shown with force arrows pointing away from the pin, toward the member.)[16]

[16]The method of showing tension and compression on a truss drawing may appear incorrect. This is because the arrows show the forces on the pins, not on the members.

With typical bridge trusses supported at the ends and loaded downward at the joints, the upper chords are almost always in compression, and the end panels and lower chords are almost always in tension.

32. DETERMINATE TRUSSES

A truss will be statically determinate if Eq. 41.48 holds.

$$\text{no. of members} = 2(\text{no. of joints}) - 3 \qquad 41.48$$

If the left-hand side is greater than the right-hand side (i.e., there are *redundant members*), the truss is statically indeterminate. If the left-hand side is less than the right-hand side, the truss is unstable and will collapse under certain types of loading.

Equation 41.48 is a special case of the following general criterion.

$$\begin{aligned} &\text{no. of members} \\ &+ \text{no. of reactions} \\ &- 2(\text{no. of joints}) = 0 \quad \text{[determinate]} \\ &\qquad\qquad\qquad > 0 \quad \text{[indeterminate]} \\ &\qquad\qquad\qquad < 0 \quad \text{[unstable]} \end{aligned} \qquad 41.49$$

For a structure with one roller and one pinned support, there are three reactions (counting the x- and y-components of the pinned support separately). Thus, Eq. 41.48 is for use only with structures supported in this manner.

Furthermore, Eq. 41.48 is a necessary, but not sufficient, condition for truss stability. It is possible to arrange the members in such a manner as to not contribute to truss stability. This will seldom be the case in actual practice, however.

33. ZERO-FORCE MEMBERS

Forces in truss members can sometimes be determined by inspection. One of these cases is where there are *zero-force members*. A third member framing into a joint already connecting two collinear members carries no internal force unless there is a load applied at that joint. Similarly, both members forming an apex of the truss are zero-force members unless there is a load applied at the apex.

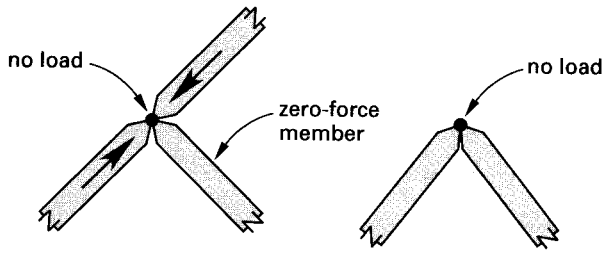

Figure 41.15 *Zero-Force Members*

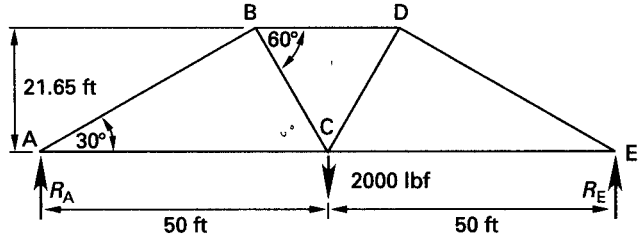
34. METHOD OF JOINTS



The *method of joints* is one of three methods that can be used to find the internal forces in each truss member. This method is useful when most or all of the truss member forces are to be calculated. Because this method advances from joint to adjacent joint, it is inconvenient when a single isolated member force is to be calculated.

The method of joints is a direct application of the equations of equilibrium in the x- and y-directions. Traditionally, the method starts by finding the reactions supporting the truss. Next, the joint at one of the reactions is evaluated, which determines all the member forces framing into the joint. Then, knowing one or more of the member forces from the previous step, an adjacent joint is analyzed. The process is repeated until all the unknown quantities are determined.

At a joint, there may be up to two unknown member forces, each of which can have dependent x- and y-components.[17] Since there are two equilibrium equations, the two unknown forces can be determined. Even though determinate, however, the sense of a force will often be unknown. If the sense cannot be determined by logic, an arbitrary decision can be made. If the incorrect direction is chosen, the force will be negative.

Example 41.8

Use the method of joints to calculate the force **BD** in the truss shown.

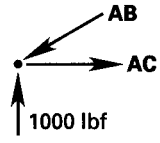
Solution

First, find the reactions. Assume clockwise is positive and take moments about point A.

$$\sum M_A = (2000 \text{ lbf})(50 \text{ ft}) - R_E(50 \text{ ft} + 50 \text{ ft}) = 0$$

$$R_E = 1000 \text{ lbf}$$

Since the sum of forces in the y-direction is also zero,



$$\sum F_y = R_A + 1000 \text{ lbf} - 2000 \text{ lbf} = 0$$

$$R_A = 1000 \text{ lbf}$$

[17] Occasionally, there will be three unknown member forces. In that case, an additional equation must be derived from an adjacent joint.

There are three unknowns at joint B (and also at D). Therefore, the analysis must start at joint A (or E) where there are only two unknowns (forces **AB** and **AC**).

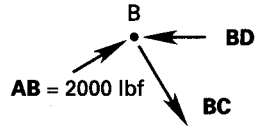
The free-body diagram of pin A is shown. The direction of R_A is known to be upward. The directions of forces **AB** and **AC** can be assumed, but logic can be used to determine them. Only the vertical component of **AB** can oppose R_A. Therefore, **AB** is directed downward. (This means that member AB is in compression.) Similarly, **AC** must oppose the horizontal component of **AB**. Therefore, **AC** is directed to the right. (This means that member AC is in tension.)

Resolve force **AB** into horizontal and vertical components using trigonometry, direction cosines, or similar triangles. (R_A and **AC** are already parallel to an axis.) Then, use the equilibrium equations to determine the forces.

By inspection, $AB_y = 1000$.

$$\mathbf{AB}_y = \mathbf{AB} \sin 30^\circ$$

$$1000 \text{ lbf} = \mathbf{AB}(0.5)$$



$$\mathbf{AB} = 2000 \text{ lbf (C)}$$

$$\mathbf{AB}_x = \mathbf{AB} \cos 30^\circ$$

$$= (2000 \text{ lbf})(0.866)$$

$$= 1732 \text{ lbf}$$

Now, draw the free-body diagram of pin B. (Notice that the direction of force **AB** is toward the pin, just as it was for pin A.) Although the true directions of the forces are unknown, they can be determined logically. The direction of force **BC** is chosen to counteract the vertical component of force **AB**. The direction of force **BD** is chosen to counteract the horizontal components of forces **AB** and **BC**.

$\mathbf{AB}_x$ and $\mathbf{AB}_y$ are already known. Resolve the force **BC** into horizontal and vertical components.

$$\mathbf{BC}_x = \mathbf{BC} \sin 30^\circ = \mathbf{BC}(0.5)$$

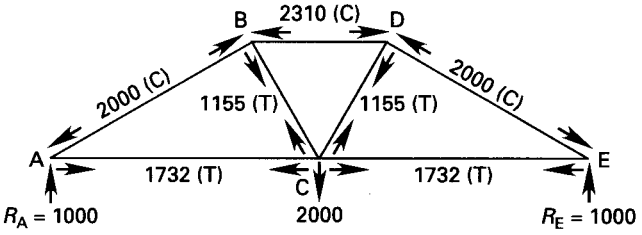
$$\mathbf{BC}_y = \mathbf{BC} \cos 30^\circ = \mathbf{BC}(0.866)$$

Now, write the equations of equilibrium for point B.

$$\sum F_x = 1732 + 0.5\mathbf{BC} - \mathbf{BD} = 0$$

$$\sum F_y = 1000 \text{ lbf} - 0.866\mathbf{BC} = 0$$

From the second equation, $\mathbf{BC} = 1155$ lbf. Substituting this into the first equation,



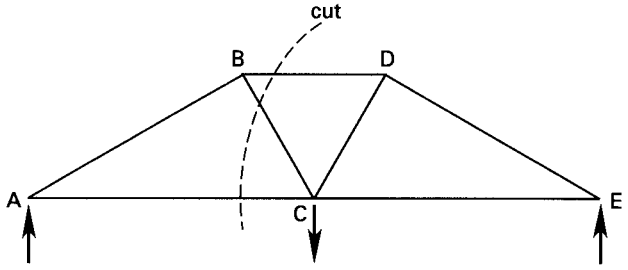
$$1732 \text{ lbf} + (0.5)(1155 \text{ lbf}) - \mathbf{BD} = 0$$

$$\mathbf{BD} = 2310 \text{ lbf (C)}$$

Since **BD** turned out to be positive, its direction was chosen correctly.

The direction of the arrow indicates that the member is compressing the pin. Consequently, the pin is compressing the member. Member BD is in compression.

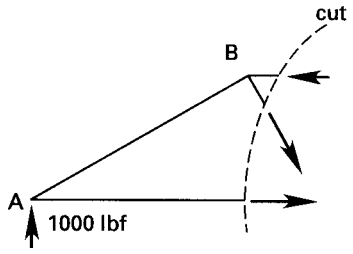
If the process is continued, all forces can be determined. However, the truss is symmetrical, and it is not necessary to evaluate every joint to calculate all forces.



35. CUT-AND-SUM METHOD

The *cut-and-sum method* can be used to find forces in inclined members. This method is strictly an application of the vertical equilibrium condition ($\Sigma F_y = 0$).

The method starts by finding all of the support reactions on a truss. Then a cut is made through the truss in such a way as to pass through one inclined or vertical member only. (At this point, it should be clear that the vertical component of the inclined member must balance all of the external vertical forces.) The equation for vertical equilibrium is written for the free body of the remaining truss portion.



Example 41.9

Find the force in member BC for the truss in Ex. 41.8.

Solution

The reactions were determined in Ex. 41.8. The truss is cut in such a way as to pass through member BC but through no other inclined member. The free body of the remaining portion of the truss is

The vertical equilibrium equation is

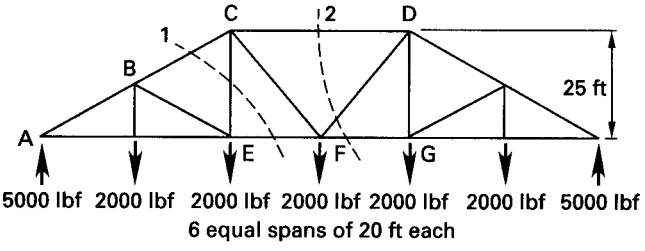
$$\sum F_y = R_A - \mathbf{BC}_y$$

$$= 0$$

$$= 1000 \text{ lbf} - 0.866\mathbf{BC}$$

$$= 0$$

$$\mathbf{BC} = 1155 \text{ lbf}$$

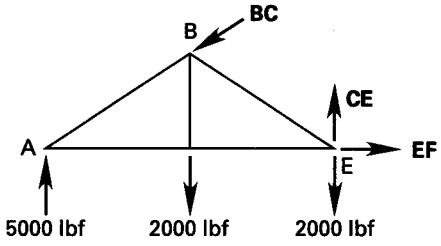


36. METHOD OF SECTIONS

The *method of sections* is a direct approach to finding forces in any truss member. This method is convenient when only a few truss member forces are unknown.

As with the previous two methods, the first step is to find the support reactions. Then a cut is made through the truss, passing through the unknown member.[18] Finally, all three conditions of equilibrium are applied as needed to the remaining truss portion. (Since there are three equilibrium equations, the cut cannot pass through more than three members in which the forces are unknown.)

Example 41.10

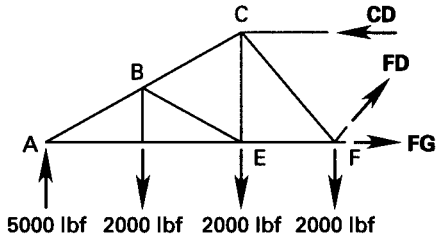


Find the forces in members CD and CE. The support reactions have already been determined.

[18]Knowing where to cut the truss is the key part of this method. Such knowledge is developed only by practice.

Solution

To find the force **CE**, the truss is cut at section 1.



Taking moments about point A will eliminate all of the unknown forces except **CE**. Assume clockwise moments are positive.

$$\sum M_A = (2000 \text{ lbf})(20 \text{ ft}) + (2000 \text{ lbf})(40 \text{ ft}) - (40 \text{ ft})\mathbf{CE} = 0$$

$$\mathbf{CE} = 3000 \text{ lbf}$$

To find the force **CD**, the truss is cut at section 2.

Taking moments about point F will eliminate all unknowns except **CD**. Assume clockwise moments are positive.

$$\sum M_F = (5000 \text{ lbf})(60 \text{ ft}) - (25)\mathbf{CD} - (2000 \text{ lbf})(20 \text{ ft}) - (2000 \text{ lbf})(40 \text{ ft}) = 0$$

$$\mathbf{CD} = 7200 \text{ lbf}$$

37. SUPERPOSITION OF LOADS

Superposition is a term used to describe the process of determining member forces by considering loads one at a time. Suppose, for example, that the force in member FG is unknown and that the truss carries three loads. If the method of superposition is used, the force in member FG (call it $\mathbf{FG}_1$) is determined with only the first load acting on the truss. $\mathbf{FG}_2$ and $\mathbf{FG}_3$ are similarly found. The true member force **FG** is found by adding $\mathbf{FG}_1$, $\mathbf{FG}_2$, and $\mathbf{FG}_3$.

Superposition should be used with discretion since trusses can change shape under load. If a truss deflects such that the load application points are significantly different from those in the undeflected truss, superposition cannot be used for that truss.

In simple truss analysis, change of shape under load is neglected. Superposition, therefore, can be assumed to apply.

38. TRANSVERSE TRUSS MEMBER LOADS

Truss members are usually designed as axial members, not as beams. Trusses are traditionally considered to be loaded at joints only. Figure 41.16, however, illustrates cases of nontraditional *transverse loading* that can actually occur. For example, a truss member's own weight would contribute to a uniform load, as would a severe ice buildup.

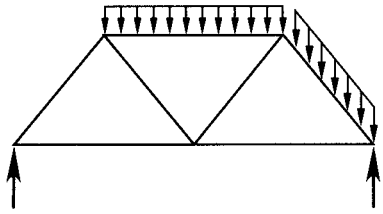


Figure 41.16 *Transverse Truss Member Loads*

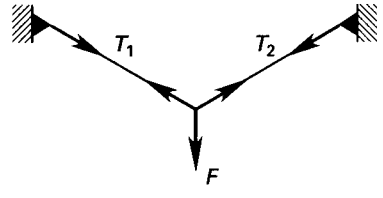
Transverse loads add two solution steps to a truss problem. First, the truss member must be individually considered as a beam simply supported at its pinned connections, and the reactions needed to support the transverse loading must be found. These reactions become additional loads applied to the truss joints, and the truss can then be evaluated in the normal manner.

The second step is to check the structural adequacy (deflection, bending stress, shear stress, buckling, etc.) of the truss member under transverse loading.

39. CABLES CARRYING CONCENTRATED LOADS

An *ideal* cable is assumed to be completely flexible, massless, and incapable of elongation. It therefore acts as an axial two-force tension member between points of concentrated loading. In fact, the term *tension* or *tensile force* is commonly used in place of "member force" when dealing with cables.



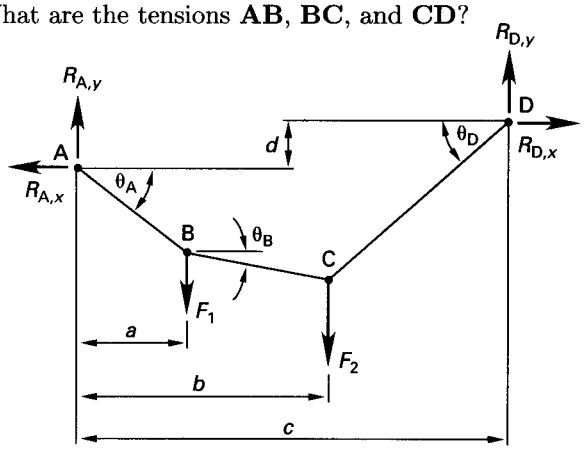


Figure 41.17 *Cable with Concentrated Load*

The methods of joints and sections used in truss analysis can be used to determine the tensions in cables carrying concentrated loads. After separating the reactions into x- and y-components, it is particularly useful to sum moments about one of the reaction points. All cables

will be found to be in tension, and (with vertical loads only) the horizontal tension component will be the same in all cable segments. Unlike the case of a rope passing over a series of pulleys, however, the total tension in the cable will not be the same in every cable segment.

Example 41.11

What are the tensions **AB**, **BC**, and **CD**?

Solution

Separate the two reactions into x- and y-components. (The total reactions R_A and R_D are also the tensions **AB** and **CD**, respectively.)

$$R_{A,x} = -\mathbf{AB}\cos\theta_A$$
$$R_{A,y} = -\mathbf{AB}\sin\theta_A$$
$$R_{D,x} = -\mathbf{CD}\cos\theta_D$$
$$R_{D,y} = -\mathbf{CD}\sin\theta_D$$

Next, take moments about point A to find **CD**. Assume clockwise to be positive.

$$\sum M_A = aF_1 + bF_2 - d\,\mathbf{CD}_x + c\,\mathbf{CD}_y = 0$$

None of the applied loads are in the x-direction. Therefore, the only horizontal loads are the x-components of the reactions. To find tension **AB**, take the entire cable as a free body. Then, sum the external forces in the x-direction.

$$\sum F_x = R_{D,x} - R_{A,x} = 0$$
$$\mathbf{CD}\cos\theta_D = \mathbf{AB}\cos\theta_A$$

The x-component of force is the same in all cable segments. To find **BC**, sum the x-direction forces at point B.

$$\sum F_x = \mathbf{BC}_x - \mathbf{AB}_x = 0$$
$$\mathbf{BC}\cos\theta_B = \mathbf{AB}\cos\theta_A$$

40. PARABOLIC CABLES

If the distributed load per unit length, w, on a cable is constant with respect to the horizontal axis (as is the load from a bridge floor), the cable will be parabolic in shape.[19] This is illustrated in Fig. 41.18.

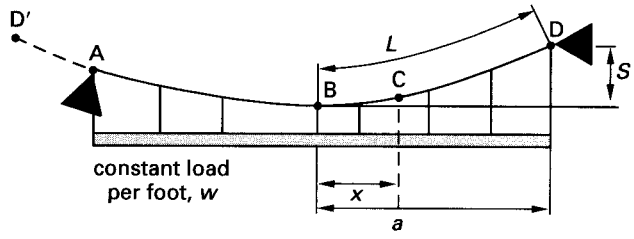

Figure 41.18 *Parabolic Cable*

If the location of the maximum sag (i.e., the lowest cable point) is known, the horizontal component of tension, H, can be found by taking moments about a reaction point. If the cable is cut at the maximum sag point, B, the cable tension on the free body will be horizontal since there is no vertical component to the cable. Cutting the cable in Fig. 41.18 at point B and taking moments about point D will determine the minimum cable tension, H.

$$\sum M_D = wa\left(\frac{a}{2}\right) - HS = 0 \qquad 41.50$$

$$H = \frac{wa^2}{2S} \qquad 41.51$$

Since the load is vertical everywhere, the horizontal component of tension is constant everywhere in the cable. The tension, T_C, at any point C can be found by applying the equilibrium conditions to the cable segment BC.

$$T_{C,x} = H = \frac{wa^2}{2S} \qquad 41.52$$

$$T_{C,y} = wx \qquad 41.53$$

$$T_C = \sqrt{(T_{C,x})^2 + (T_{C,y})^2}$$
$$= w\sqrt{\left(\frac{a^2}{2S}\right)^2 + x^2} \qquad 41.54$$

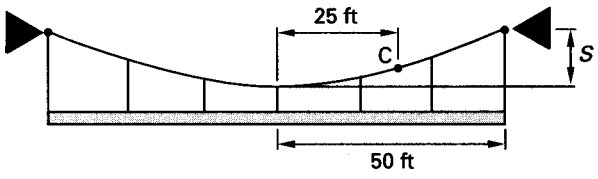
The angle of the cable at any point is

$$\tan\theta = \frac{wx}{H} \qquad 41.55$$

The tension and angle are maximum at the supports.

If the lowest sag point, point B, is used as the origin, the shape of the cable is

$$y(x) = \frac{wx^2}{2H} \qquad 41.56$$



[19]The parabolic case can also be assumed with cables loaded only by their own weight (e.g., telephone and trolley wires), if both ends are at the same elevations and if the sag is no more than 10% of the distance between supports.

The approximate length of the cable from the lowest point to the support (i.e., length BD) is

$$L \approx a\left(1 + \left(\tfrac{2}{3}\right)\left(\frac{S}{a}\right)^2 - \left(\tfrac{2}{5}\right)\left(\frac{S}{a}\right)^4\right) \qquad 41.57$$

Example 41.12

A pedestrian foot bridge has two suspension cables and a flexible floor weighing 28 lbf/ft. The span of the bridge is 100 ft. When the bridge is empty, the tension at point C is 1500 lbf. Assuming a parabolic shape, what is the maximum cable sag, S?

Solution

Since there are two cables, the floor weight per suspension cable is

$$w = \frac{28\ \frac{\text{lbf}}{\text{ft}}}{2}$$

$$= 14\ \text{lbf/ft}$$

From Eq. 41.54,

$$T_C = w\sqrt{\left(\frac{a^2}{2S}\right)^2 + x^2}$$

$$1500\ \text{ft} = 14\ \frac{\text{lbf}}{\text{ft}}\sqrt{\left(\frac{(50\ \text{ft})^2}{2S}\right)^2 + (25\ \text{ft})^2}$$

$$S = 12\,\text{ft}$$

41. CABLES CARRYING DISTRIBUTED LOADS

An idealized tension cable with a distributed load is similar to a linkage made up of a very large number of axial members. The cable is an axial member in the sense that the internal tension acts tangentially to the cable everywhere.

Since the load is vertical everywhere, the horizontal component of cable tension is constant along the cable. The cable is horizontal at the point of lowest sag. There is no vertical tension component, and the cable tension is minimum. By similar reasoning, the cable tension is maximum at the supports.

Figure 41.19 illustrates a general cable with a distributed load. The shape of the cable will depend on the relative distribution of the load. A free-body diagram of segment BC is also shown.

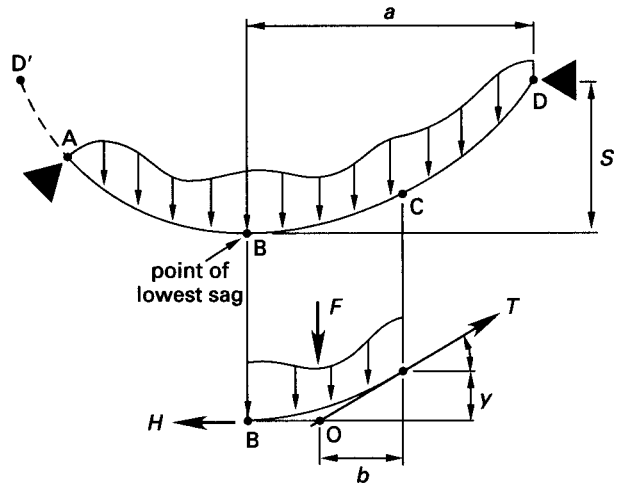


Figure 41.19 *Cable with Distributed Load*

F is the resultant of the distributed load on segment BC, T is the cable tension at point C, and H is the tension at the point of lowest sag (i.e., the point of minimum tension). Since segment BC taken as a free body is a three-force member, the three forces (H, F, and T) must be concurrent to be in equilibrium. The horizontal component of tension can be found by taking moments about point C.

$$\sum M_C = Fb - Hy = 0 \qquad 41.58$$

$$H = \frac{Fb}{y} \qquad 41.59$$

Also, $\tan\theta = y/b$. Therefore,

$$H = \frac{F}{\tan\theta} \qquad 41.60$$

The basic equilibrium conditions can be applied to the free-body cable segment BC to determine the tension in the cable at point C.

$$\sum F_x = T_C\cos\theta - H = 0 \qquad 41.61$$

$$\sum F_y = T_C\sin\theta - F = 0 \qquad 41.62$$

The resultant tension at point C is

$$T_C = \sqrt{H^2 + F^2} \qquad 41.63$$

42. CATENARY CABLES

If the distributed load is constant along the length of the cable, as it is with a loose cable loaded by its own weight, the cable will have the shape of a *catenary*. A vertical axis catenary has a shape determined by Eq. 41.64, where c is a constant and cosh is the *hyperbolic cosine*. The quantity x/c is in radians.[20]

$$y(x) = c\,\cosh\left(\frac{x}{c}\right) \qquad 41.64$$

[20]In order to use Eqs. 41.64 through 41.67, you must reset your calculator from degrees to radians.

Referring to Fig. 41.20, the vertical distance, y, to any point C on the catenary is measured from a reference plane located a distance c below the point of greatest sag, point B. The distance c is known as the *parameter of the catenary*. Although the value of c establishes the location of the x-axis, the value of c does not correspond to any physical distance, nor is the reference plane the ground level.

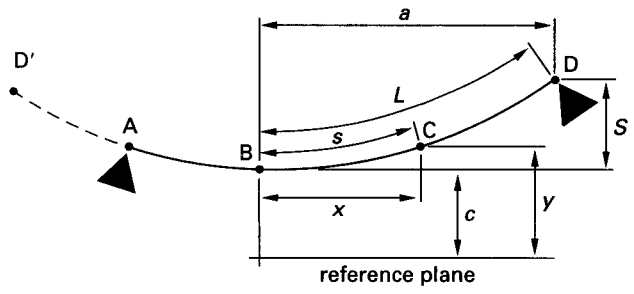

Figure 41.20 *Catenary Cable*

In order to define the cable shape and determine cable tensions, it is necessary to have enough information to calculate c. For example, if a and S are known, Eq. 41.67 can be solved by trial and error for c.[21] Once c is known, the cable geometry and forces are determined by the remaining equations.

For any point C, the equations most useful in determining the shape of the catenary are

$$y = \sqrt{s^2 + c^2} = c\left(\cosh\left(\frac{x}{c}\right)\right) \qquad 41.65$$

$$s = c\left(\sinh\left(\frac{x}{c}\right)\right) \qquad 41.66$$

$$\text{sag} = S = y_D - c = c\left(\cosh\left(\frac{a}{c}\right) - 1\right) \qquad 41.67$$

$$\tan\theta = \frac{s}{c} \qquad 41.68$$

The equations most useful in determining the cable tensions are

$$H = wc \qquad 41.69$$

$$F = ws \qquad 41.70$$

$$T = wy \qquad 41.71$$

$$\tan\theta = \frac{ws}{H} \qquad 41.72$$

$$\cos\theta = \frac{H}{T} \qquad 41.73$$

Example 41.13

A cable 100 m long is loaded by its own weight. The maximum sag is 25 m, and the supports are on the same level. What is the distance between the supports?

[21] Because obtaining the solution may require trial and error, it will be advantageous to assume a parabolic shape if the cable is taut. (See Ftn. 19.) The error will generally be small.

Solution

Since the two supports are on the same level, the cable length, L, between the point of maximum sag and support D is half of the total length.

$$L = \frac{100\,\text{m}}{2} = 50\,\text{m}$$

Writing Eqs. 41.65 and 41.67 for point D (with $S = 25$ m),

$$y_D = c + S = \sqrt{L^2 + c^2}$$

$$c + 25\ \text{m} = \sqrt{(50\ \text{m})^2 + c^2}$$

$$c = 37.5\ \text{m}$$

Substituting a for x and $L = 50$ for s in Eq. 41.66,

$$s = c\left(\sinh\left(\frac{x}{c}\right)\right)$$

$$50 = (37.5)\left(\sinh\left(\frac{a}{37.5}\right)\right)$$

$$a = 41.2\ \text{m}$$

The distance between supports is

$$2a = (2)(41.2\ \text{m}) = 82.4\ \text{m}$$

43. CABLES WITH ENDS AT DIFFERENT ELEVATIONS

A cable will be asymmetrical if its ends are at different elevations. In some cases, as shown in Fig. 41.21, the cable segment will not include the lowest point B. However, if the location of the theoretical lowest point can be derived, the positions and elevations of the cable supports will not affect the analysis. The same procedure is used in proceeding from the theoretical point B to either support. In fact, once the theoretical shape of a cable has been determined, the supports can be relocated anywhere along the cable line without affecting the equilibrium of the supported segment.

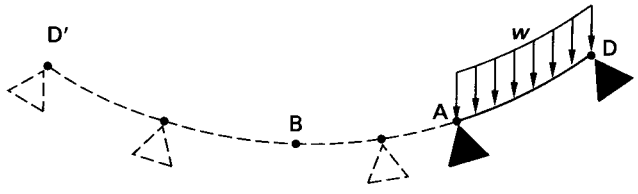

Figure 41.21 *Asymmetrical Segment of Symmetrical Cable*

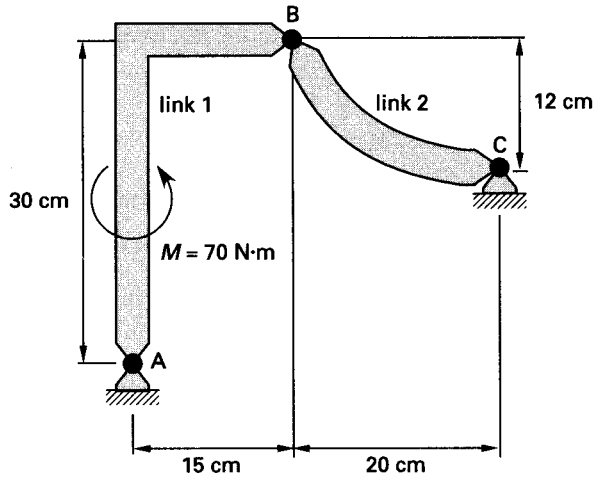
44. TWO-DIMENSIONAL MECHANISMS

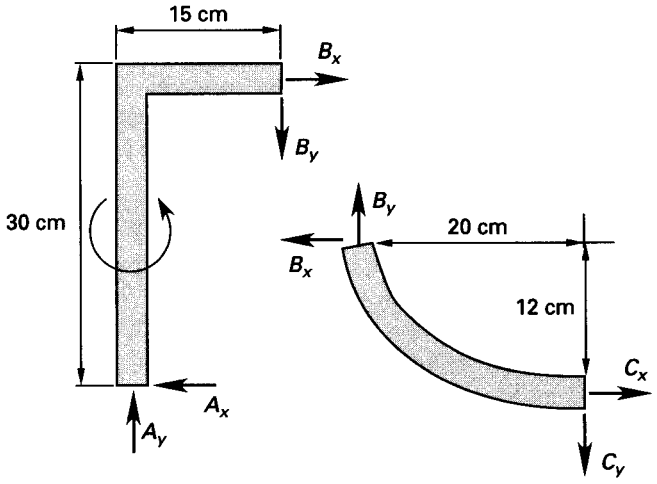
A two-dimensional *mechanism* (*machine*) is a nonrigid structure. Although parts of the mechanism move, the relationships between forces in the mechanism can be



Structural

determined by statics. In order to determine an unknown force, one or more of the mechanism components must be considered as a free body. All input forces and reactions must be included on this free body. In general, the resultant force on such a free body will not be in the direction of the member.

Several free bodies may be needed for complicated mechanisms. Sign conventions of acting and reacting forces must be strictly adhered to when determining the effect of one component on another.



Example 41.14

A 70 N·m couple is applied to the mechanism shown. All connections are frictionless hinges. What are the x- and y-components of the reactions at B?

Solution

Isolate links 1 and 2 and draw their free bodies.

Assume clockwise moments are positive. Take moments about point A on link 1.

$$\sum M_A = B_x(0.3\text{ m}) + B_y(0.15\text{ m}) - 70\text{ N·m} = 0$$

Assume clockwise moments are positive. Take moments about point C on link 2.

$$\sum M_C = B_y(0.20\text{ m}) - B_x(0.12\text{ m}) = 0$$

Solving these two equations simultaneously determines the force at joint B.

$$B_x = 179\,\text{N}$$

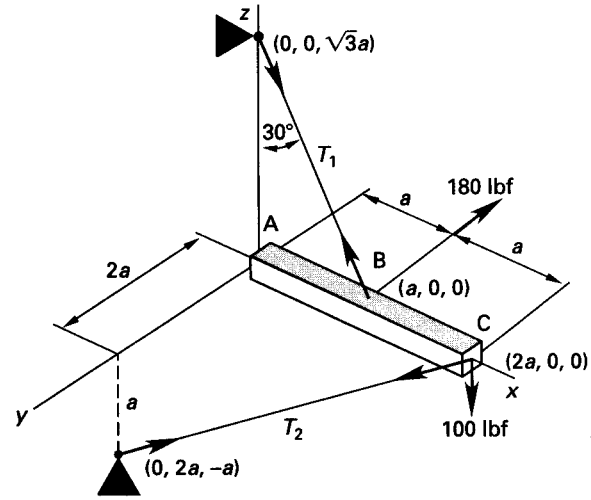
$$B_y = 108\,\text{N}$$

45. EQUILIBRIUM IN THREE DIMENSIONS

The basic equilibrium equations can be used with vector algebra to solve a three-dimensional statics problem. When a manual calculation is required, however, it is often more convenient to write the equilibrium equations for one orthogonal direction at a time, thereby avoiding the use of vector notation and reducing the problem to two dimensions. The following method can be used to analyze a three-dimensional structure.

step 1: Establish the $(0, 0, 0)$ origin for the structure.

step 2: Determine the (x, y, z) coordinates of all load and reaction points.



step 3: Determine the x-, y-, and z-components of all loads and reactions. This is accomplished by using direction cosines calculated from the (x, y, z) coordinates.

step 4: Draw a *coordinate free body* of the structure for each of the three coordinate axes. Include only forces, reactions, and moments that affect the coordinate free body.

step 5: Apply the basic two-dimensional equilibrium equations.

Example 41.15

Beam AC is supported at point A by a frictionless ball joint and at points B and C by cables. A 100 lbf load is applied vertically to point C, and a 180 lbf load is applied horizontally to point B. What are the cable tensions T_1 and T_2?

Solution

steps 1 and 2: Point A has already been established as the origin. The locations of all support and load points are shown on the illustration.

step 3: By inspection, for the 180 lbf horizontal load at point B,

$$F_x = 0$$
$$F_y = -180 \text{ lbf}$$
$$F_z = 0$$

By inspection, for the 100 lbf vertical load at point C,

$$F_x = 0$$
$$F_y = 0$$
$$F_z = -100 \text{ lbf}$$

The length of cable 1 is

$$L_1 = \sqrt{(a-0)^2 + (0-0)^2 + (0-\sqrt{3}\,a)^2}$$
$$= 2a$$

The direction cosines of the force from cable 1 at point B are

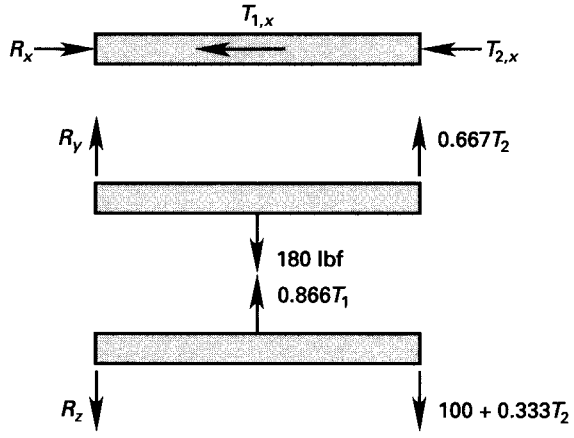
$$\cos\theta_x = \frac{d_x}{L_1} = \frac{0-a}{2a} = -0.5$$
$$\cos\theta_y = \frac{d_y}{L_1} = \frac{0-0}{2a} = 0$$
$$\cos\theta_z = \frac{d_z}{L_1} = \frac{\sqrt{3}\,a-0}{2a} = 0.866$$

Therefore, the components of the tension in cable 1 are

$$T_{1,x} = -0.5\,T_1$$
$$T_{1,y} = 0$$
$$T_{1,z} = 0.866\,T_1$$

Similarly, for cable 2,

$$L_2 = \sqrt{(2a-0)^2 + (0-2a)^2 + \big(0-(-a)\big)^2}$$
$$= 3a$$



The direction cosines for the force from cable 2 at point C are

$$\cos\theta_x = \frac{d_x}{L_2} = \frac{0-2a}{3a} = -0.667$$
$$\cos\theta_y = \frac{d_y}{L_2} = \frac{2a-0}{3a} = 0.667$$
$$\cos\theta_z = \frac{d_z}{L_2} = \frac{-a-0}{3a} = -0.333$$

Therefore, the components of the tension in cable 2 are

$$T_{2,x} = -0.667\,T_2$$
$$T_{2,y} = 0.667\,T_2$$
$$T_{2,z} = -0.333\,T_2$$

step 4: The three coordinate free-body diagrams are

step 5: Tension T_2 can be found by taking moments about point A on the y-coordinate free body.

$$\sum M_A = (0.667T_2)(2a) - (180 \text{ lbf})(a) = 0$$
$$T_2 = 135 \text{ lbf}$$

Tension T_1 can be found by taking moments about point A on the z-coordinate free body.

$$\sum M_A = (0.866\,T_1)(a) - (0.333)(135 \text{ lbf})(2a) - (100 \text{ lbf})(2a) = 0$$
$$T_1 = 335 \text{ lbf}$$

46. TRIPODS

A *tripod* is a simple three-dimensional truss (frame) that consists of three axial members. One end of each member is connected at the *apex* of the tripod, while the other ends are attached to the supports. All connections are assumed to allow free rotation in all directions.

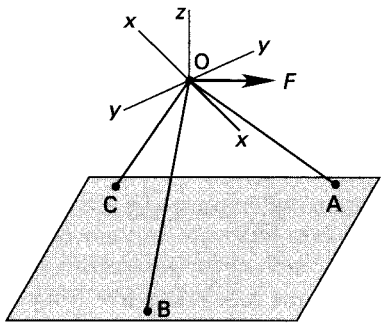


Figure 41.22 *Tripod*

The general solution procedure given in the preceding section can be made more specific for tripods.

step 1: Establish the apex as the origin.

step 2: Determine the x-, y-, and z-components of the force applied to the apex.

step 3: Determine the (x, y, z) coordinates of points A, B, and C—the three support points.

step 4: Determine the length of each tripod leg from the coordinates of the support points.

$$L = \sqrt{x^2 + y^2 + z^2} \qquad 41.74$$

step 5: Determine the direction cosines for the leg forces at the apex. For leg A, for example,

$$\cos\theta_{A,x} = \frac{x_A}{L} \qquad 41.75$$

$$\cos\theta_{A,y} = \frac{y_A}{L} \qquad 41.76$$

$$\cos\theta_{A,z} = \frac{z_A}{L} \qquad 41.77$$

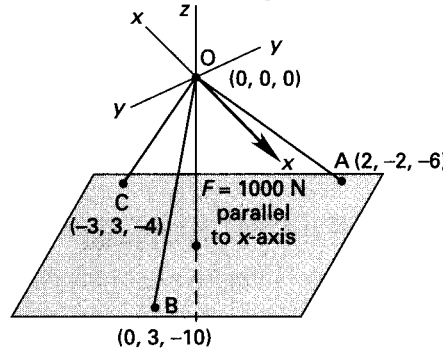
step 6: Write the x-, y-, and z-components of each leg force in terms of the direction cosines. For leg A, for example,

$$F_{A,x} = F_A \cos\theta_{A,x} \qquad 41.78$$

$$F_{A,y} = F_A \cos\theta_{A,y} \qquad 41.79$$

$$F_{A,z} = F_A \cos\theta_{A,z} \qquad 41.80$$

step 7: Write the three sum-of-forces equilibrium equations for the apex.



$$F_{A,x} + F_{B,x} + F_{C,x} + F_x = 0 \qquad 41.81$$

$$F_{A,y} + F_{B,y} + F_{C,y} + F_y = 0 \qquad 41.82$$

$$F_{A,z} + F_{B,z} + F_{C,z} + F_z = 0 \qquad 41.83$$

Example 41.16

Determine the force in each leg of the tripod.

Solution

step 1: The origin is at the apex.

step 2: By inspection, $F_x = +1000\,\text{N}$. All other components are zero.

steps 3 and 4: The direction cosines for the tripod legs have been calculated and are presented in the following table.

member	x^2	y^2	z^2	L^2	L	$\cos\theta_x$	$\cos\theta_y$	$\cos\theta_z$
OA	4	4	36	44	6.63	0.3015	−0.3015	−0.9046
OB	0	9	100	109	10.44	0.0	0.2874	−0.9579
OC	9	9	16	34	5.83	−0.5146	0.5146	−0.6861

steps 5 and 6: The equilibrium equations are

$$\begin{aligned} 0.3015\,F_A + \quad 0\,F_B - 0.5146\,F_C + 1000 &= 0 \\ -0.3015\,F_A + 0.2874\,F_B + 0.5146\,F_C &= 0 \\ -0.9046\,F_A - 0.9579\,F_B - 0.6861\,F_C &= 0 \end{aligned}$$

The solution to these simultaneous equations is

$$F_A = +1531\,\text{N} \quad \text{(T)}$$

$$F_B = -3480\,\text{N} \quad \text{(C)}$$

$$F_C = +2841\,\text{N} \quad \text{(T)}$$

PRACTICE PROBLEMS

1. Two towers are located on level ground 100 ft (30 m) apart. They support a transmission line with a mass of 2 lbm/ft (3 kg/m). The midpoint sag is 10 ft (3 m).

(a) What is the midpoint tension?

(A) 125 lbf (5.5 kN)

(B) 250 lbf (12 kN)

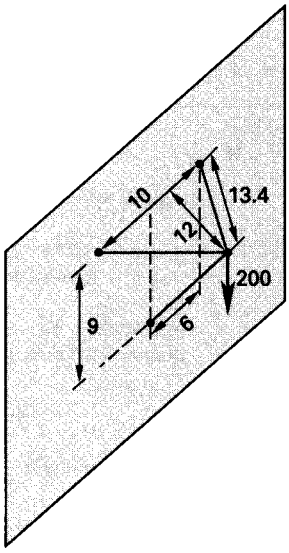
(C) 375 lbf (16 kN)

(D) 500 lbf (22 kN)

The answer is (B).

(b) What is the maximum tension in the transmission line?

(A) 170 lbf (7.0 kN)
(B) 210 lbf (8.6 kN)
(C) 270 lbf (12 kN)
(D) 330 lbf (14 kN)

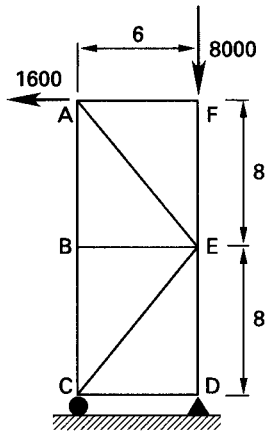


The answer is (C).

(c) If the maximum tension is 500 lbf (2000 N), what is the sag in the cable?

(A) 1.3 ft (0.4 m)
(B) 3.2 ft (1.0 m)
(C) 4.0 ft (1.2 m)
(D) 5.1 ft (1.5 m)

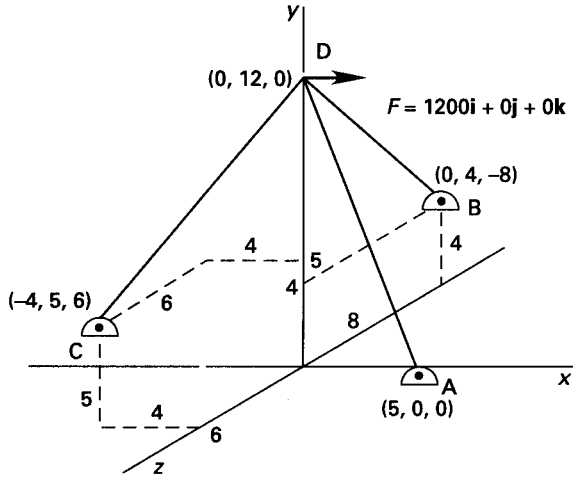
The answer is (D).



2. Two legs of a tripod are mounted on a vertical wall. Both legs are horizontal. The apex is 12 distance units from the wall. The right leg is 13.4 units long. The wall mounting points are 10 units apart. A third leg is mounted on the wall 6 units to the left of the right upper leg and and 9 units below the two top legs. A vertical downward load of 200 is supported at the apex. What is the reaction at the lowest mounting point?

(A) 120
(B) 170
(C) 250
(D) 330

The answer is (B).

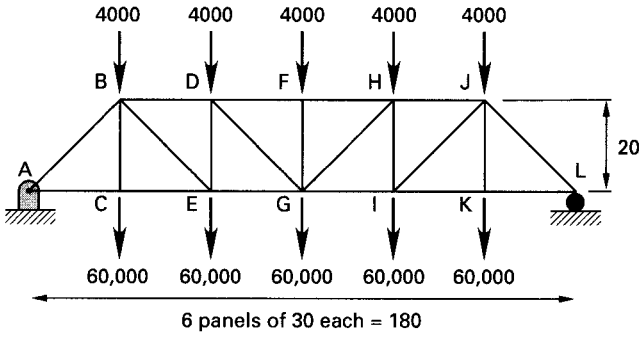


3. The ideal truss shown is supported by a pinned connection at point D and a roller connection at point C. Loads are applied at points A and F. What is the force in member DE?

(A) 1200
(B) 2700
(C) 3300
(D) 3700

The answer is (D).

4. A pin-connected tripod is loaded at the apex by a horizontal force of 1200 as shown. What is the magnitude of the force in member AD?



(A) 1100
(B) 1300
(C) 1800
(D) 2500

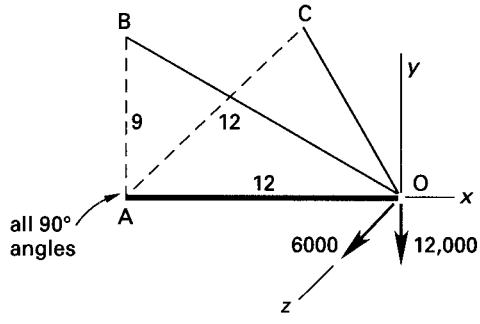
The answer is (C).

Structural

5. A truss is loaded by forces of 4000 at each upper connection point and forces of 60,000 at each lower connection point as shown.

(a) What is the force in member DE?

(A) 36,000
(B) 45,000
(C) 60,000
(D) 160,000



The answer is (A).

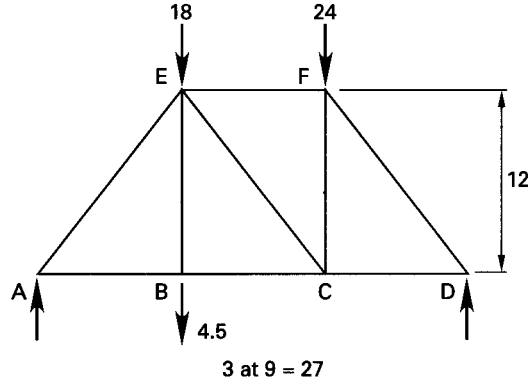
(b) What is the force in member HJ?

(A) 24,000
(B) 60,000
(C) 160,000
(D) 380,000

The answer is (D).

6. The rigid rod AO is supported by guy wires BO and CO, as shown. (Points A, B, and C are all in the same vertical plane.) Vertical and horizontal forces are 12,000 and 6000, respectively, as carried at the end of the rod. What are the x-, y-, and z-components of the reactions at point C?

(A) $(C_x, C_y, C_z) = (0, 6000, 0)$
(B) $(C_x, C_y, C_z) = (6000, 0, 6000)$
(C) $(C_x, C_y, C_z) = (6000, 0, 4200)$
(D) $(C_x, C_y, C_z) = (4200, 0, 8500)$



The answer is (B).

7. When the temperature is 70°F (21.11°C), sections of steel railroad rail are welded end to end to form a continuous, horizontal track exactly 1 mi long (1.6 km). Both ends of the track are constrained by preexisting installed sections of rail. Before the 1 mi section of track can be nailed to the ties, however, the sun warms it to a uniform temperature of 99.14°F (37.30°C). Laborers watch in amazement as the rail pops up in the middle and takes on a parabolic shape. The laborers prop the rail up (so that it does not buckle over) while they take souvenir pictures. How high off the ground is the midpoint of the hot rail?

(A) 0.8 ft (2.4 m)
(B) 2.1 ft (3.6 m)
(C) 17 ft (5.1 m)
(D) 45 ft (14 m)

The answer is (D).

8. (a) Find the force in member FC.

(A) 0.5
(B) 17
(C) 23
(D) 29

The answer is (A).

(b) What is the force in member CE?

(A) 0.50
(B) 0.63
(C) 11
(D) 17

The answer is (B).

c	centroidal

1. CENTROID OF AN AREA

The *centroid* of an area is analogous to the center of gravity of a homogeneous body.[1] The centroid is often described as the point at which a thin homogeneous plate would balance. This definition, however, combines the definitions of centroid and center of gravity and implies that gravity is required to identify the centroid, which is not true.

[1]The analogy has been simplified. A three-dimensional body also has a centroid. However, the centroid and center of gravity will not coincide unless the body is homogeneous.

The location of the centroid of an area bounded by the x- and y-axes and the mathematical function $y = f(x)$ can be found by the *integration method* by using Eqs. 42.1 through 42.4. The centroidal location depends only on the geometry of the area and is identified by the coordinates (x_c, y_c). Some references place a bar over the coordinates of the centroid to indicate an average point, such as $(\overline{x}, \overline{y})$.

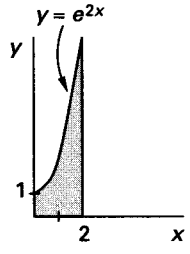
$$x_c = \frac{\int x\,dA}{A} \qquad 42.1$$

$$y_c = \frac{\int y\,dA}{A} \qquad 42.2$$

$$A = \int f(x)\,dx \qquad 42.3$$

$$dA = f(x)\,dx = g(y)\,dy \qquad 42.4$$

The locations of the centroids of *basic shapes*, such as triangles and rectangles, are well known. The most common basic shapes have been included in App. 42.A. There should be no need to derive centroidal locations for these shapes by the integration method.



The centroid of a complex area can be found from Eqs. 42.5 and 42.6 if the area can be divided into the basic shapes in App. 42.A. This process is simplified when all or most of the subareas adjoin the reference axis. Example 42.1 illustrates this method.

$$x_c = \frac{\sum_i A_i x_{ci}}{\sum_i A_i} \qquad 42.5$$

$$y_c = \frac{\sum_i A_i y_{ci}}{\sum_i A_i} \qquad 42.6$$

Example 42.1

An area is bounded by the x- and y-axes, the line $x = 2$, and the function $y = e^{2x}$. Find the x-component of the centroid.

Structural

Solution

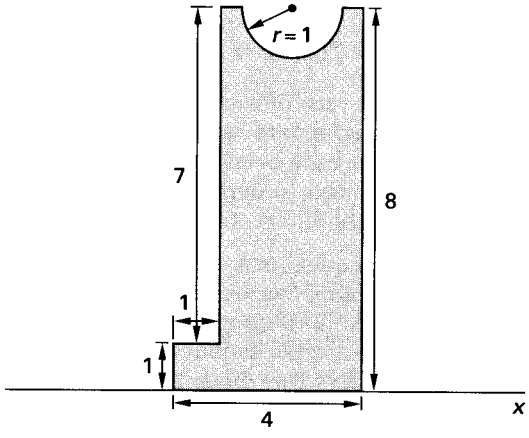
First, use Eq. 42.3 to find the area.

$$A = \int f(x)\,dx = \int_{x=0}^{x=2} e^{2x}\,dx$$

$$= \left[\tfrac{1}{2}e^{2x}\right]_0^2 = 27.3 - 0.5 = 26.8 \text{ units}^2$$

Since y is a function of x, dA must be expressed in terms of x. From Eq. 42.4,

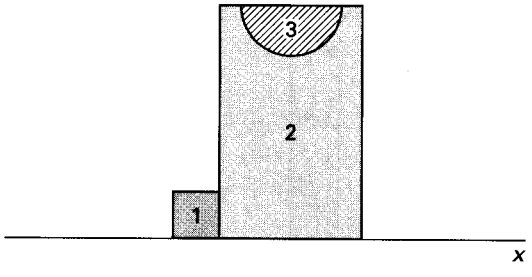
$$dA = f(x)\,dx = e^{2x}\,dx$$



Finally, use Eq. 42.1 to find x_c.

$$x_c = \frac{\int x\,dA}{A} = \frac{1}{26.8}\int_{x=0}^{x=2} xe^{2x}\,dx$$

$$= \left(\frac{1}{26.8}\right)\left[\tfrac{1}{2}xe^{2x} - \tfrac{1}{4}e^{2x}\right]_0^2 = 1.54 \text{ units}$$



Example 42.2

Find the y-coordinate of the centroid of the area shown.

Solution

The x-axis is the reference axis. The area is divided into basic shapes of a 1×1 square, a 3×8 rectangle, and a half-circle of radius 1. (The area could also have been divided into 1×4 and 3×7 rectangles and the half-circle, but the 3×7 rectangle would not then adjoin the x-axis.)

First, calculate the areas of the basic shapes. Notice that the half-circle area is negative since it represents a cutout.

$$A_1 = (1.0)(1.0) = 1.0 \text{ units}^2$$

$$A_2 = (3.0)(8.0) = 24.0 \text{ units}^2$$

$$A_3 = -\tfrac{1}{2}\pi r^2 = -\tfrac{1}{2}\pi(1.0)^2 = -1.57 \text{ units}^2$$

Next, find the y-components of the centroids of the basic shapes. Most are found by inspection, but App. 42.A can be used for the half-circle. Notice that the centroidal location for the half-circle is positive.

$$y_{c1} = 0.5 \text{ units}$$

$$y_{c2} = 4.0 \text{ units}$$

$$y_{c3} = 8.0 - 0.424 = 7.576 \text{ units}$$

Finally, use Eq. 42.6.

$$y_c = \frac{\sum A_i y_{ci}}{\sum A_i}$$

$$= \frac{(1.0)(0.5)+(24.0)(4.0)+(-1.57)(7.576)}{1.0 + 24.0 - 1.57}$$

$$= \frac{0.5 + 96.0 - 11.9}{23.43} = 3.61 \text{ units}$$

2. FIRST MOMENT OF THE AREA

The quantity $\int x\,dA$ is known as the *first moment of the area* or *first area moment* with respect to the y-axis. Similarly, $\int y\,dA$ is known as the first moment of the area with respect to the x-axis. By rearranging Eqs. 42.1 and 42.2, it is obvious that the first moment of the area can be calculated from the area and centroidal distance.

$$Q_y = \int x\,dA = x_c A \qquad 42.7$$

$$Q_x = \int y\,dA = y_c A \qquad 42.8$$

In basic engineering, the two primary applications of the first moment concept are to determine centroidal locations and shear stress distributions. In the latter application, the first moment of the area is known as the *statical moment*.

3. CENTROID OF A LINE

The location of the *centroid of a line* is defined by Eqs. 42.9 and 42.10, which are analogous to the equations used for centroids of areas.

$$x_c = \frac{\int x\,dL}{L} \qquad 42.9$$

$$y_c = \frac{\int y\,dL}{L} \qquad 42.10$$

Since equations of lines are typically in the form $y = f(x)$, dL must be expressed in terms of x or y.

$$dL = \left(\sqrt{\left(\frac{dy}{dx}\right)^2 + 1}\right) dx \qquad 42.11$$

$$dL = \left(\sqrt{\left(\frac{dx}{dy}\right)^2 + 1}\right) dy \qquad 42.12$$

4. THEOREMS OF PAPPUS-GULDINUS

The *Theorems of Pappus-Guldinus* define the surface and volume of revolution (i.e., the surface area and volume generated by revolving a curve around a fixed axis).

- *Theorem I:* The area of a surface of revolution is equal to the product of the length of the generating curve and the distance traveled by the centroid of the curve while the surface is being generated.

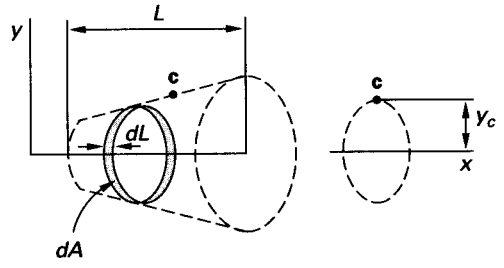


Figure 42.1 *Surface of Revolution*

When a part, dL, of a line L is revolved about the x-axis, a differential ring having surface area dA is generated.

$$dA = 2\pi y\, dL \qquad 42.13$$

$$A = \int dA = 2\pi \int y\, dL = 2\pi y_c L \qquad 42.14$$

- *Theorem II:* The volume of a surface of revolution is equal to the generating area times the distance traveled by the centroid of the area in generating the volume.

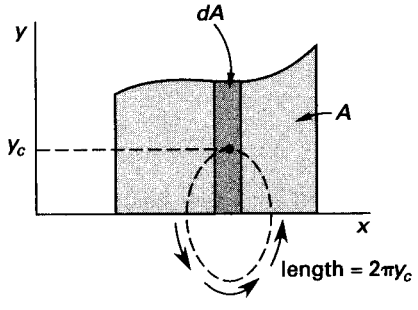

Figure 42.2 *Volume of Revolution*

When a differential plane area, dA, is revolved about the x-axis and does not intersect the y-axis, it generates a ring of volume dV.

$$dV = \pi y^2 dx = \pi y\, dA \qquad 42.15$$

$$V = 2\pi y_c A \qquad 42.16$$

5. MOMENT OF INERTIA OF AN AREA

The *moment of inertia*, I, of an area is needed in mechanics of materials problems. It is convenient to think of the moment of inertia of a beam's cross-sectional area as a measure of the beam's ability to resist bending. Thus, given equal loads, a beam with a small moment of inertia will bend more than a beam with a large moment of inertia.

Since the moment of inertia represents a resistance to bending, it is always positive. Since a beam can be unsymmetrical (e.g., a rectangular beam) and can be stronger in one direction than another, the moment of inertia depends on orientation. Therefore, a reference axis or direction must be specified.

The moment of inertia taken with respect to one of the axes in the rectangular coordinate system is sometimes referred to as the *rectangular moment of inertia.*

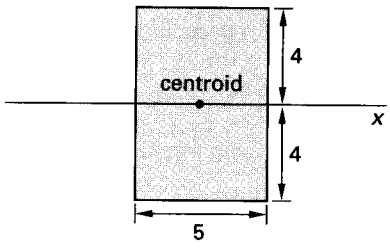
The symbol I_x is used to represent a moment of inertia with respect to the x-axis. Similarly, I_y is the moment of inertia with respect to the y-axis. I_x and I_y do not normally combine and are not components of some resultant moment of inertia.

Any axis can be chosen as the reference axis, and the value of the moment of inertia will depend on the reference selected. The moment of inertia taken with respect to an axis passing through the area's centroid is known as the *centroidal moment of inertia*, I_{cx} or I_{cy}. The centroidal moment of inertia is the smallest possible moment of inertia for the shape.

The *integration method* can be used to calculate the moment of inertia of a function that is bounded by the x- and y-axes and a curve $y = f(x)$. From Eqs. 42.17 and 42.18, it is apparent why the moment of inertia is also known as the *second moment of the area* or *second area moment.*

$$I_x = \int y^2\, dA \qquad 42.17$$

$$I_y = \int x^2\, dA \qquad 42.18$$



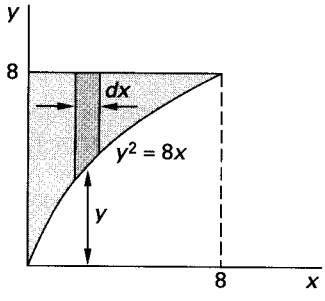
$$dA = f(x)\, dx = g(y)\, dy \qquad 42.19$$

The moments of inertia of the *basic shapes* are well known and are listed in App. 42.A.

Structural

Example 42.3

What is the centroidal moment of inertia with respect to the x-axis of a rectangle 5.0 units wide and 8.0 units tall?



Solution

Since the centroidal moment of inertia is needed, the reference line passes through the centroid. From App. 42.A, the centroidal moment of inertia is

$$I_{cx} = \frac{bh^3}{12} = \frac{(5)(8)^3}{12} = 213.3 \text{ units}^4$$

Example 42.4

What is the moment of inertia with respect to the y-axis of the area bounded by the y-axis, the line $y = 8.0$, and the parabola $y^2 = 8x$?

Solution

This problem is more complex than it first appears, since the area is above the curve, bounded not by $y = 0$ but by $y = 8$. In particular, dA must be determined correctly.

$$y = \sqrt{8x}$$

Use Eq. 42.4.

$$\begin{aligned} dA &= (8 - f(x))\,dx = (8 - y)\,dx \\ &= (8 - \sqrt{8x})\,dx \end{aligned}$$

Equation 42.18 is used to calculate the moment of inertia with respect to the y-axis.

$$I_y = \int x^2\,dA = \int_0^8 x^2\left(8 - \sqrt{8x}\right)\,dx$$

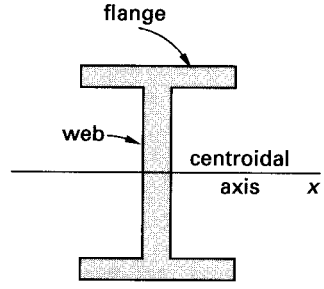
$$= \left[\left(\frac{8}{3}\right)x^3 - \left(\frac{4\sqrt{2}}{7}\right)x^{\frac{7}{2}}\right]_0^8 = 195.0 \text{ units}^4$$

6. PARALLEL AXIS THEOREM

If the moment of inertia is known with respect to one axis, and the moment of inertia with respect to another, the parallel axis can be calculated from the *parallel axis theorem*, also known as the *transfer axis theorem*. This theorem is used to evaluate the moment of inertia of areas that are composed of two or more basic shapes. In Eq. 42.20, d is the distance between the centroidal axis and the second, parallel axis.

$$I_{\text{parallel axis}} = I_c + Ad^2 \qquad 42.20$$

The second term in Eq. 42.20 is often much larger than the first term. Areas close to the centroidal axis do not affect the moment of inertia considerably. This principle is exploited by structural steel shapes that derive bending resistance from *flanges* located away from the centroidal axis. The *web* does not contribute significantly to the moment of inertia.



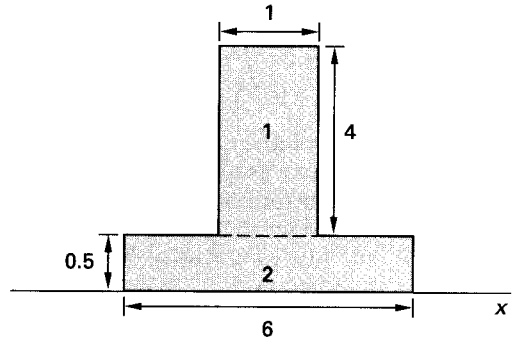


Figure 42.3 *Structural Steel W-Shape*

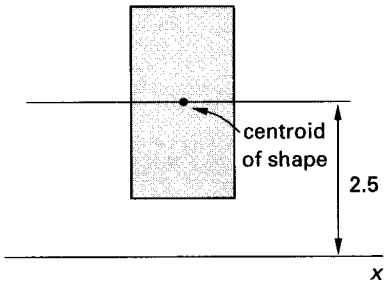
Example 42.5

Find the moment of inertia about the x-axis for the inverted-T area shown.

Solution

The area is divided into two basic shapes: 1 and 2. From App. 42.A, the moment of inertia of basic shape 2 with respect to the x-axis is



$$I_{x2} = \frac{bh^3}{3} = \frac{(6.0)(0.5)^3}{3} = 0.25 \text{ units}^4$$

The moment of inertia of basic shape 1 about its own centroid is

$$I_{cx1} = \frac{bh^3}{12} = \frac{(1)(4)^3}{12} = 5.33 \text{ units}^4$$

The x-axis is located 2.5 units from the centroid of basic shape 1. Therefore, from the parallel axis theorem, Eq. 42.20, the moment of inertia of basic shape 1 about the x-axis is

$$I_{x1} = 5.33 + (4)(2.5)^2 = 30.33 \text{ units}^4$$

The total moment of inertia of the T-area is

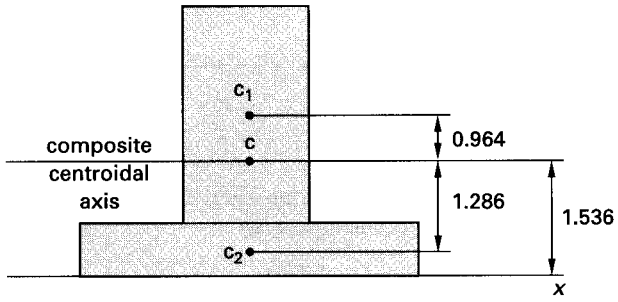
$$\begin{aligned} I_x &= I_{x1} + I_{x2} = 30.33 \text{ units}^4 + 0.25 \text{ units}^4 \\ &= 30.58 \text{ units}^4 \end{aligned}$$

Example 42.6

Find the moment of inertia about the horizontal centroidal axis for the inverted-T area shown in Ex. 42.5.

Solution

The first step is to find the location of the centroid. The areas and centroidal locations (with respect to the x-axis) of the two basic shapes are



$$\begin{aligned} A_1 &= (4.0)(1.0) = 4.0 \text{ units}^2 \\ A_2 &= (0.5)(6.0) = 3.0 \text{ units}^2 \\ y_{c1} &= 2.5 \text{ units} \\ y_{c2} &= 0.25 \text{ units} \end{aligned}$$

From Eq. 42.6, the composite centroid is located at

$$\begin{aligned} y_c &= \frac{A_1 y_{c1} + A_2 y_{c2}}{A_1 + A_2} = \frac{(4.0)(2.5) + (3.0)(0.25)}{4.0 + 3.0} \\ &= 1.536 \text{ units} \end{aligned}$$

The distances between the centroids of the basic shapes and the composite shape are

$$\begin{aligned} d_1 &= 2.5 - 1.536 = 0.964 \text{ units} \\ d_2 &= 1.536 - 0.25 = 1.286 \text{ units} \end{aligned}$$

The centroidal moments of inertia of the basic shapes with respect to an axis parallel to the x-axis are

$$\begin{aligned} I_{cx1} &= \frac{bh^3}{12} = \frac{(1)(4)^3}{12} = 5.33 \text{ units}^4 \\ I_{cx2} &= \frac{bh^3}{12} = \frac{(6)(0.5)^3}{12} = 0.0625 \text{ units}^4 \end{aligned}$$

Using Eq. 42.20, the centroidal moment of inertia of the inverted-T area is

$$\begin{aligned} I_{cx} &= I_{cx1} + I_{cx2} \\ &= I_{cx1} + A_1 d_1^2 + I_{cx2} + A_2 d_2^2 \\ &= 5.33 + (4.0)(0.964)^2 + 0.0625 + (3.0)(1.286)^2 \\ &= 14.07 \text{ units}^4 \end{aligned}$$

7. POLAR MOMENT OF INERTIA

The *polar moment of inertia*, J, is required in torsional shear stress calculations.[2] It can be thought of as a measure of an area's resistance to torsion (twisting). The definition of a polar moment of inertia of a two-dimensional area requires three dimensions because the reference axis for a polar moment of inertia of a plane area is perpendicular to the plane area.

The polar moment of inertia can be derived from Eq. 42.21.

$$J = \int (x^2 + y^2)\, dA \qquad 42.21$$

It is often easier to use the *perpendicular axis theorem* to quickly calculate the polar moment of inertia.

- *perpendicular axis theorem:* The moment of inertia of a plane area about an axis normal to the plane is equal to the sum of the moments of inertia about any two mutually perpendicular axes lying in the plane and passing through the given axis.

$$J = I_x + I_y \qquad 42.22$$

Since the two perpendicular axes can be chosen arbitrarily, it is most convenient to use the centroidal moments of inertia.

$$J = I_{cx} + I_{cy} \qquad 42.23$$

[2]The symbols I_z and I_{xy} are also encountered and are more consistent with the nomenclature. However, the symbol J is more common.

Structural

Example 42.7

What is the centroidal polar moment of inertia of a circular area of radius r?

Solution

From App. 42.A, the centroidal moment of inertia of a circle with respect to the x-axis is

$$I_{cx} = \frac{\pi r^4}{4}$$

Since the area is symmetrical, I_{cy} and I_{cx} are the same. From Eq. 42.23,

$$J_c = I_{cx} + I_{cy} = \frac{\pi r^4}{4} + \frac{\pi r^4}{4} = \frac{\pi r^4}{2}$$

8. RADIUS OF GYRATION

Every nontrivial area has a centroidal moment of inertia. Usually, some portions of the area are close to the centroidal axis and other portions are farther away. The *radius of gyration*, r, is an imaginary distance from the centroidal axis at which the entire area can be assumed to exist without affecting the moment of inertia. Despite the name "radius," the radius of gyration is not limited to circular shapes or polar axes. This concept is illustrated in Fig. 42.4.

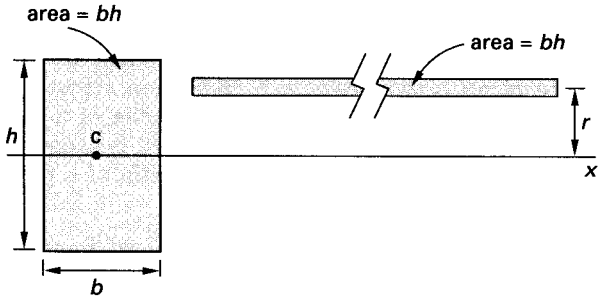


Figure 42.4 *Radius of Gyration*

The method of calculating the radius of gyration is based on the parallel axis theorem. If all of the area is located a distance r from the original centroidal axis, there will be no I_c term in Eq. 42.20. Only the Ad^2 term will contribute to the moment of inertia.

$$I = r^2 A \qquad 42.24$$

$$r = \sqrt{\frac{I}{A}} \qquad 42.25$$

The concept of *least radius of gyration* comes up frequently in column design problems. (The column will tend to buckle about an axis that produces the smallest radius of gyration.) Usually, finding the least radius of gyration for symmetrical sections means solving Eq. 42.25 twice: once with I_x to find r_x and once with I_y to find r_y. The smallest value of r is the least radius of gyration.

The analogous quantity in the polar system is

$$r = \sqrt{\frac{J}{A}} \qquad 42.26$$

Just as the polar moment of inertia, J, can be calculated from the two rectangular moments of inertia, the polar radius of gyration can be calculated from the two rectangular radii of gyration.

$$r^2 = r_x^2 + r_y^2 \qquad 42.27$$

Example 42.8

What is the radius of gyration of the rectangular shape in Ex. 42.3?

Solution

The area of the rectangle is

$$A = bh = (5)(8) = 40 \text{ units}^2$$

From Eq. 42.25, the radius of gyration is

$$r_x = \sqrt{\frac{I_x}{A}} = \sqrt{\frac{213.3}{40}} = 2.31 \text{ units}$$

2.31 units is the distance from the centroidal x-axis that an infinitely long strip with an area of 40 square units would have to be located in order to have a moment of inertia of 213.3 units^4.

9. PRODUCT OF INERTIA

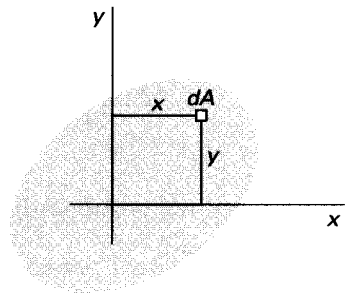
The *product of inertia*, P_{xy}, of a two-dimensional area is found by multiplying each differential element of area by its x- and y-coordinate and then summing over the entire area.

$$P_{xy} = \int xy \, dA \qquad 42.28$$

The product of inertia is zero when either axis is an axis of symmetry. Since the axes can be chosen arbitrarily, the area may be in one of the negative quadrants, and the product of inertia may be negative.

The parallel axis theorem for products of inertia is given by Eq. 42.29. (Both axes are allowed to move to new positions.) x'_c and y'_c are the coordinates of the centroid in the new coordinate system.

$$P_{x'y'} = P_{c,xy} + x'_c y'_c A \qquad 42.29$$



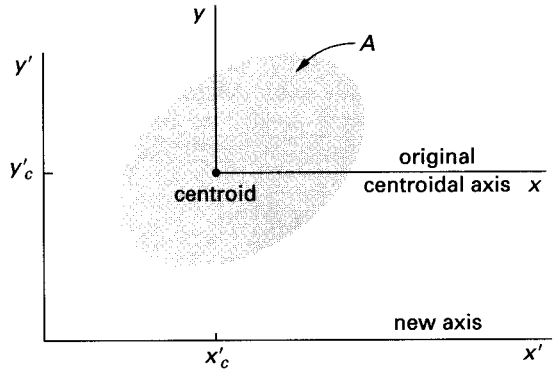


Figure 42.5 *Calculating the Product of Inertia*

$$P_{x'y'} = P_{c,xy} + x'_c x'_c A$$

Figure 42.6 *Parallel Axis Theorem for Products of Inertia*

10. SECTION MODULUS

In the analysis of beams, the outer compressive (or tensile) surface is known as the *extreme fiber*. The distance, c, from the centroidal axis of the beam cross section to the extreme fiber is the "distance to the extreme fiber." The *section modulus*, S, combines the centroidal moment of inertia and the distance to the extreme fiber. (In practice, the symbol Z is also occasionally encountered for section modulus.)

$$S = \frac{I_c}{c} \qquad 42.30$$

11. ROTATION OF AXES

Figure 42.7 shows rotation of the x-y axes through an angle, θ, into a new set of u-v axes, without rotating the area. If the moments and product of inertia of the area are known with respect to the old x-y axes, the new properties can be calculated from Eqs. 42.31 through 42.33.

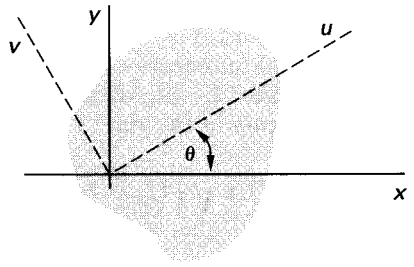
$$\begin{aligned} I_u &= I_x \cos^2\theta - 2P_{xy} \sin\theta \cos\theta + I_y \sin^2\theta \\ &= \tfrac{1}{2}(I_x + I_y) + \tfrac{1}{2}(I_x - I_y)\cos 2\theta \\ &\quad - P_{xy} \sin 2\theta \end{aligned} \qquad 42.31$$

$$\begin{aligned} I_v &= I_x \sin^2\theta + 2P_{xy} \sin\theta \cos\theta + I_y \cos^2\theta \\ &= \tfrac{1}{2}(I_x + I_y) - \tfrac{1}{2}(I_x - I_y)\cos 2\theta \\ &\quad + P_{xy} \sin 2\theta \end{aligned} \qquad 42.32$$

$$\begin{aligned} P_{uv} &= I_x \sin\theta \cos\theta + P_{xy}(\cos^2\theta - \sin^2\theta) \\ &\quad - I_y \sin\theta \cos\theta \\ &= \tfrac{1}{2}(I_x - I_y)\sin 2\theta + P_{xy} \cos 2\theta \end{aligned} \qquad 42.33$$

Since the polar moment of inertia about a fixed axis perpendicular to any two orthogonal axes in the plane is constant, the polar moment of inertia is unchanged by the rotation.

$$J_{xy} = I_x + I_y = I_u + I_v = J_{uv} \qquad 42.34$$



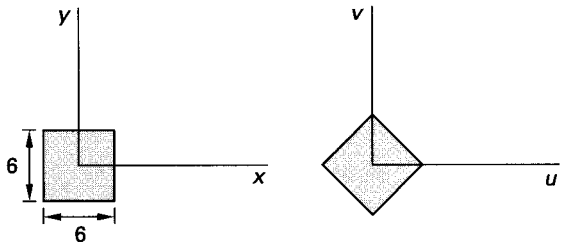


Figure 42.7 *Rotation of Axes*

Example 42.9

What is the centroidal area moment of inertia of a 6×6 square that is rotated 45° from its "flat" orientation?

Solution

The centroidal moments of inertia with respect to the x- and y-axes are

$$I_x = I_y = \frac{s^4}{12} = \frac{(6)^4}{12} = 108 \text{ units}^4$$

Since the centroidal x- and y-axes are axes of symmetry, the product of inertia is zero.

Use Eq. 42.31.

$$\begin{aligned} I_u &= I_x \cos^2\theta - 2P_{xy} \sin\theta \cos\theta + I_y \sin^2\theta \\ &= (108)\cos^2 45° - 0 + (108)\sin^2 45° \\ &= 108 \text{ units}^4 \end{aligned}$$

The centroidal moment of inertia of a square is the same regardless of rotation angle.

12. PRINCIPAL AXES

Referring to Fig. 42.7, there is one angle, θ, that will maximize the moment of inertia, I_u. This angle can be found from calculus by setting $dI_u/d\theta = 0$. The resulting equation defines two angles, one that maximizes I_u and one that minimizes I_u.

$$\tan 2\theta = \frac{-2P_{xy}}{I_x - I_y} \qquad 42.35$$

Structural

The two angles that satisfy Eq. 42.35 are 90° apart. The set of u-v axes defined by Eq. 42.35 are known as *principal axes*. The moments of inertia about the principal axes are defined by Eq. 42.36 and are known as the *principal moments of inertia.*

$$I_{\max,\min} = \tfrac{1}{2}(I_x + I_y) \pm \sqrt{\tfrac{1}{4}(I_x - I_y)^2 + P_{xy}^2} \qquad 42.36$$

13. MOHR'S CIRCLE

Once I_x, I_y, and P_{xy} are known, *Mohr's circle* can be drawn to graphically determine the moments of inertia about the principal axes. The procedure for drawing Mohr's circle is given as follows.

step 1: Determine I_x, I_y, and P_{xy} for the existing set of axes.

step 2: Draw a set of I-P_{xy} axes.

step 3: Plot the center of the circle, point **c**, by calculating distance c along the I-axis.

$$c = \tfrac{1}{2}(I_x + I_y) \qquad 42.37$$

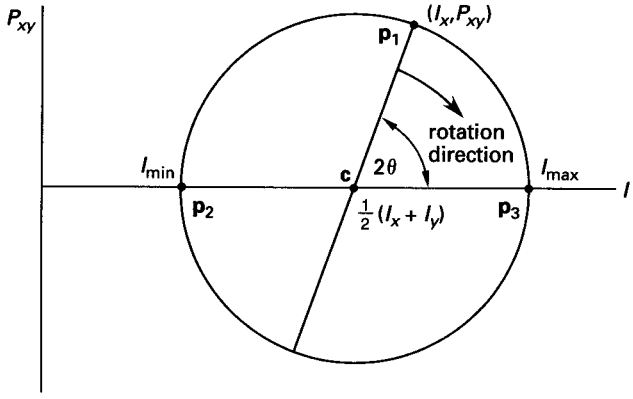

Figure 42.8 *Mohr's Circle*

step 4: Plot the point $\mathbf{p}_1 = (I_x, P_{xy})$.

step 5: Draw a line from point $\mathbf{p}_1$ through center **c** and extend it an equal distance below the I-axis. This is the diameter of the circle.

step 6: Using the center **c** and point $\mathbf{p}_1$, draw the circle. An alternate method of constructing the circle is to draw a circle of radius r.

$$r = \sqrt{\tfrac{1}{4}(I_x - I_y)^2 + P_{xy}^2} \qquad 42.38$$

step 7: Point $\mathbf{p}_2$ defines $I_{\min}$. Point $\mathbf{p}_3$ defines $I_{\max}$.

step 8: Determine the angle θ as half of the angle 2θ on the circle. This angle corresponds to $I_{\max}$. (The axis giving the minimum moment of inertia is perpendicular to the maximum axis.) The sense of this angle and the sense of the rotation are the same. That is, the direction that the diameter would have to be turned in order to coincide with the $I_{\max}$-axis has the same sense as the rotation of the x-y axes needed to form the principal u-v axes.

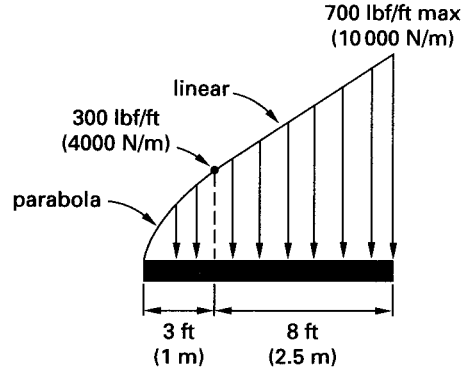
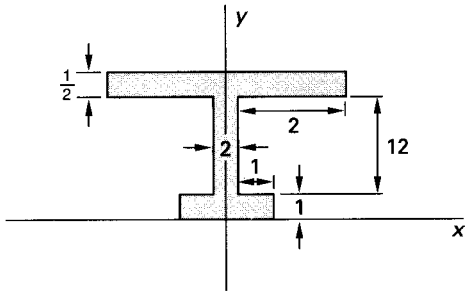
PRACTICE PROBLEMS



1. Locate the centroid of the area.

(A) 2.7
(B) 2.9
(C) 3.1
(D) 3.3



The answer is (D).

2. Replace the distributed load with three concentrated loads, and indicate the points of application.

Answer: 600 lbf at 1.8 ft (2670 N at 0.6 m); 1600 lbf at 2.67 ft (7500 N at 0.83 m); and 2400 lbf at 4 ft (10,000 N at 1.25 m)

3. Find the centroidal moment of inertia about an axis parallel to the x-axis.

(A) 160 units^4
(B) 290 units^4
(C) 570 units^4
(D) 740 units^4

The answer is (C).

1. TENSILE TEST

Many useful material properties are derived from the results of a standard *tensile test*. In this test, a prepared material sample (i.e., a *specimen*) is axially loaded in tension, and the resulting elongation, δ, is measured as the load, F, increases. A *load-elongation curve* of tensile test data for a ductile ferrous material (e.g., low-carbon steel or other BCC transition metal) is shown in Fig. 43.1.

When elongation is plotted against the applied load, the graph is applicable only to an object with the same length and area as the test specimen. To generalize the test results, the data are converted to stresses and strains by the use of Eqs. 43.1 and 43.2.[1]

[1]The most common *test specimen* in the United States has a length of 2.00 in and a diameter of 0.505 in. Since the cross-sectional area of this *0.505 bar* is 0.2 in^2, the stress in lbf/in^2 is calculated by multiplying the force in pounds by five.

Structural

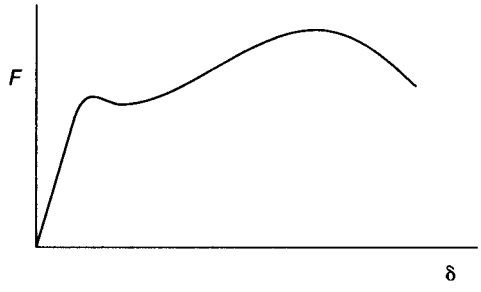

Figure 43.1 *Typical Tensile Test Results for a Ductile Material*

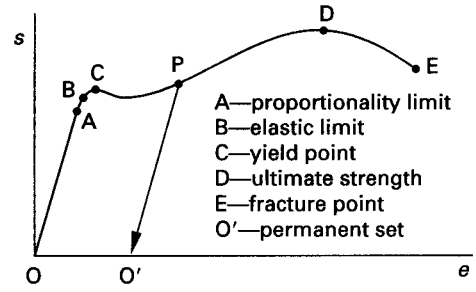

Figure 43.2 *Typical Stress-Strain Curve for Steel*

Engineering stress, s (usually called *stress*), is the load per unit original area. Typical engineering stress units are lbf/in^2 and MPa. *Engineering strain*, e (usually called *strain*), is the elongation of the test specimen expressed as a percentage or decimal fraction of the original length. The units in/in and m/m are also used for strain.

$$s = \frac{F}{A_o} \qquad 43.1$$

$$e = \frac{\delta}{L_o} \qquad 43.2$$

If the stress-strain data are plotted, the shape of the resulting line will be essentially the same as the force-elongation curve, although the scales will change.

Segment O-A in Fig. 43.2 is a straight line. The relationship between the stress and strain in this linear region is given by *Hooke's law*, Eq. 43.3. The slope of line segment O-A is the *modulus of elasticity*, E, also known as *Young's modulus*. Table 43.1 lists approximate values of the modulus of elasticity for materials at room temperature. The modulus of elasticity will be lower at higher temperatures.[2]

$$s = Ee \qquad 43.3$$

The stress at point A in Fig. 43.2 is known as the *proportionality limit* (i.e, the maximum stress for which the linear relationship is valid). Strain in the *proportional region* is called *proportional strain*.

The *elastic limit*, point B in Fig. 43.2, is slightly higher than the proportionality limit. As long as the stress is kept below the elastic limit, there will be no *permanent set* (permanent deformation) when the stress is removed. Strain that disappears when the stress is removed is known as *elastic strain*, and the stress is said to be in the *elastic region*. When the applied stress is removed, the *recovery* is 100%, and the material follows the original curve back to the origin.

If the applied stress exceeds the elastic limit, the recovery will be along a line parallel to the straight line portion of the curve, as shown in line segment P-O'. The strain that results (line O-O') is *permanent set* (i.e, a permanent deformation). The terms *plastic strain* and *inelastic strain* are used to distinguish this behavior from elastic strain.

For steel, the *yield point*, point C, is very close to the elastic limit. For all practical purposes, the *yield strength* or *yield stress*, S_y (or S_{yt} to indicate yield in tension), can be taken as the stress that accompanies the beginning of plastic strain. Yield strengths are reported in lbf/in^2, ksi, and MPa.[3]

Figure 43.2 does not show the full complexity of the stress-strain curve near the yield point. Rather than being smooth, the curve is ragged near the yield point. At the upper yield strength, there is a pronounced drop (i.e., "drop of beam") in load-carrying ability to a

Table 43.1 *Approximate Modulus of Elasticity of Representative Materials at Room Temperature*

material	lbf/in^2	GPa

[2]For steel at higher temperatures, the modulus of elasticity is reduced approximately as follows.

temperature °F	temperature °C	% of original value
70	20	100%
400	200	90%
800	425	75%
1000	540	65%
1200	650	60%

[3]A *kip* is a thousand pounds. *ksi* is the abbreviation for kips per square inch (thousands of lbf/in^2).

plateau yield strength after the initial yielding occurs. The plateau value is known as the *lower yield strength* and is commonly reported as the yield strength.

The *ultimate strength* or *tensile strength*, S_u (or S_{ut} to indicate an ultimate tensile strength), point D in Fig. 43.2, is the maximum stress the material can support without failure. However, since stresses near the ultimate strength are accompanied by large plastic strains, this property is not used for the design of ductile materials.

The *breaking strength* or *fracture strength*, S_f, is the stress at which the material actually fails (point E in Fig. 43.2). For ductile materials, the breaking strength is less than the ultimate strength due to the necking down in the cross-sectional area that accompanies high plastic strains.

2. STRESS-STRAIN CHARACTERISTICS OF NONFERROUS METALS

Most nonferrous materials, such as aluminum, magnesium, copper, and other FCC and HCP metals, do not have well-defined yield points. The stress-strain curve starts to bend at low stresses, as illustrated by Fig. 43.4. In such cases, the yield strength is commonly defined as the stress that will cause a 0.2% *parallel offset* (i.e., a plastic strain of 0.002).[4] However, the yield strength can also be defined by other offset values (e.g., 0.1% for metals and 1.0% for plastics).

The yield strength is found by extending a line from the offset strain value parallel to the linear portion of the curve until it intersects the curve.

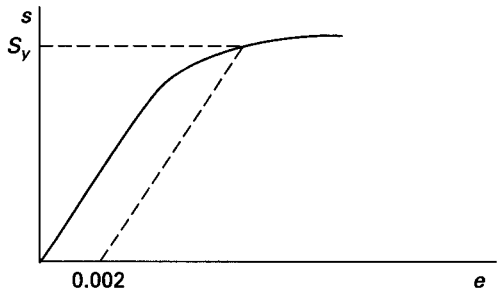

Figure 43.4 *Typical Stress-Strain Curve for a Nonferrous Metal*

With nonferrous metals, the difference between parallel offset and total strain characteristics is important. Sometimes, the yield point will be determined as the stress accompanying *0.5% total strain*.

3. STRESS-STRAIN CHARACTERISTICS OF BRITTLE MATERIALS

Brittle materials, such as glass, cast iron, and ceramics, can support only small stresses before they fail catastrophically (i.e., without warning). As the stress is increased, the elongation is linear and Hooke's law (Eq. 43.3) can be used to predict the strain. Failure occurs within the linear region, and there is very little, if any, necking down. Since the failure occurs at a low strain, brittle materials are not ductile. (The words "brittle" and "ductile" are antonyms.) Figure 43.5 is typical of the stress-strain curve of a brittle material.

[4]In Great Britain, the 0.2% offset strength is known as the *proof stress*.

Structural

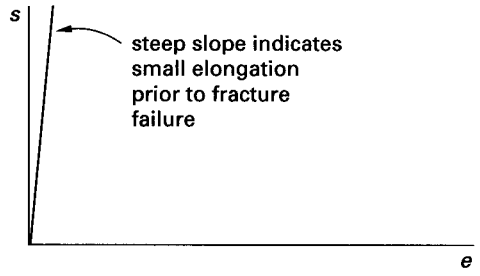

Figure 43.5 *Stress-Strain Curve of a Brittle Material*

4. SECANT MODULUS

The modulus of elasticity, E, is usually determined from the steepest portion of the stress-strain curve. (This avoids the difficulty of locating the starting part of the curve.) For materials operating in the nonlinear region, the *secant modulus* gives the average ratio of stress to strain. The secant modulus is the slope of the straight line connecting the origin and the point of operation. Some designs using elastomers or concrete may be based on the secant modulus.

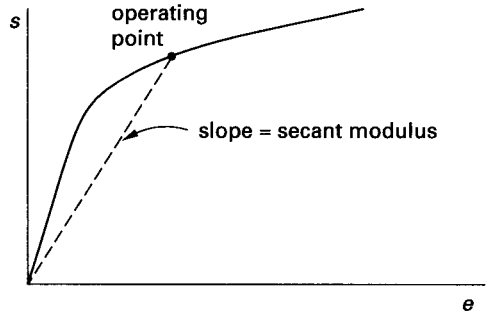

Figure 43.6 *Secant Modulus*

5. POISSON'S RATIO

As a specimen elongates axially during a tensile test, it will also decrease slightly in diameter or breadth. For any specific material, the percentage decrease in diameter, known as the *lateral strain*, will be a fraction of the *axial strain*. The ratio of the lateral strain to the axial strain is known as *Poisson's ratio*, ν, which is taken as approximately 0.3 for most metals.

$$\nu = \frac{e_{\text{lateral}}}{e_{\text{axial}}} = \frac{\dfrac{\Delta D}{D_o}}{\dfrac{\delta}{L_o}} \qquad 43.4$$

Poisson's ratio applies only to elastic strain. When the stress is removed, the lateral strain disappears along with the axial strain.

6. STRAIN HARDENING AND NECKING DOWN

When the applied stress exceeds the yield strength, the specimen will experience plastic deformation and will strain harden. (Plastic deformation is primarily due to the shear stress-induced movement of dislocations.) Since the specimen volume is constant (i.e., $A_oL_o = AL$), the cross-sectional area decreases. Initially, the strain hardening more than compensates for the decrease in area, so the material's strength increases and the engineering stress increases with larger strains.

Table 43.3 *Approximate Values of Poisson's Ratio*

material	Poisson's ratio
liquids	0.50[a]
rubber	0.49

[a]Limiting value.
[b]Commonly used for design.

Eventually, a point is reached when the available strain hardening and increase in strength cannot keep up with the decrease in cross-sectional area. The specimen then begins to neck down (at some local weak point), and all subsequent plastic deformation is concentrated at the neck. The cross-sectional area decreases even more rapidly thereafter since only a small portion of the specimen volume is strain hardening. The engineering stress decreases to failure.

Figure 43.7 shows necking down in two different specimens tested to failure. Very ductile materials pull out to a point, while most moderately ductile materials exhibit a *cup-and-cone failure*. (Failed brittle materials, not shown, do not exhibit any reduction in area.)

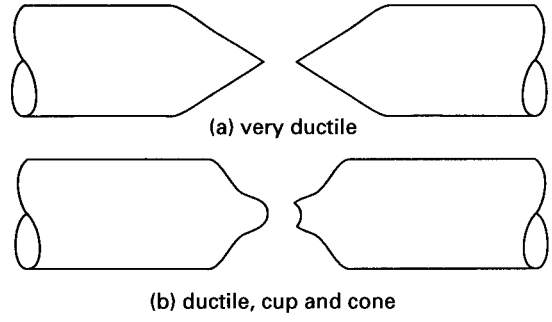

Figure 43.7 *Types of Tensile Ductile Failure*

7. TRUE STRESS AND STRAIN

Engineering stress, given by Eq. 43.1, is calculated for all stress levels from the original cross-sectional area. However, during a tensile test, the area of a specimen decreases as the stress increases. The decrease is only slight in the elastic region but is much more significant after plastic deformation begins.

If the stress is calculated from the instantaneous area, it is known as *true stress* or *physical stress*, σ. (Fractional reduction in area, RA, used in Eq. 43.5, is expressed as a number between 0 and 1.) Equation 43.5 assumes there is no change in total volume with strain.

$$\begin{aligned}\sigma &= \frac{F}{A} \\ &= \frac{F}{(1-\text{RA})\,A_o} \\ &= s(1+e) = \frac{s}{(1-\nu e)^2}\end{aligned} \qquad 43.5$$

Engineering strain, given by Eq. 43.2, is calculated from the original length, although the actual length increases during the tensile test. The *true strain* or *physical strain*, ϵ, is found from Eqs. 43.8 and 43.9.

$$\begin{aligned}\epsilon &= \int_{L_0}^{L} \frac{dL}{L} = \ln\left(\frac{L}{L_o}\right) \\ &= \ln(1+e) \quad \text{[prior to necking]}\end{aligned} \qquad 43.6$$

Since the plastic deformation occurs through a shearing process, there is essentially no volume decrease during elongation.

$$A_o L_o = AL \qquad 43.7$$

Therefore, true strain can be calculated from the cross-sectional areas and, for a circular specimen, from diameters. If necking down has occurred, true strain must be calculated from the areas or diameters, not the lengths.

$$\epsilon = \ln\left(\frac{A_o}{A}\right) = \ln\left(\frac{D_o}{D}\right)^2 = 2\ln\left(\frac{D_o}{D}\right) \qquad 43.8$$

Figure 43.8 compares engineering and true stresses and strains for a ferrous alloy. A graph of true stress and true strain is known as a *flow curve*. Log σ can also be plotted against log ϵ, resulting in a straight-line relationship.

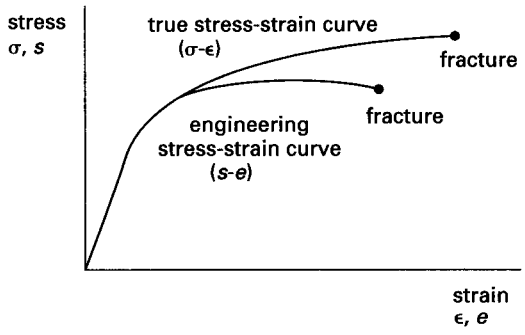

Figure 43.8 *True and Engineering Stresses and Strains for a Ferrous Alloy*

The flow curve of many metals in the plastic region can be expressed by the relationship of Eq. 43.9. K is known as the *strength coefficient*, and n is the *strain-hardening exponent*. Values of both vary greatly with material, composition, and heat treatment. n can vary from 0 (for a perfectly inelastic solid) to 1.0 (for an elastic solid). Typical values are between 0.1 and 0.5.

$$\sigma = K\epsilon^n \qquad 43.9$$

Although true stress and strain are more accurate, almost all engineering work is based on engineering stress and strain, which is justifiable for two reasons: (a) design using ductile materials is limited to the elastic region where engineering and true values differ little, and (b) the reduction in area of most parts at their service stresses is not known; only the original area is known.

Example 43.1

The engineering stress in a solid tension member was 47,000 lbf/in^2 at failure. The reduction in area was 80%. What were the true stress and strain at failure?

Solution

Since engineering stress, s, is F/A_o, from Eq. 43.5 the true stress is

$$\begin{aligned}\sigma &= \frac{s}{1-\text{reduction in area}} \\ &= \frac{47{,}000\ \frac{\text{lbf}}{\text{in}^2}}{1-0.80} = 235{,}000\ \text{lbf/in}^2\end{aligned}$$

From Eq. 43.8, the true strain is

$$\epsilon = \ln\left(\frac{1}{1-0.80}\right) = 1.61 \quad (161\%)$$

8. DUCTILITY

A material that deforms and elongates a great deal before failure is said to be a *ductile material*. (Steel, for example, is a ductile material.) The *percent elongation*, short for *percent elongation at failure*, is the total plastic strain at failure. (Percent elongation does not include the elastic strain, because even at ultimate failure the material snaps back an amount equal to the elastic strain.)

$$\begin{aligned}\text{percent elongation} &= \frac{L_f - L_o}{L_o} \times 100\% \\ &= e_f \times 100\%\end{aligned} \qquad 43.10$$

The value of the final strain to be used in Eq. 43.10 is found by extending a line from the failure point downward to the strain axis, parallel to the linear portion of

the curve. This is equivalent to putting the two broken specimen pieces together and measuring the total length.

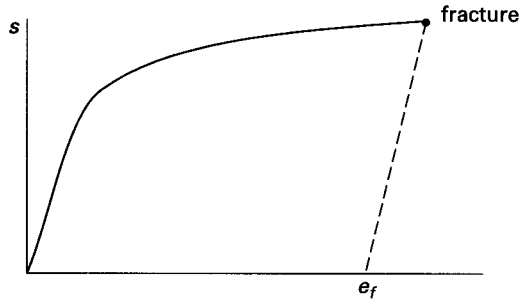

Figure 43.9 *Percent Elongation*

Highly ductile materials exhibit large percent elongations. However, percent elongation is not the same as *ductility*.

$$\text{ductility} = \frac{\text{ultimate failure strain}}{\text{yielding strain}} \qquad 43.11$$

The *reduction in area* (at the point of failure), expressed as a percentage or decimal fraction, is a third measure of a material's ductility. The reduction in area due to necking down will be 50% or greater for ductile materials and less than 10% for brittle materials.[5]

$$\text{reduction in area} = \frac{A_o - A_f}{A_o} \times 100\% \qquad 43.12$$

9. STRAIN ENERGY

Strain energy, also known as *internal work*, is the energy per unit volume stored in a deformed material. The strain energy is equivalent to the work done by the applied tensile force. Simple work is calculated as the product of a force moving through a distance.

$$\text{work} = \text{force} \times \text{distance} = \int F\,dL \qquad 43.13$$

$$\text{work per unit volume} = \int \frac{F\,dL}{AL} = \int_0^{\epsilon_{\text{final}}} \sigma\,d\epsilon \qquad 43.14$$

This work per unit volume corresponds to the area under the true stress-strain curve. Units are in-lbf/in^3 (i.e., inch-pounds (a unit of energy) per cubic inch (a unit of volume)), usually shortened to lbf/in^2 (MPa). (Equation 43.14 cannot be simplified further because stress is not proportional to strain for the entire curve.)

[5] *Notch-brittle materials* have reductions in area that are moderate (e.g., 25 to 35%) when tested in the usual manner but close to zero when the test specimen is given a small notch or crack.

10. RESILIENCE

A *resilient material* is able to absorb and release *strain energy* without permanent deformation. *Resilience* is measured by the *modulus of resilience*, also known as the *elastic toughness*, which is the strain energy per unit volume required to reach the yield point. This is represented by the area under the stress-strain curve up to the yield point. Since the stress-strain curve is essentially a straight line up to that point, the area is triangular.

$$U_R = \int_0^{\epsilon_y} \sigma\,d\epsilon = E\int_0^{\epsilon_y} \epsilon\,d\epsilon = \frac{E\epsilon_y^2}{2} = \frac{S_y\epsilon_y}{2} \qquad 43.15$$

The modulus of resilience varies greatly for steel. It can be more than ten times higher for high-carbon spring steel ($U_R = 320$ lbf/in^2, 2.2 MPa) than for low-carbon steel ($U_R = 20$ lbf/in^2, 0.14 MPa).

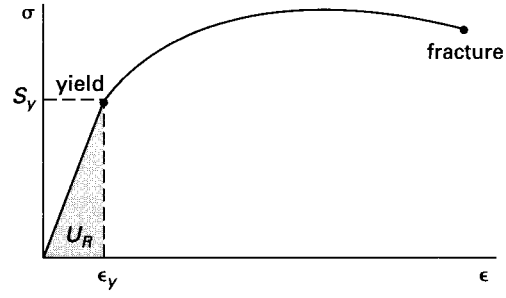

Figure 43.10 *Modulus of Resilience*

11. TOUGHNESS

A *tough material* will be able to withstand occasional high stresses without fracturing. Products subjected to sudden loading, such as chains, crane hooks, railroad couplings, and so on, should be tough. One measure of a material's *toughness* is the *modulus of toughness* (i.e, the strain energy or work per unit volume required to cause fracture). This is the total area under the stress-strain curve, and is given the symbol U_T. Since the area is irregular the modulus of toughness cannot be exactly calculated by a simple formula. However, the modulus of toughness of ductile materials (with large strains at failure) can be approximately calculated from either Eq. 43.16 or Eq. 43.17.

$$U_T \approx S_u\epsilon_f \quad \text{[ductile]} \qquad 43.16$$

$$U_T \approx \left(\frac{S_y + S_u}{2}\right)\epsilon_f \quad \text{[ductile]} \qquad 43.17$$

For brittle materials, the stress-strain curve may be either linear or parabolic. If the curve is parabolic, Eq. 43.18 approximates the modulus of toughness.

$$U_T \approx \tfrac{2}{3}S_u\epsilon_f \quad \text{[brittle]} \qquad 43.18$$

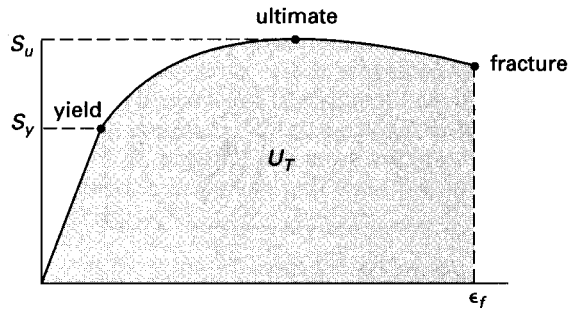

Figure 43.11 *Modulus of Toughness*

12. UNLOADING AND RELOADING

If the load is removed after a specimen is stressed elastically, the material will return to its original state. If the load is removed after a specimen is stressed into the plastic region, the *unloading curve* will follow a sloped path back to zero stress. The slope of the unloading curve will be equal to the original modulus of elasticity, E, illustrated by Fig. 43.12.

If this same material is subsequently reloaded, the *reloading curve* will follow the previous unloading curve up to the continuation of the original stress-strain curve. Therefore, the *apparent yield stress* of the reloaded specimen will be higher. This extra strength is the result of the strain hardening that has occurred.[6] Although the material will have a higher strength, its ductility will have been reduced.

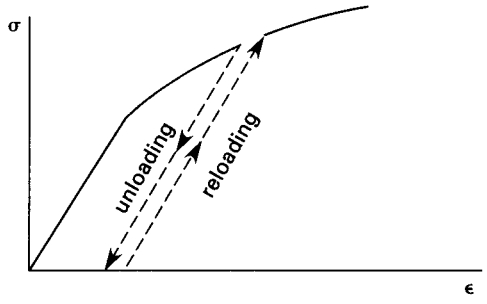

Figure 43.12 *Unloading and Reloading Curves*

13. COMPRESSIVE STRENGTH

Compressive strength, S_{yc} (i.e, ultimate strength in compression), is an important property for brittle materials such as concrete and cast iron that are primarily loaded in compression only.[7] The compressive strengths of these materials are much greater than their tensile strengths, whereas the compressive strengths for ductile materials, such as steel, are the same as their tensile yield strengths.

Within the linear (elastic) region, Hooke's law is valid for compression of both brittle and ductile materials.

The failure mechanism for ductile materials is plastic deformation alone. Such materials do not rupture in compression. Thus, a ductile material can support a load long after the material is distorted beyond a useful shape.

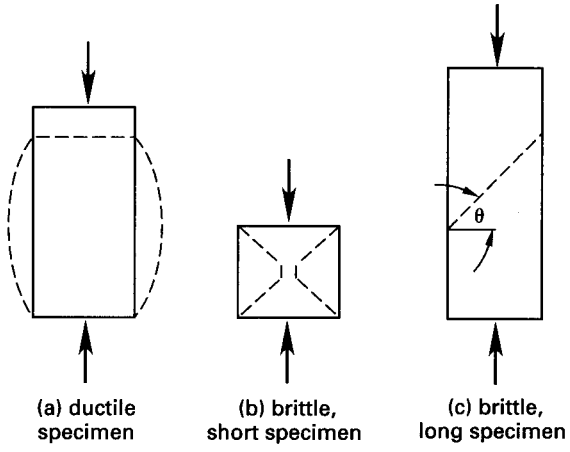

Figure 43.13 *Compressive Failures*

The failure mechanism for brittle materials is shear along an inclined plane. The characteristic plane and hourglass failures for brittle materials are shown in Fig. 43.13.[8] Theoretically, only *cohesion* contributes to compressive strength, and the *angle of rupture* (i.e., the incline angle), θ, should be 45°. In real materials, however, internal friction also contributes strength. The angles of rupture for cast iron, concrete, brick, and so on vary roughly between 50° and 60°. If the *angle of internal friction*, ϕ, is known for the material, the angle of rupture can be calculated exactly from *Mohr's theory of rupture*.

$$\theta = 45^\circ + \frac{\phi}{2} \qquad 43.19$$

14. TORSION TEST

Figure 43.14 illustrates a simple cube loaded by a shear stress, τ. The volume of the cube does not decrease when loaded, but the shape changes. The *shear strain* is the angle, θ, expressed in radians. The shear strain is proportional to the shear stress, analogous to Hooke's law for tensile loading. G is the *shear modulus*, also known as the *modulus of shear*, *modulus of elasticity in shear*, and *modulus of rigidity*.

$$\tau = G\theta \qquad 43.20$$

[6]The additional strength is lost if the material is subsequently annealed.

[7]f'_c is commonly used as the symbol for the compressive strength of concrete.

[8]The *hourglass failure* appears when the material is too short for a complete failure surface to develop.

Structural

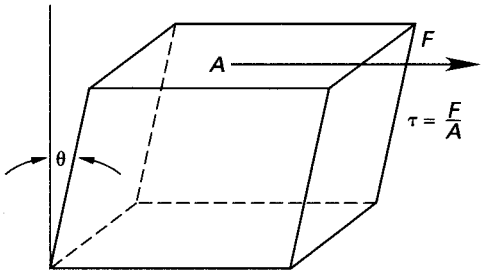

Figure 43.14 *Cube Loaded in Shear*

Table 43.4 *Approximate Values of Shear Modulus*

material	lbf/in^2	GPa
aluminum	3.8×10^6	26
brass	5.5×10^6	38
copper	6.2×10^6	43
cast iron	8.0×10^6	55
magnesium	2.4×10^6	17
steel	11.5×10^6	79
stainless steel	10.6×10^6	73
titanium	6.0×10^6	41
glass	4.2×10^6	29

(Multiply lbf/in^2 by 6.89×10^{-6} to obtain GPa.)

The shear modulus can be calculated from the modulus of elasticity and Poisson's ratio and, therefore, can be derived from the results of a tensile test.

$$G = \frac{E}{2(1+\nu)} \qquad 43.21$$

The shear stress can also be calculated from a torsion test, as illustrated by Fig. 43.15. Equation 43.22 relates the angle of twist (in radians) to the shear modulus.

$$\gamma = \frac{TL}{JG} = \frac{\tau L}{rG} \quad \text{[radians]} \qquad 43.22$$

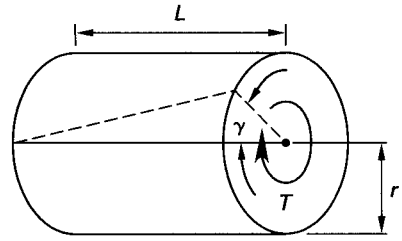

Figure 43.15 *Uniform Bar in Torsion*

The *shear strength*, S_s or S_{ys}, of a material is the maximum shear stress that the material can support without yielding in shear. (The ultimate shear strength property is rarely encountered.) For ductile materials, *maximum shear stress theory* predicts the shear strength as one-half of the tensile yield strength. A more accurate relationship is derived from the *distortion energy theory* (also known as *von Mises theory*).

$$S_{ys} = \frac{S_{yt}}{\sqrt{3}} = 0.577S_{yt} \qquad 43.23$$

15. RELATIONSHIP BETWEEN THE ELASTIC CONSTANTS

The elastic constants (modulus of elasticity, shear modulus, bulk modulus, and Poisson's ratio) are related in elastic materials. Table 43.5 lists the common relationships.

16. FATIGUE TESTING

A material can fail after repeated stress loadings even if the stress level never exceeds the ultimate strength, a condition known as *fatigue failure*.

Table 43.5 *Relationships Between Elastic Constants*

	in terms of				
elastic constants	E, ν	E, G	B, ν	B, G	E, B
E	–	–	$3(1-2\nu)B$	$\frac{9BG}{3B+G}$	–
ν	–	$\frac{E}{2G} - 1$	–	$\frac{3B-2G}{2(3B+G)}$	$\frac{3B-E}{6B}$
G	$\frac{E}{2(1+\nu)}$	–	$\frac{3(1-2\nu)B}{2(1+\nu)}$	–	$\frac{3EB}{9B-E}$
B	$\frac{E}{3(1-2\nu)}$	$\frac{GE}{3(3G-E)}$	–	–	–

The behavior of a material under repeated loadings is evaluated by a fatigue test. A specimen is loaded repeatedly to a specific stress amplitude, s, and the number of applications of that stress required to cause failure, N, is counted. Rotating beam tests that load the specimen in bending are more common than alternating deflection and push-pull tests but are limited to round specimens.[9]

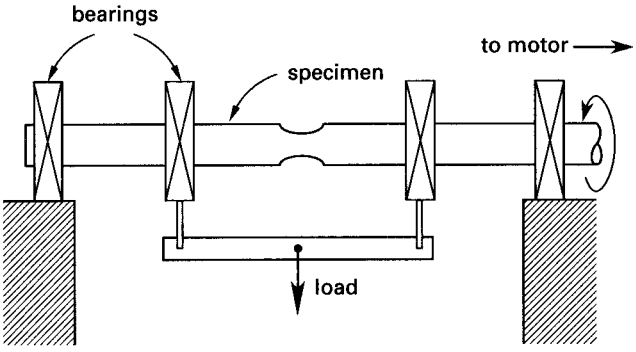

Figure 43.16 *Rotating Beam Test*

This procedure is repeated for different stresses, using eight to fifteen specimens. The results of these tests are graphed, resulting in an *S-N curve* (i.e., stress-number of cycles) shown in Fig. 43.17.

For an alternating stress test, the stress plotted on the S-N curve can be the maximum, minimum, or mean value. The choice depends on the method of testing as well as the intended application. The maximum stress should be used in rotating beam tests, since the mean stress is zero. For cyclic, one-dimensional bending, the maximum and mean stresses are commonly used.

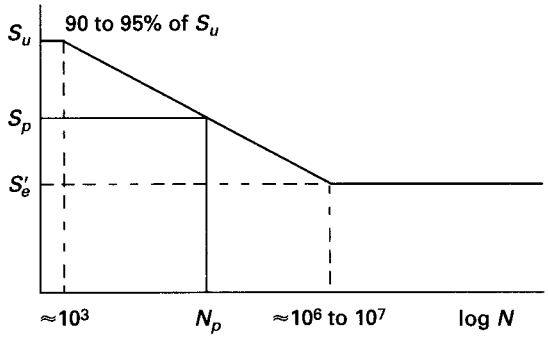

Figure 43.17 *Typical S-N Curve for Steel*

For a specific stress level, say S_p in Fig. 43.17, the number of cycles required to cause failure, N_p, is the *fatigue life*. S_p is the *fatigue strength* corresponding to N_p.

[9]In the design of ductile steel buildings, the static case is assumed up to 20,000 cycles. However, in critical applications (such as nuclear steam vessels, turbines, and so on) that experience temperature swings, fatigue failure can occur with a smaller number of cycles due to *cyclic strain*, not due to *cyclic stress*.

For steel subjected to fewer than approximately 10^3 loadings, the fatigue strength starts at the ultimate strength and drops to 90 to 95% of the ultimate strength at 10^3 cycles. (Although *low-cycle fatigue* theory has its own peculiarities, a part experiencing a small number of cycles can usually be designed or analyzed for static loading.) The curve is linear between 10^3 and 10^6 cycles if a logarithmic N-scale is used. Beyond 10^6 to 10^7 cycles, there is no further decrease in strength.

Therefore, below a certain stress level, called the *endurance limit* or *endurance strength*, S'_e, the material will withstand an almost infinite number of loadings without experiencing failure.[10] This is characteristic of steel and titanium. Therefore, if a dynamically loaded part is to have an infinite life, the stress must be kept below the endurance limit. The ratio S'_e/S_u is known as the *endurance ratio* or *fatigue ratio*. For carbon steel, the endurance ratio is approximately 0.4 for pearlitic, 0.60 for ferritic, and 0.25 for martensitic microstructures. For martensitic alloy steels, it is approximately 0.35.

For steel whose microstructure is unknown, the endurance strength is given approximately by Eq. 43.24.[11]

$$S'_{e,\text{steel}} \begin{cases} = 0.5S_u & [S_u < 200{,}000\,\text{lbf/in}^2] \\ & [S_u < 1.4\,\text{GPa}] \\ = 100{,}000\,\text{lbf/in}^2 & [S_u > 200{,}000\,\text{lbf/in}^2] \\ \quad (700\,\text{MPa}) & [S_u > 1.4\,\text{GPa}] \end{cases} \qquad 43.24$$

For cast iron, the endurance ratio is lower.

$$S'_{e,\text{cast iron}} = 0.4S_u \qquad 43.25$$

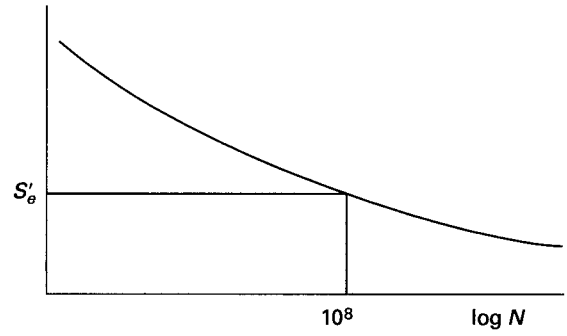
Steel and titanium are the most important engineering materials that have well-defined endurance limits. Many nonferrous metals and alloys, such as aluminum, magnesium, and copper alloys, do not have well-defined endurance limits. The strength continues to decrease with cyclic loading and never levels off. In such cases, the endurance limit is taken as the stress that causes failure at 10^8 or 5×10^8 loadings. Alternatively, the endurance strength is approximated by Eq. 43.26.

$$S'_{e,\text{aluminum}} = \begin{cases} 0.3S_u & [\text{cast}] \\ 0.4S_u & [\text{wrought}] \end{cases} \qquad 43.26$$

[10]Most endurance tests use some form of sinusoidal loading. However, the fatigue and endurance strengths do not depend much on the shape of the loading curve. Only the maximum amplitude of the stress is relevant. Therefore, the endurance limit can be used with other types of loading (sawtooth, square wave, random, etc.).

[11]The coefficient in Eq. 43.24 actually varies between 0.25 and 0.6. However, 0.5 is commonly quoted.

Structural



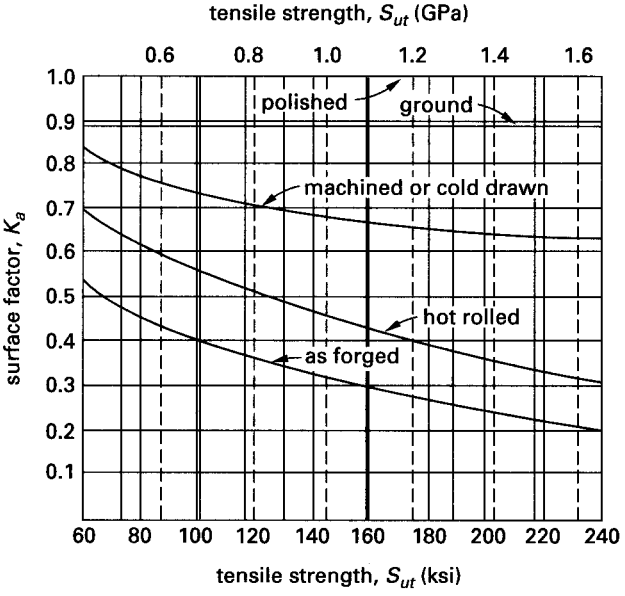


Figure 43.18 *Typical S-N Curve for Aluminum*

Reprinted with permission from *Mechanical Engineering Design*, 3rd ed., by Joseph Edward Shigley, copyright © 1977, The McGraw-Hill Companies.

Figure 43.19 *Surface Finish Reduction Factors for Endurance Strength*

The yield strength is an irrelevant factor in cyclic loading. Fatigue failures are fracture failures; they are not yielding failures. They start with microscopic cracks at the material surface. Some of the cracks are present initially; others form when repeated cold working reduces the ductility in strain-hardened areas. These cracks grow minutely with each loading. Since cracks start at the location of surface defects, the endurance limit is increased by proper treatment of the surface. Such treatments include polishing, surface hardening, shot peening, and filleting joints.

The endurance limit is not a true property of the material since the other significant influences, particularly surface finish, are never eliminated. However, representative values of S'_e obtained from ground and polished specimens provide a baseline to which other factors can be applied to account for the effects of surface finish, temperature, stress concentration, notch sensitivity, size, environment, and desired reliability. These other influences are accounted for by fatigue reduction factors, K_f, which are used to calculate a working endurance strength, S_e, for the material.

$$S_e = K_f S'_e \qquad 43.27$$

Since a rough surface significantly decreases the endurance strength of a specimen, it is not surprising that notches (and other features that produce stress concentration) do so as well. In some cases, the theoretical tensile *stress concentration factor*, K_t, due to notches and other features can be determined theoretically or experimentally. The ratio of the fatigue strength of a polished specimen to the fatigue strength of a notched specimen at the same number of cycles is known as the *fatigue notch factor*, K_f, also known as the *fatigue stress concentration factor*. The *fatigue notch sensitivity*, q, is a measure of the degree of agreement between the stress concentration factor and the fatigue notch factor.

$$q = \frac{K_f - 1}{K_t - 1} \qquad 43.28$$

17. TESTING OF PLASTICS

With reasonable variations, mechanical properties of plastics are evaluated using the same methods as for metals.[12] Although temperature is an important factor in the testing of plastics, tests for tensile strength, endurance, hardness, toughness, and creep rate are similar or the same as for metals. Figure 43.20 illustrates typical tensile test results.[13]

Unlike metals, which follow Hooke's law, plastics are non-Hookean. (They may be Hookean for a short-duration loading.) The modulus of elasticity, for example, changes with stress level, temperature, time, and chemical environment. A plastic that appears to be satisfactory under one set of conditions can fail quickly under slightly different conditions. Therefore, properties of plastics determined from testing (and from tables) should be used only to compare similar materials, not to predict long-term behavior. Plastic tests are used to determine material specifications, not performance specifications.

[12]For example, plastic specimens for tensile testing can be produced by injection molding as well as by machining from compression-molded plaques, rather than machining from bar stock.

[13]Plastics are sensitive to the rate of loading. Figure 43.20 illustrates tensile performance based on a 2 in/min loading rate. However, for a fast loading rate (e.g., 2 in/sec), most plastics would exhibit brittle performance. On the other hand, given a slow loading rate (e.g., 2 in/month), most would behave as a soft and flexible plastic. Therefore, with different rates of loading, all three types of stress-strain performance shown in Fig. 43.20 can be obtained from the same plastic.

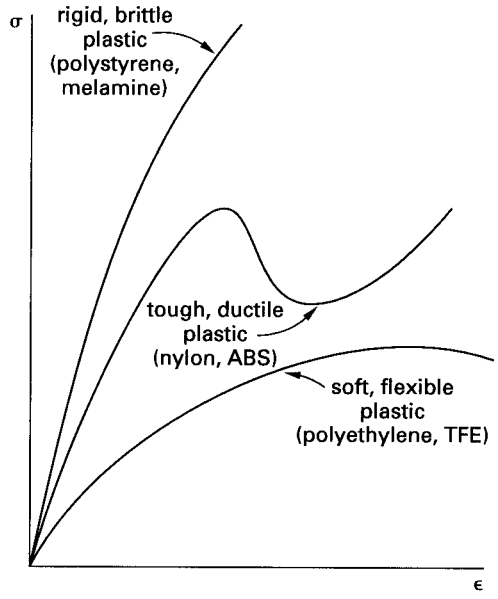

Figure 43.20 *Typical Tensile Test Performance for Plastics (loaded at 2 in/min)*

On a short-term basis, plastics behave elastically. They distort when loaded and spring back when unloaded. Under prolonged loading, however, creep (cold flow) becomes significant. When loading is removed, there is some instantaneous recovery, some delayed recovery, and some permanent deformation. The recovery might be complete if the load is removed within 10 hours, but if the loading is longer (e.g., 100 hours), recovery may be only partial. Because of this behavior, plastics are subjected to various other tests.

Additional tests used to determine the mechanical properties of plastics include deflection temperature, long-term (e.g., 3000 hours) tensile creep, creep rupture, and *stress-relaxation* (long-duration, constant-strain tensile testing at elevated temperatures).[14] Because some plastics deteriorate when exposed to light, plasma, or chemicals, performance under these conditions can be evaluated, as can be the insulating and dielectric properties.

The *creep modulus* (also known as *apparent modulus*), determined from tensile creep testing, is the instantaneous ratio of stress to creep strain. The creep modulus decreases with time. The *deflection temperature* test indicates the dimensional stability of a plastic at high temperatures. A plastic bar is loaded laterally (as a beam) to a known stress level, and the temperature of the bar is gradually increased. The temperature at which the deflection reaches 0.010 in (0.254 mm) is taken as the *thermal deflection temperature* (TDT). The *Vicat softening point*, primarily used with polyethylenes, is the temperature at which a loaded standard needle penetrates 1 mm when the temperature is uniformly increased at a standard rate.

[14]Plastic pipes have their own special tests (ASTM D1598).

18. NONDESTRUCTIVE TESTING

Nondestructive testing (NDT) or *nondestructive evaluation* (NDE) is used when it is impractical or uneconomical to perform destructive sampling on manufactured products and their parts. Typical applications of NDT are inspection of helicopter blades, cast aluminum wheels, and welds in nuclear pressure vessels. Some procedures are particularly useful in providing quality monitoring on a continuous, real-time basis. In addition to visual processes, the main types of nondestructive testing are magnetic particle, eddy current, liquid penetrant, ultrasonic imaging, acoustic emission, and infrared testing, as well as radiography.

The *visual-optical* process differs from normal visual inspection in the use of optical scanning systems, borescopes, magnifiers, and holographic equipment. Flaws are identified as changes in light intensity (reflected, transmitted, or refracted), color changes, polarization changes, or phase changes. This method is limited to the identification of surface flaws or interior flaws in transparent materials.

Magnetic particle testing takes advantage of the attraction of ferromagnetic powders (e.g., the *Magnaflux™ process*) and fluorescent particles (e.g., the *Magnaglow™ process*) to leakage flux at surface flaws in magnetic materials. The particles accumulate and become visible at such flaws when an intense magnetic field is set up in a workpiece.

This method can locate most surface flaws (such as cracks, laps, and seams) and, in some special cases, subsurface flaws. The procedure is fast and simple to interpret. However, workpieces must be ferromagnetic and clean. Following the test, demagnetization may be required. A high-current power source is required.

Eddy current testing uses alternating current from a test coil to induce eddy currents in electrically conducting, metallic objects. Flaws and other material properties affect the current flow. The change in current is monitored by a detection circuit or on a meter or screen. This method can be used to locate defects of many types, including cracks, voids, inclusions, and weld defects, as well as to find changes in composition, structure, hardness, and porosity.

Intimate contact between the material and the test coil is not required. Operation can be continuous, automatic, and monitored electronically. Sensitivity is easily adjusted. Therefore, this method is ideal for unattended continuous processing. Many variables, however, can affect the current flow, and only electrically conducting materials can be tested with this method.

With *infrared testing*, infrared radiation emitted from objects can be detected and correlated with quality. Any discontinuities that interrupt heat flow, such as flaws, voids, and inclusions, can be detected.

Infrared testing requires access to only one side and is highly sensitive. It is applicable to complex shapes and

assemblies of dissimilar components but is relatively slow. The detection can be performed electronically. Results are affected by variations in material size, coatings, and colors, and hot spots can be hidden by cool surface layers.

Liquid penetrant testing is based on a fluorescent dye being drawn by capillary action into surface defects. A developer substance is commonly used to aid in visual inspection. This method can be used with any nonporous material, including metals, plastics, and glazed ceramics. It is capable of finding cracks, porosities, pits, seams, and laps.

Liquid penetrant tests are simple, can be used with complex shapes, and can be performed on site. Workpieces must be clean and nonporous. However, only small surface defects are detectable.

In *ultrasound imaging testing (ultrasonics)*, mechanical vibrations in the 0.1 to 25 MHz range are induced by pressing a piezoelectric transducer against a workpiece. The transmitted waves are normally reflected back, but the waves are scattered by interior defects. The results are interpreted by reading a screen or meter. The method can be used for metals, plastics, glass, rubber, graphite, and concrete. It is excellent for detecting internal defects such as inclusions, cracks, porosities, laminations, and changes in material structure.

Ultrasound testing is extremely flexible. It can be automated and is very fast. Results can be recorded or interpreted electronically. Penetration through thick steel layers is possible. Direct contact (or immersion in a fluid) is required, but only one surface needs to be accessible. Rough surfaces and complex shapes may cause difficulties, however. A related method, *acoustic emission monitoring*, is used to test pressurized systems.

There are two types of *holographic NDT methods*. *Acoustic holography* is a form of ultrasonic testing that passes an ultrasonic beam through the workpiece (or through a medium such as water surrounding the workpiece) and measures the displacement of the workpiece (or medium). With suitable processing, a three-dimensional hologram is formed that can be visually inspected.

In one form of *optical holography*, a hologram of the unloaded workpiece is imposed on the actual workpiece. If the workpiece is then loaded (stressed), the observed changes (e.g., deflections) from the holographic image will be non-uniform when discontinuities and defects are present.

Radiography (i.e., *nuclear sensing*) uses neutron, X-ray, gamma-ray (e.g., Ce-137), and isotope (e.g., Co-60) sources. (When neutrons are used, the method is known as *neutron radiography* or *neutron gaging*.) The intensity of emitted radiation is changed when the rays pass through defects, and the intensity changes are monitored on a fluoroscope or recorded on film. This method can be used to detect internal defects, changes in material structure, thickness, and the absence of internal workpieces. It is also used to check liquid levels in filled containers.

Up to 30 in (0.75 m) of steel can be penetrated by X-ray sources. Gamma sources, which are more portable and lower in cost than X-ray sources, can be used with steel up to 10 in (0.25 m).

Radiography requires access to both sides of the workpiece. Radiography involves some health risk, and there may be government standards associated with its use. Electrical power and cooling water may be required in large installations. Shielding and film processing are also required, making this the most expensive form of nondestructive testing.

19. HARDNESS TESTING

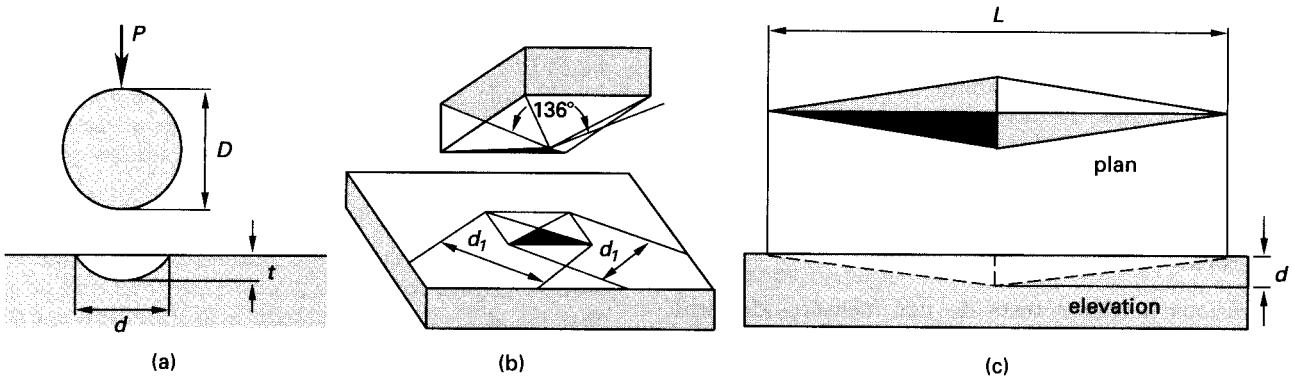
Hardness tests measure the capacity of a surface to resist deformation. The main use of hardness testing is to verify heat treatments, an important factor in product service life. Through empirical correlations, it is also possible to predict the ultimate strength and toughness of some materials.

The *Brinell hardness test* is used primarily with iron and steel castings. The *Brinell hardness number*, BHN, is determined by pressing a hardened steel ball into the surface of a specimen. The diameter of the resulting depression is correlated to the hardness. The standard ball is 10 mm in diameter and loads are 500 kg and 3000 kg for soft and hard materials, respectively.

The Brinell hardness number is the load per unit contact area. If a load, P (in kilograms), is applied through a steel ball of diameter D (in millimeters) and produces a depression of diameter d (in millimeters) and depth t (in millimeters), the Brinell hardness number is calculated from Eq. 43.29.

$$\begin{aligned}\text{BHN} &= \frac{P}{A_{\text{contact}}} = \frac{P}{\pi D t} \\ &= \frac{2P}{\pi D\left(D - \sqrt{D^2 - d^2}\right)}\end{aligned} \qquad 43.29$$

For heat-treated plain-carbon and medium-alloy steels, the ultimate tensile strength in lbf/in^2 can be approximately calculated from the steel's Brinell hardness number.



$$S_u \approx 500(\text{BHN}) \qquad 43.30$$

The *Rockwell hardness test* is similar to the Brinell test. A steel ball or diamond spheroconical penetrator (known as a *brale indentor*) is pressed into the material. The machine applies an initial load (10 kg) that sets the penetrator below surface imperfections. Then a significant load is applied. The Rockwell hardness is determined from the depth of penetration and is read directly from a dial.

Table 43.6 *Hardness Penetration Tests*

test	penetrator	diagram	measured dimension	hardness
Brinell	sphere	(a)	diameter, d	$\text{BHN} = \dfrac{2P}{\pi D\left(D - \sqrt{D^2 - d^2}\right)}$
Rockwell[a]	sphere or penetrator	(b)	depth, t	$R = C_1 - C_2 t$
Vickers	square pyramid	(b)	mean diagonal, d_1	$\text{VHN} = \dfrac{1.854P}{d_1^2}$
Meyer	sphere	(a)	diameter, d	$\text{MHN} = \dfrac{4P}{\pi d^2}$
Meyer-Vickers	square pyramid	(b)	mean diagonal, d_1	$M_V = \dfrac{2P}{d_1^2}$
Knoop	asymmetrical pyramid	(c)	long diagonal, L	$K = \dfrac{14.2P}{L^2}$

[a] C_1 and C_2 are constants that depend on the scale.

Although a number of Rockwell scales (A through G) exist, the B and C scales are commonly used for steel. The *Rockwell B scale* is used with a steel ball for mild steel and high-strength aluminum. The *Rockwell C scale* is used with the brale indentor for hard steels having ultimate tensile strengths up to 300 ksi (2 GPa). The *Rockwell A scale* has a wide range and can be used with both soft materials (such as annealed brass) and hard materials (such as cemented carbides).

Other penetration hardness tests include the *Meyer*, *Vickers*, *Meyer-Vickers*, and *Knoop* tests, as described in Table 43.6.

Cutting hardness is a measure of the force per unit area to cut a chip at low speed.

$$\text{cutting hardness} = \frac{F}{bt} \qquad 43.31$$

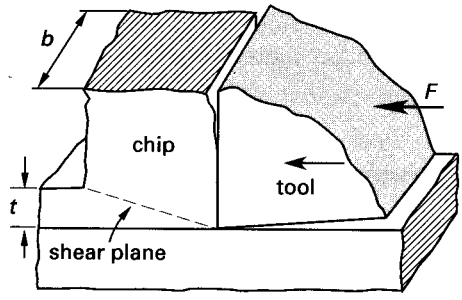


Figure 43.21 *Cutting Hardness*

The *scratch hardness test*, also known as the *Mohs test*, compares the hardness of the material to that of minerals. Minerals of increasing hardness are used to scratch the sample. The resulting *Mohs scale* hardness can be used or correlated to other hardness scales, as in Fig. 43.22.

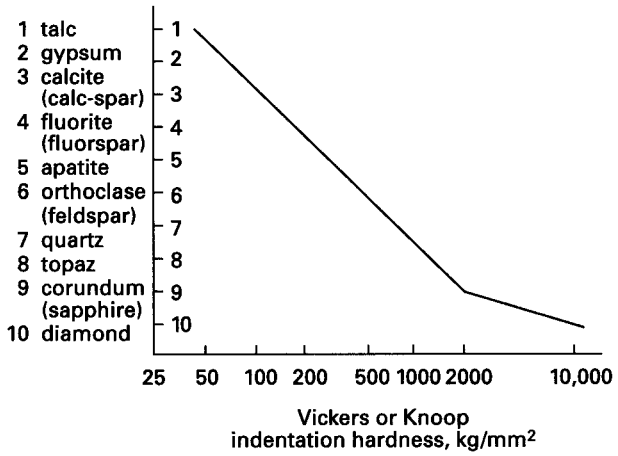

Figure 43.22 *Mohs Hardness Scale*

The *file hardness* test is a combination of the cutting and scratch tests. Files of known hardness are drawn across the sample. The file ceases to cut the material when the material and file hardnesses are the same.

All of the preceding hardness tests are *destructive tests* because they mar the material surface. However, *ultrasonic tests* and various *rebound tests* (e.g., the *Shore hardness test* and the *scleroscopic hardness test*) are *nondestructive tests*. In a rebound test, a standard object, usually a diamond-tipped hammer, is dropped from a standard height onto the sample. The height of the rebound is measured and correlated to other hardness scales.

The various hardness tests do not measure identical properties of the material, so correlations between the various scales are not exact. For steel, the Brinell and Vickers hardness numbers are approximately the same below values of 320 Brinell. Also, the Brinell hardness is approximately ten times the Rockwell C hardness (R_c) for $R_c > 20$. Table 43.7 is an accepted correlation between several of the scales for steel. The table should not be used for other materials.

Table 43.7 *Correlations Between Hardness Scales for Steel*

Brinell number	Vickers number	Rockwell numbers C	Rockwell numbers B	scleroscope number

20. TOUGHNESS TESTING

During World War II, the United States experienced spectacular failures in approximately 25% of its Liberty ships and T-2 tankers. The mild steel plates of these ships were connected by welds that lost their ductility and became brittle at winter temperatures. Some of the ships actually broke into two sections. Such *brittle failures* are most likely to occur when three conditions are met: (a) triaxial stress, (b) low temperature, and (c) rapid loading.

Toughness is a measure of the material's ability to yield and absorb highly localized and rapidly applied stresses. *Notch toughness* is evaluated by measuring the *impact energy* that causes a notched sample to fail.[15]

In the *Charpy test*, popular in the United States, a standardized beam specimen is given a 45° notch. The specimen is then centered on simple supports with the notch down. A falling pendulum striker hits the center of the specimen. This test is performed several times with different heights and different specimens until a sample fractures.

The kinetic energy expended at impact, equal to the initial potential energy less the rebound or follow-through height of the pendulum striker, is calculated from measured heights. It is designated C_V and is expressed in either foot-pounds (ft-lbf) or joules (J).[16] The energy required to cause failure is a measure of toughness.

[15]Without a notch, the specimen would experience uniaxial stress (tension and compression) at impact. The notch allows triaxial stresses to develop. Most materials become more brittle under triaxial stresses than under uniaxial stresses.

[16]In Europe, the energy is often expressed per unit cross section of specimen area.

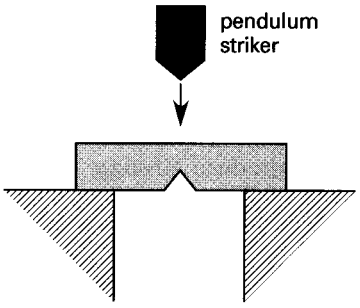

Figure 43.23 *Charpy Test*

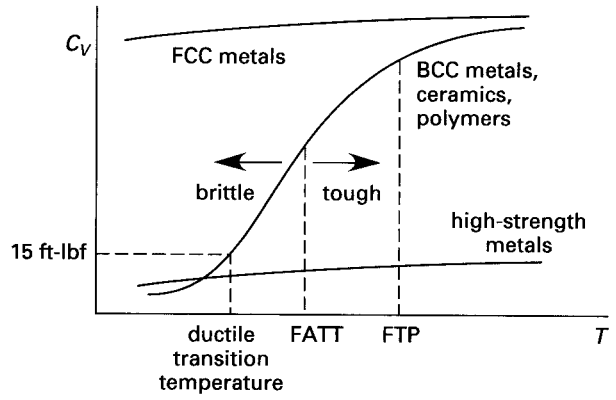

Figure 43.24 *Failure Energy versus Temperature*

At 70°F (21°C), the energy required to cause failure ranges from 45 ft-lbf (60 J) for carbon steels to approximately 110 ft-lbf (150 J) for chromium-manganese steels. As temperature is reduced, however, the toughness decreases. In BCC metals, such as steel, at a low enough temperature the toughness decreases sharply. The transition from high-energy ductile failures to low-energy brittle failures begins at the *fracture transition plastic (FTP) temperature*.

Since the transition occurs over a wide temperature range, the *transition temperature* (also known as the *ductile transition temperature*) is taken as the temperature at which an impact of 15 ft-lbf (20 J) will cause failure. (15 ft-lbf is used for low-carbon ship steels. Other values may be used with other materials.) This occurs at approximately 30°F (−1°C) for low-carbon steel.

The appearance of the fractured surface is also used to evaluate the transition temperature. The fracture can be fibrous (from shear fracture) or granular (from cleavage fracture), or a mixture of both. The fracture planes are studied and the percentages of ductile failure plotted against temperature. The temperature at which the failure is 50% fibrous and 50% granular is known as the *fracture appearance transition temperature*, FATT.

Table 43.8 *Approximate Ductile Transition Temperatures*

type of steel	transition ductile temperature, °F
carbon steel	30°
high-strength, low-alloy steel	0° to 30°
heat-treated, high-strength, carbon steel	−25°
heat-treated, construction alloy steel	−40° to −80°

Not all materials have a ductile-brittle transition. Aluminum, copper, other FCC metals, and most HCP metals do not lose their toughness abruptly. Figure 43.24 illustrates the failure energy curves for several different types of materials.

Another toughness test is the *Izod test*. This is illustrated in Fig. 43.25 and is similar to the Charpy test in its use of a notched specimen. The height to which a swinging pendulum follows through after causing the specimen to fail determines the energy of failure.

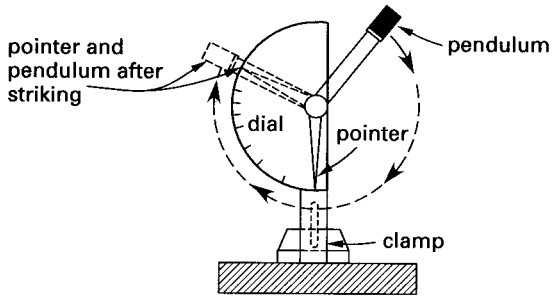

Figure 43.25 *Izod Test*

21. CREEP TEST

Creep or *creep strain* is the continuous yielding of a material under constant stress. For metals, creep is negligible at low temperatures (i.e., less than half of the absolute melting temperature), although the usefulness of nonreinforced plastics as structural materials is seriously limited by creep at room temperature.

During a *creep test*, a low tensile load of constant magnitude is applied to a specimen, and the strain is measured as a function of time. The *creep strength* is the stress that results in a specific creep rate, usually 0.001% or 0.0001% per hour. The *rupture strength*, determined from a *stress-rupture test*, is the stress that results in a failure after a given amount of time, usually 100, 1000, or 10,000 hours.

If strain is plotted as a function of time, three different curvatures will be apparent following the initial elastic extension.[17] During the first stage, the *creep*

[17]In Great Britain, the initial elastic elongation is considered the first stage. Therefore, creep has four stages in British nomenclature.

Structural

rate ($d\epsilon/dt$) decreases since strain hardening (dislocation generation and interaction with grain boundaries and other barriers) is occurring at a greater rate than annealing (annihilation of dislocations, climb, cross-slip, and some recrystallization). This is known as *primary creep*.

During the second stage, the creep rate is constant, with strain hardening and annealing occurring at the same rate. This is known as *secondary creep* or *cold flow*. During the third stage, the specimen begins to neck down, and rupture eventually occurs. This region is known as *tertiary creep*.

The secondary creep rate is lower than the primary and tertiary creep rates. The secondary creep rate, represented by the slope (on a log-log scale) of the line during the second stage, is temperature and stress dependent. This slope increases at higher temperatures and stresses. The creep rate curve can be represented by the following empirical equation, known as *Andrade's equation*.

$$\epsilon = \epsilon_o \left(1 + \beta t^{\frac{1}{3}}\right) e^{kt} \qquad 43.32$$

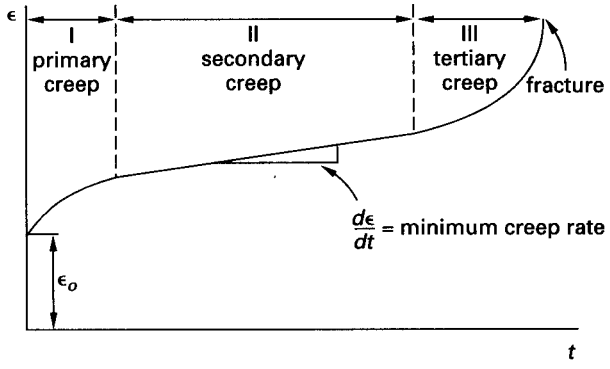

Figure 43.26 *Stages of Creep*

Dislocation climb (glide and creep) is the primary creep mechanism, although diffusion creep and grain boundary sliding also contribute to creep on a microscopic level. On a larger scale, the mechanisms of creep involve slip, subgrain formation, and grain-boundary sliding.

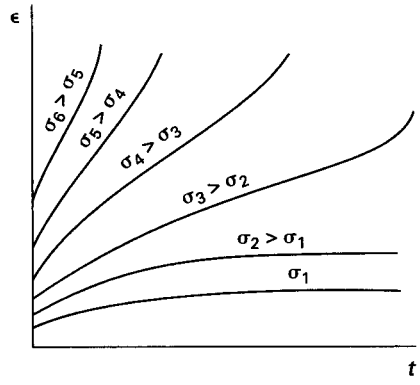

Figure 43.27 *Effect of Stress on Creep Rates*

22. EFFECTS OF IMPURITIES AND STRAIN ON MECHANICAL PROPERTIES

Anything that restricts the movement of dislocations will increase the strength of metals and reduce ductility. Alloying materials, impurity atoms, imperfections, and other dislocations produce stronger materials. This is illustrated in Fig. 43.28.

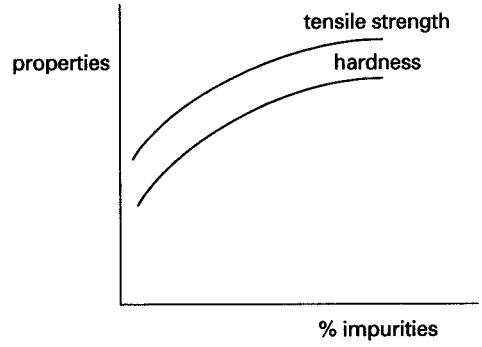

Figure 43.28 *Effect of Impurities on Mechanical Properties*

Additional dislocations are generated by the plastic deformation (i.e., cold working) of metals, and these dislocations can strain-harden the metal. Figure 43.29 shows the effect of strain-hardening on mechanical properties.

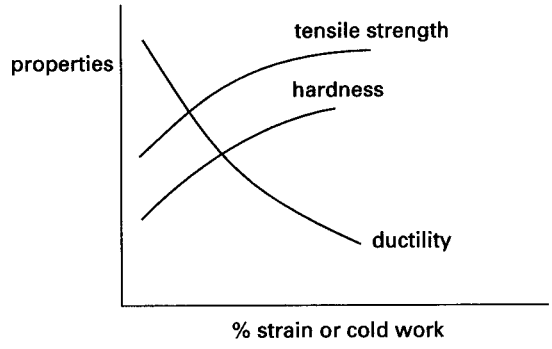

Figure 43.29 *Effect of Strain-Hardening on Mechanical Properties*

23. CLASSIFICATION OF MATERIALS

When used to describe engineering materials, the terms "strong" and "tough" are not synonymous. Similarly, "weak," "soft," and "brittle" have different engineering meanings. A *strong material* has a high ultimate strength, whereas a *weak material* has a low ultimate strength. A *tough material* will yield greatly before breaking, whereas a *brittle material* will not. (A brittle material is one whose strain at fracture is less than approximately 0.5%.) A *hard material* has a high modulus of elasticity, whereas a *soft material* does not. Figure 43.30 illustrates some of the possible combinations of these classifications.

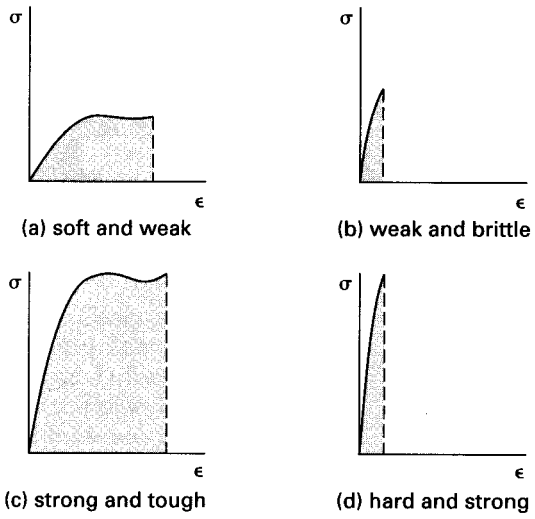

Figure 43.30 *Types of Engineering Materials*

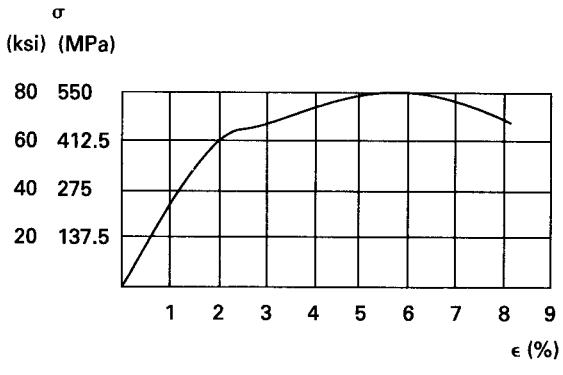
PRACTICE PROBLEMS

1. The engineering stress and engineering strain for a copper specimen are 20,000 lbf/in^2 (140 MPa) and 0.0200 in/in (0.0200 mm/mm), respectively. Poisson's ratio for the specimen is 0.3.

(a) What is the true stress?

(A) 14,000 lbf/in^2 (98 MPa)
(B) 18,000 lbf/in^2 (130 MPa)
(C) 20,000 lbf/in^2 (140 MPa)
(D) 22,000 lbf/in^2 (160 MPa)



The answer is (C).

(b) What is the true strain?

(A) 0.0182 in/in (0.0182 mm/mm)
(B) 0.0189 in/in (0.0189 mm/mm)
(C) 0.0194 in/in (0.0194 mm/mm)
(D) 0.0198 in/in (0.0198 mm/mm)

The answer is (D).

2. A graph of engineering stress-strain is shown. Poisson's ratio for the material is 0.3.

(a) Find the 0.5% yield strength.

(A) 70,000 lbf/in^2 (480 MPa)
(B) 76,000 lbf/in^2 (530 MPa)
(C) 84,000 lbf/in^2 (590 MPa)
(D) 98,000 lbf/in^2 (690 MPa)

The answer is (A).

(b) Find the elastic modulus.

(A) 2.4×10^6 lbf/in^2 (17 GPa)
(B) 2.7×10^6 lbf/in^2 (19 GPa)
(C) 2.9×10^6 lbf/in^2 (20 GPa)
(D) 3.0×10^6 lbf/in^2 (21 GPa)

The answer is (D).

(c) Find the ultimate strength.

(A) 72,000 lbf/in^2 (500 MPa)
(B) 76,000 lbf/in^2 (530 MPa)
(C) 80,000 lbf/in^2 (550 MPa)
(D) 84,000 lbf/in^2 (590 MPa)

The answer is (C).

(d) Find the fracture strength.

(A) 62,000 lbf/in^2 (430 MPa)
(B) 70,000 lbf/in^2 (480 MPa)
(C) 76,000 lbf/in^2 (530 MPa)
(D) 84,000 lbf/in^2 (590 MPa)

The answer is (B).

(e) Find the percentage of elongation at fracture.

(A) 6%
(B) 8%
(C) 10%
(D) 12%

The answer is (A).

(f) Find the shear modulus.

(A) 0.9×10^6 lbf/in^2 (6.3 GPa)
(B) 1.1×10^6 lbf/in^2 (7.7 GPa)
(C) 1.2×10^6 lbf/in^2 (7.9 GPa)
(D) 1.5×10^6 lbf/in^2 (11 GPa)

The answer is (C).

(g) Find the toughness.

(A) 5100 in-lbf/in^3 (35 MJ/m^3)
(B) 5700 in-lbf/in^3 (38 MJ/m^3)
(C) 6300 in-lbf/in^3 (42 MJ/m^3)
(D) 8900 in-lbf/in^3 (60 MJ/m^3)

The answer is (A).

Structural

3. A specimen with an unstressed cross-sectional area of 4 in^2 (25 cm^2) necks down to 3.42 in^2 (22 cm^2) before breaking in a standard tensile test. What is the reduction in area of the material?

(A) 0.094 (0.089)
(B) 0.10 (0.094)
(C) 0.13 (0.10)
(D) 0.15 (0.12)

The answer is (D).

4. A constant 15,000 lbf/in^2 (100 MPa) tensile stress is applied to a specimen. The stress is known to be less than the material's yield strength. The strain is measured at various times. What is the steady-state creep rate for the material?

time (hr)	strain (in/in)
5	0.018
10	0.022
20	0.026
30	0.031
40	0.035
50	0.040
60	0.046
70	0.058

(A) 0.00037 hr^{-1}
(B) 0.00041 hr^{-1}
(C) 0.00046 hr^{-1}
(D) 0.00049 hr^{-1}

The answer is (C).

1. BASIC CONCEPTS

Strength of materials (known also as *mechanics of materials*) deals with the elastic behavior of loaded engineering materials.[1] This subject draws heavily on the topics in Chaps. 42 and 43.

Stress is force per unit area, F/A. Typical units of stress are lbf/in^2, ksi (thousands of pounds per square inch), and MPa. Although there are many names given to stress, there are only two primary types, differing in the orientation of the loaded area. With *normal stress*, σ, the area is normal to the force carried. With *shear stress*, τ, the area is parallel to the force.

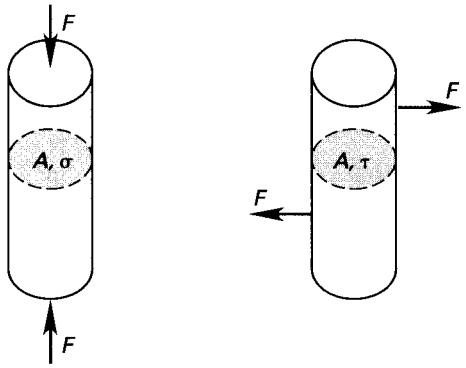

Figure 44.1 *Normal and Shear Stress*

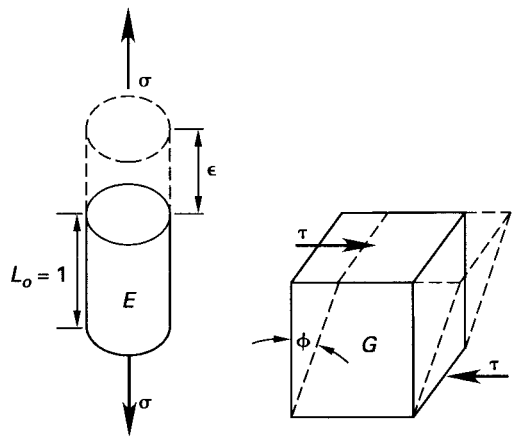
Strain, ϵ, is elongation expressed on a fractional or percentage basis. It may be listed as having units of in/in, mm/mm, and percent, or no units at all. A strain in one direction will be accompanied by strains in orthogonal directions in accordance with Poisson's ratio. *Dilation* is the sum of the strains in the three coordinate directions.

$$\text{dilation} = \epsilon_x + \epsilon_y + \epsilon_z \qquad 44.1$$

2. HOOKE'S LAW



Hooke's law is a simple mathematical statement of the relationship between elastic stress and strain: Stress is proportional to strain. For normal stress, the constant of proportionality is the *modulus of elasticity* (*Young's modulus*), E.

$$\sigma = E\epsilon \qquad 44.2$$

For shear stress, the constant of proportionality is the *shear modulus*, G.

$$\tau = G\phi \qquad 44.3$$

[1]Plastic behavior and ultimate strength design are not covered in this chapter.

(a) normal stress (b) shear stress

Figure 44.2 *Application of Hooke's Law*

3. ELASTIC DEFORMATION

Since stress is F/A and strain is δ/L_o, Hooke's law can be rearranged in form to give the elongation of an axially loaded member with a uniform cross section experiencing normal stress. Tension loading is considered positive; compressive loading is negative.

$$\delta = L_o\epsilon = \frac{L_o\sigma}{E} = \frac{L_oF}{EA} \qquad 44.4$$

The actual length of a member under loading is given by Eq. 44.5. The algebraic sign of the deformation must be observed.

$$L = L_o + \delta \qquad 44.5$$

4. TOTAL STRAIN ENERGY

The energy stored in a loaded member is equal to the work required to deform the member. Below the proportionality limit, the total *strain energy* for a member loaded in tension or compression is given by Eq. 44.6.

$$U = \tfrac{1}{2}F\delta = \frac{F^2L_o}{2AE} = \frac{\sigma^2L_oA}{2E} \qquad 44.6$$

5. STIFFNESS AND RIGIDITY

Stiffness is the amount of force required to cause a unit of deformation (displacement) and is often referred to as a *spring constant*. Typical units are pounds per inch and newtons per meter. The stiffness of a spring or other structure can be calculated from the deformation equation by solving for F/δ. Equation 44.7 is valid for tensile and compressive normal stresses. For torsion and bending, the stiffness equation will depend on how the deflection is calculated.

$$k = \frac{F}{\delta} \quad \text{[general form]} \qquad 44.7(a)$$

$$k = \frac{AE}{L_o} \quad \text{[normal stress form]} \qquad 44.7(b)$$

When more than one spring or resisting member share the load, the relative stiffnesses are known as *rigidities*. Rigidities have no units, and the individual rigidity values have no significance. A ratio of two rigidities, however, indicates how much stronger one member is compared to another. Equation 44.8 is one method of calculating rigidity in a multi-member structure. (Since rigidities are relative numbers, they can be multiplied by the least common denominator to obtain integer values.)

$$R_j = \frac{k_j}{\sum_i k_i} \qquad 44.8$$

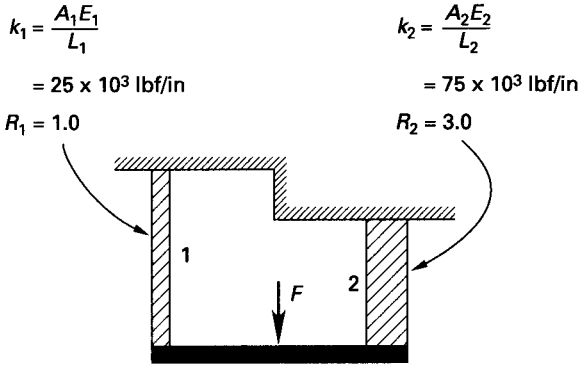


Figure 44.3 *Stiffness and Rigidity*

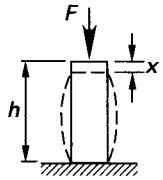
Rigidity is the reciprocal of deflection. *Flexural rigidity* is the reciprocal of deflection in members that are acted upon by a moment (i.e., are in bending), although that term may also be used to refer to the product, EI, of the modulus of elasticity and the moment of inertia.

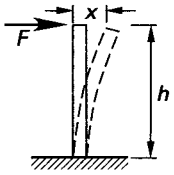
6. THERMAL DEFORMATION

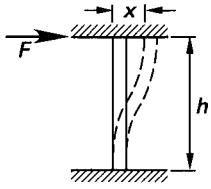
If the temperature of an object is changed, the object will experience length, area, and volume changes. The magnitude of these changes will depend on the *coefficient of linear expansion*, α, which is widely tabulated for solids. The *coefficient of volumetric expansion*, β, is encountered less often for solids but is used extensively with liquids and gases.

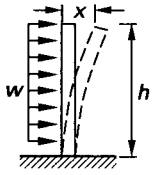
$$\Delta L = \alpha L_o(T_2 - T_1) \qquad 44.9$$

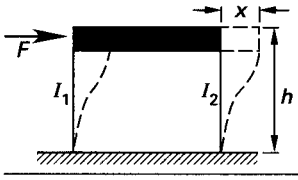
$$\Delta A = \gamma A_o(T_2 - T_1) \qquad 44.10$$

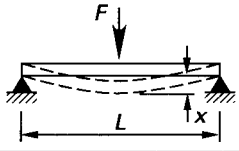


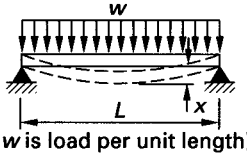


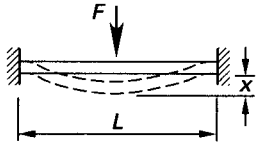


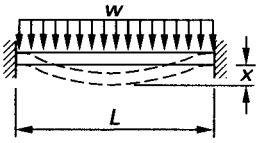












$$\gamma \approx 2\alpha \qquad 44.11$$

$$\Delta V = \beta V_o(T_2 - T_1) \qquad 44.12$$

$$\beta \approx 3\alpha \qquad 44.13$$

It is a common misconception that a hole in a plate will decrease in size when the plate is heated (because the surrounding material "squeezes in" on the hole). However, changes in temperature affect all dimensions the same way. In this case, the circumference of the hole is a linear dimension that follows Eq. 44.9. As the circumference increases, the hole area also increases.

Table 44.1 *Deflection and Stiffness for Various Systems (due to bending moment alone)*

system	maximum deflection (x)	stiffness (k)
	$\frac{Fh}{AE}$	$\frac{AE}{h}$
	$\frac{Fh^3}{3EI}$	$\frac{3EI}{h^3}$
	$\frac{Fh^3}{12EI}$	$\frac{12EI}{h^3}$
	$\frac{wL^4}{8EI}$	$\frac{8EI}{L^3}$
	$\frac{Fh^3}{12E(I_1+I_2)}$	$\frac{12E(I_1+I_2)}{h^3}$
	$\frac{FL^3}{48EI}$	$\frac{48EI}{L^3}$
 (w is load per unit length)	$\frac{5wL^4}{384EI}$	$\frac{384EI}{5L^3}$
	$\frac{FL^3}{192EI}$	$\frac{192EI}{L^3}$
 (w is load per unit length)	$\frac{wL^4}{384EI}$	$\frac{384EI}{L^3}$

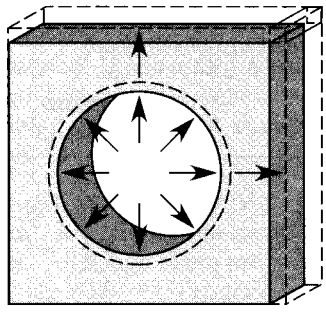


Figure 44.4 *Thermal Expansion of an Area*

If Eq. 44.9 is rearranged, an expression for the *thermal strain* is obtained.

$$\epsilon_{\text{th}} = \frac{\Delta L}{L_o} = \alpha(T_2 - T_1) \qquad 44.14$$

Thermal strain is handled in the same manner as strain due to an applied load. For example, if a bar is heated but is not allowed to expand, the stress can be calculated from the thermal strain and Hooke's law.

$$\sigma_{\text{th}} = E\epsilon_{\text{th}} \qquad 44.15$$

Low values of the coefficient of expansion, such as with Pyrex™ glassware, result in low thermally induced stresses and high insensitivity to temperature extremes. Differences in the coefficients of expansion of two materials are used in *bimetallic elements*, such as thermostatic springs and strips.

Table 44.2 *Average Coefficients of Linear Thermal Expansion (multiply all values by 10^{-6})*

substance	1/°F	1/°C
aluminum alloy	12.8	23.0
brass	10.0	18.0
cast iron	5.6	10.1
chromium	3.8	6.8
concrete	6.7	12.0
copper	8.9	16.0
glass (plate)	4.9	8.9
glass (Pyrex™)	1.8	3.2
invar	0.39	0.7
lead	15.6	28.0
magnesium alloy	14.5	26.1
marble	6.5	11.7
platinum	5.0	9.0
quartz, fused	0.2	0.4
steel	6.5	11.7
tin	14.9	26.9
titanium alloy	4.9	8.8
tungsten	2.4	4.4
zinc	14.6	26.3

(Multiply 1/°F by 9/5 to obtain 1/°C.)
(Multiply 1/°C by 5/9 to obtain 1/°F.)

Example 44.1

A replacement steel rail ($L = 20.0$ m, $A = 60\times10^{-4}$ m^2) was installed when its temperature was 5°C. The rail was installed tightly in the line, without an allowance for expansion. If the rail ends are constrained by adjacent rails and if the spikes prevent buckling, what is the compressive force in the rail at 25°C?

Solution

From Table 44.2, the coefficient of linear expansion for steel is 11.7×10^{-6} 1/°C. From Eq. 44.14, the thermal strain is

$$\epsilon_{\text{th}} = \alpha(T_2 - T_1) = \left(11.7 \times 10^{-6}\ \frac{1}{\text{°C}}\right)(25\text{°C} - 5\text{°C})$$
$$= 2.34 \times 10^{-4}\ \text{m/m}$$

The modulus of elasticity of steel is 20×10^{10} N/m^2 (20×10^4 MPa). The compressive stress is given by Hooke's law. Use Eq. 44.15.

$$\sigma_{\text{th}} = E\epsilon_{\text{th}} = \left(20 \times 10^{10}\ \frac{\text{N}}{\text{m}^2}\right)\left(2.34 \times 10^{-4}\ \frac{\text{m}}{\text{m}}\right)$$
$$= 4.68 \times 10^7\ \text{N/m}^2$$

The compressive force is

$$F = \sigma_{\text{th}}A = \left(4.68 \times 10^7\ \frac{\text{N}}{\text{m}^2}\right)(60 \times 10^{-4}\ \text{m}^2)$$
$$= 281\,000\ \text{N}$$

7. STRESS CONCENTRATIONS

A *geometric stress concentration* occurs whenever there is a discontinuity or non-uniformity in an object. Examples of non-uniform shapes are stepped shafts, plates with holes and notches, and shafts with keyways. It is convenient to think of stress as streamlines within an object. There will be a stress concentration wherever local geometry forces the streamlines closer together.

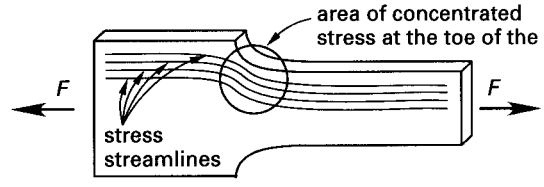

Figure 44.5 *Streamline Analogy to Stress Concentrations*

Stress values determined by simplistic F/A, Mc/I, or Tr/J calculations will be greatly understated. *Stress concentration factors (stress risers)* are correction factors used to account for the non-uniform stress distributions. The symbol K is often used, but this is not universal. The actual stress is determined as the product of the stress concentration factor, K, and the *nominal stress*, σ_0. Values of the stress concentration

factor are almost always greater than 1.0 and can run as high as 3.0 and above. The exact value for a given application must be determined from extensive experimentation or from published tabulations of standard configurations such as App. 44.A.

$$\sigma' = K\sigma_0 \qquad 44.16$$

Stress concentration factors are normally not applied to members with multiple redundancy, for static loading of ductile materials, or where local yielding around the discontinuity reduces the stress. For example, there will be many locations of stress concentration in a lap rivet connection. However, the stresses are kept low by design, and stress concentration is disregarded.

Stress concentration factors are not applicable to every point on an object; they apply only to the point of maximum stress. For example, with filleted shafts, the maximum stress occurs at the toe of the fillet. Therefore, the stress concentration factor should be applied to the stress calculated from the smaller section's properties. For objects with holes or notches, it is important to know if the nominal stress to which the factor is applied is calculated from an area that includes or excludes the holes or notches.

In addition to geometric stress concentrations, there are also *fatigue stress concentrations*. The *fatigue stress concentration* factor is the ratio of the fatigue strength without a stress concentration to the fatigue stress with a stress concentration. Fatigue stress concentration factors depend on the material, material strength, and geometry of the stress concentration (i.e., radius of the notch). Fatigue stress concentration factors can be less than the geometric factors from which they are computed.

8. COMBINED STRESSES (BIAXIAL LOADING)

Loading is rarely confined to a single direction. Many practical cases have different normal and shear stresses on two or more perpendicular planes. Sometimes, one of the stresses may be small enough to be disregarded, reducing the analysis to one dimension. In other cases, however, the shear and normal stresses must be combined to determine the maximum stresses acting on the material.

For any point in a loaded specimen, a plane can be found where the shear stress is zero. The normal stresses associated with this plane are known as the *principal stresses*, which are the maximum and minimum stresses acting at that point in any direction.

For two-dimensional (biaxial) loading (i.e., two normal stresses combined with a shearing stress), the normal and shear stresses on a plane whose normal line is inclined an angle θ from the horizontal can be found from Eqs. 44.17 and 44.18. Proper sign convention must be adhered to when using the combined stress equations. The positive senses of shear and normal stresses are shown in Fig. 44.6. As is usually the case, tensile normal stresses are positive; compressive normal stresses are negative. In two dimensions, shear stresses are designated as clockwise (positive) or counterclockwise (negative).[2]

$$\sigma_\theta = \tfrac{1}{2}(\sigma_x + \sigma_y) + \tfrac{1}{2}(\sigma_x - \sigma_y)\cos 2\theta + \tau \sin 2\theta \qquad 44.17$$

$$\tau_\theta = -\tfrac{1}{2}(\sigma_x - \sigma_y)\sin 2\theta + \tau \cos 2\theta \qquad 44.18$$

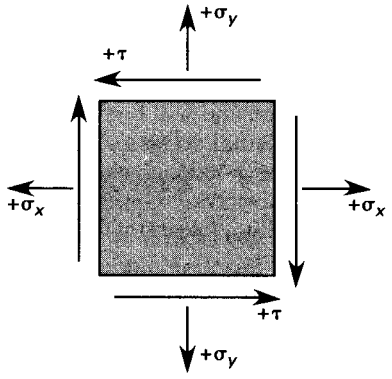

Figure 44.6 *Sign Convention for Combined Stress*

At first glance, the orientation of the shear stresses may seem confusing. However, the arrangement of stresses shown produces equilibrium in the x- and y-directions without causing rotation. Other than a mirror image or a trivial rotation of the arrangement shown in Fig. 44.6, no arrangement of shear stresses will produce equilibrium.

The maximum and minimum values (as θ is varied) of the normal stress, σ_θ, are the *principal stresses*, which can be found by differentiating Eq. 44.17 with respect to θ, setting the derivative equal to zero, and substituting θ back into Eq. 44.17. Equation 44.19 is derived in this manner. A similar procedure is used to derive the *extreme shear stresses* (i.e., maximum and minimum shear stresses) in Eq. 44.20 from Eq. 44.18. (The term *principal stress* implies a normal stress, never a shear stress.)

$$\sigma_1, \sigma_2 = \tfrac{1}{2}(\sigma_x + \sigma_y) \pm \tau_1 \qquad 44.19$$

$$\tau_1, \tau_2 = \pm\tfrac{1}{2}\sqrt{(\sigma_x - \sigma_y)^2 + (2\tau)^2} \qquad 44.20$$

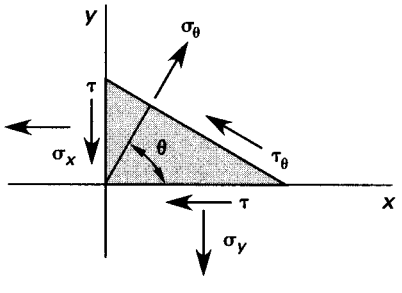

Figure 44.7 *Plane of Principal Stresses*

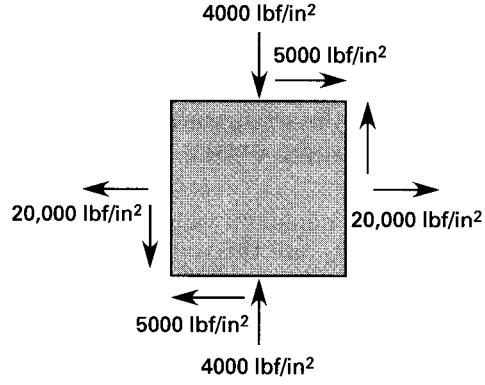
[2]Some sources refer to the shear stress as τ_{xy}; others use the symbol τ_z. When working in two dimensions only, the subscripts xy and z are unnecessary and confusing conventions.

The angles of the planes on which the normal stresses are minimum and maximum are given by Eq. 44.21. θ is measured from the x-axis, clockwise if negative and counterclockwise if positive. Equation 44.21 will yield two angles, 90° apart. These angles can be substituted back into Eqs. 44.17 and 44.18 to determine which angle corresponds to the minimum normal stress and which angle corresponds to the maximum normal stress.[3]



$$\theta_{\sigma_1,\sigma_2} = \tfrac{1}{2}\arctan\left(\frac{2\tau}{\sigma_x - \sigma_y}\right) \qquad 44.21$$

The angles of the planes on which the shear stress is minimum and maximum are given by Eq. 44.22. These planes will be 90° apart and will be rotated 45° from the planes of principal normal stresses. As with Eq. 44.21, θ is measured from the x-axis, clockwise if negative and counterclockwise if positive. Generally, the sign of a shear stress on an inclined plane will be unimportant.

$$\theta_{\tau_1,\tau_2} = \tfrac{1}{2}\arctan\left(\frac{\sigma_x - \sigma_y}{-2\tau}\right) \qquad 44.22$$

Example 44.2

Find the maximum normal and shear stresses on the object shown. Determine the angle of the plane of principal normal stresses.

Solution

Find the principal shear stresses first. The applied 4000 lbf/in^2 compressive stress is negative. Equation 44.20 can be used directly.

$$\begin{aligned}\tau_1 &= \tfrac{1}{2}\sqrt{(\sigma_x - \sigma_y)^2 + (2\tau)^2} \\ &= \frac{1}{2}\sqrt{\left(20{,}000\ \frac{\text{lbf}}{\text{in}^2} - \left(-4000\ \frac{\text{lbf}}{\text{in}^2}\right)\right)^2 + \left((2)\left(5000\ \frac{\text{lbf}}{\text{in}^2}\right)\right)^2} \\ &= 13{,}000\ \text{lbf/in}^2\end{aligned}$$

[3]Alternatively, the following procedure can be used to determine the direction of the principal planes. Let σ_x be the algebraically larger of the two given normal stresses. The angle between the direction of σ_x and the direction of σ_1, the algebraically larger principal stress, will always be less than 45°.

From Eq. 44.19, the maximum normal stress is

$$\begin{aligned}\sigma_1 &= \tfrac{1}{2}(\sigma_x + \sigma_y) + \tau_1 \\ &= \left(\tfrac{1}{2}\right)\left(20{,}000\ \frac{\text{lbf}}{\text{in}^2} + \left(-4000\ \frac{\text{lbf}}{\text{in}^2}\right)\right) + 13{,}000\ \frac{\text{lbf}}{\text{in}^2} \\ &= 21{,}000\ \text{lbf/in}^2 \quad \text{[tension]}\end{aligned}$$

The angle of the principal normal stresses is given by Eq. 44.21.

$$\begin{aligned}\theta &= \tfrac{1}{2}\arctan\left(\frac{2\tau}{\sigma_x - \sigma_y}\right) \\ &= \tfrac{1}{2}\arctan\left(\frac{(2)\left(5000\ \frac{\text{lbf}}{\text{in}^2}\right)}{20{,}000\ \frac{\text{lbf}}{\text{in}^2} - \left(-4000\ \frac{\text{lbf}}{\text{in}^2}\right)}\right) \\ &= \left(\tfrac{1}{2}\right)(22.6°, 202.6°) \\ &= 11.3°, 101.3°\end{aligned}$$

It is not obvious which angle produces which normal stress. One of the angles can be substituted back into the general equation (Eq. 44.17) for σ_θ.

$$\begin{aligned}\sigma_{11.3°} &= \left(\tfrac{1}{2}\right)\left(20{,}000\ \frac{\text{lbf}}{\text{in}^2} - 4000\ \frac{\text{lbf}}{\text{in}^2}\right) \\ &\quad + \left(\tfrac{1}{2}\right)\left(20{,}000\ \frac{\text{lbf}}{\text{in}^2} + \left(-4000\ \frac{\text{lbf}}{\text{in}^2}\right)\right) \\ &\quad \times \cos(2)(11.3°) + (5000)\sin(2)(11.3°) \\ &= 21{,}000\ \text{lbf/in}^2\end{aligned}$$

Thus, the 11.3° angle corresponds to the maximum normal stress of 21,000 lbf/in^2.

9. MOHR'S CIRCLE FOR STRESS

Mohr's circle can be constructed to graphically determine the principal stresses.

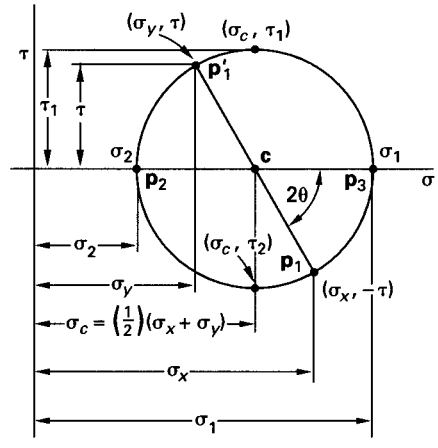


Figure 44.8 *Mohr's Circle for Stress*

step 1: Determine the applied stresses: σ_x, σ_y, and τ. (Tensile normal stresses are positive; compressive normal stresses are negative. Clockwise shear stresses are positive; counterclockwise shear stresses are negative.)

step 2: Draw a set of σ-τ axes.

step 3: Plot the center of the circle, point **c**, by calculating $\sigma_c = \frac{1}{2}(\sigma_x + \sigma_y)$.

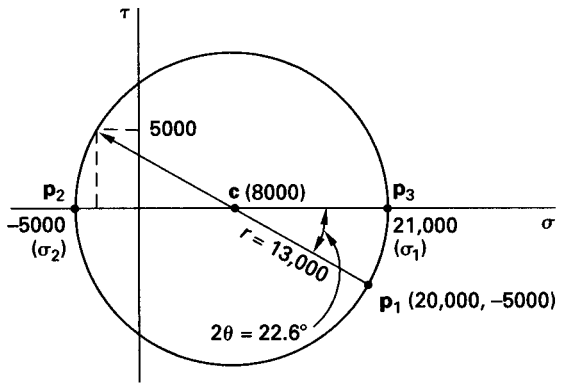
step 4: Plot the point $\mathbf{p}_1 = (\sigma_x, -\tau)$. (Alternatively, plot $\mathbf{p}_1'$ at $(\sigma_y, +\tau)$.)

step 5: Draw a line from point $\mathbf{p}_1$ through center **c** and extend it an equal distance below the σ-axis. This is the diameter of the circle.

step 6: Using the center **c** and point $\mathbf{p}_1$, draw the circle. An alternative method is to draw a circle of radius r about point **c**.

$$r = \sqrt{\tfrac{1}{4}(\sigma_x - \sigma_y)^2 + \tau^2} \qquad 44.23$$

step 7: Point $\mathbf{p}_2$ defines the smaller principal stress, σ_2. Point $\mathbf{p}_3$ defines the larger principal stress, σ_1.



step 8: Determine the angle θ as half of the angle 2θ on the circle. This angle corresponds to the larger principal stress, σ_1. On Mohr's circle, angle 2θ is measured counterclockwise from the $\mathbf{p}_1$-$\mathbf{p}_1'$ line to the horizontal axis.

Example 44.3

Construct Mohr's circle for Ex. 44.2.

Solution

$$\begin{aligned}
\sigma_c &= \tfrac{1}{2}(\sigma_x + \sigma_y) \\
&= \left(\tfrac{1}{2}\right)\left(20{,}000\ \frac{\text{lbf}}{\text{in}^2} + \left(-4000\ \frac{\text{lbf}}{\text{in}^2}\right)\right) \\
&= 8000\ \text{lbf/in}^2 \\
r &= \sqrt{\tfrac{1}{4}(\sigma_x - \sigma_y)^2 + \tau^2} \\
&= \sqrt{\left(\left(\tfrac{1}{4}\right)\left(20{,}000\ \frac{\text{lbf}}{\text{in}^2} - \left(-4000\ \frac{\text{lbf}}{\text{in}^2}\right)\right)\right)^2 + \left(5000\ \frac{\text{lbf}}{\text{in}^2}\right)^2} \\
&= 13{,}000\ \text{lbf/in}^2
\end{aligned}$$

10. IMPACT LOADING

If a load is applied to a structure suddenly, the structure's response will be composed of two parts: a transient response (which decays to zero) and a steady-state response. (These two parts are also known as the *dynamic* and *static responses*.) It is not unusual for the transient loading to be larger than the steady-state response.

Although a *dynamic analysis* of the structure is preferred, the procedure is lengthy and complex. Therefore, arbitrary multiplicative factors may be applied to the steady-state stress to determine the maximum transient. For example, if a load is applied quickly as compared to the natural period of vibration of the structure (e.g., the classic definition of an *impact load*), a dynamic factor of 2.0 might be used. Actual dynamic factors should be determined or validated by testing.

The energy-conservation method (i.e., the work-energy principle) can be used to determine the maximum stress due to a falling mass. The total change in potential energy of the mass from the change in elevation and the deflection δ) is equated to the appropriate expression for total strain energy (see Sec. 4).

11. SHEAR AND MOMENT

Shear at a point is the sum of all vertical forces acting on an object. It has units of pounds, kips, tons, newtons, and so on. Shear is not the same as shear stress, since the area of the object is not considered.

The most typical application is shear at a point on a beam, V, defined as the sum of all vertical forces between the point and one of the ends.[4] The direction (i.e., to the left or right of the point) in which the summation proceeds is not important. Since the values of shear will differ only in sign for summations to the left and right ends, the direction that results in the fewest calculations should be selected.

[4]The conditions of equilibrium require that the sum of all vertical forces on a beam be zero. However, the *shear* can be nonzero because only a portion of the beam is included in the analysis. Since that portion extends to the beam end in one direction only, shear is sometimes called *resisting shear* or *one-way shear*.

$$V = \sum_{\substack{\text{point to} \\ \text{one end}}} F_i \qquad 44.24$$

Shear is taken as positive when there is a net upward force to the left of a point and negative when there is a net downward force between the point and the left end.

Moment at a point is the total bending moment acting on an object. In the case of a beam, the moment, M, will be the algebraic sum of all moments and couples located between the investigation point and one of the beam ends. As with shear, the number of calculations required to calculate the moment can be minimized by careful choice of the beam end.[5]

$$M = \sum_{\substack{\text{point to} \\ \text{one end}}} F_i d_i + \sum_{\substack{\text{point to} \\ \text{one end}}} C_i \qquad 44.25$$

Moment is taken as positive when the upper surface of the beam is in compression and the lower surface is in tension (see Fig. 44.12). Since the beam ends will usually be higher than the midpoint, it is commonly said that "a positive moment will make the beam smile."

12. SHEAR AND BENDING MOMENT DIAGRAMS

The value of the shear and moment, V and M, will depend on location along the beam. Both shear and moment can be described mathematically for simple loadings, but the formulas are likely to become discontinuous as the loadings become more complex. It is much more convenient to describe the shear and moment functions graphically. Graphs of shear and moment as functions of position along the beam are known as *shear* and *moment diagrams*. Drawing these diagrams does not require knowing the shape or area of the beam.

The following guidelines and conventions should be observed when constructing a *shear diagram.*

- The shear at any point is equal to the sum of the loads and reactions from the point to the left end.
- The magnitude of the shear at any point is equal to the slope of the moment line at that point.

$$V = \frac{dM}{dx} \qquad 44.26$$

- Loads and reactions acting upward are positive.
- The shear diagram is straight and sloping over uniformly distributed loads.
- The shear diagram is straight and horizontal between concentrated loads.
- The shear is a vertical line and is undefined at points of concentrated loads.

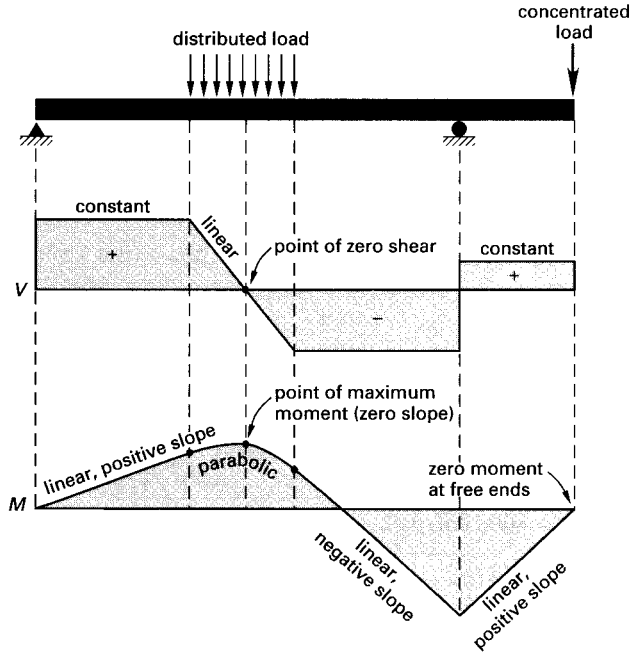
The following guidelines and conventions should be observed when constructing a *bending moment diagram.* By convention, the moment diagram is drawn on the compression side of the beam.

- The moment at any point is equal to the sum of the moments and couples from the point to the left end.[6]
- Clockwise moments about the point are positive.
- The magnitude of the moment at any point is equal to the area under the shear line up to that point. This is equivalent to the integral of the shear function.

$$M = \int V dx \qquad 44.27$$

- The *maximum moment* occurs where the shear is zero.
- The moment diagram is straight and sloping between concentrated loads.
- The moment diagram is curved (parabolic upward) over uniformly distributed loads.

These principles are illustrated in Fig. 44.9.



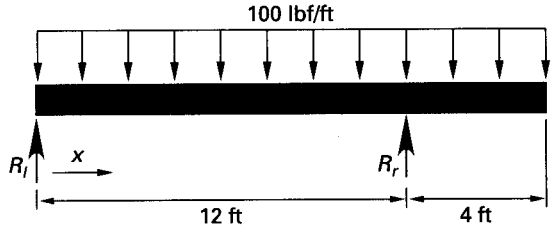


Figure 44.9 *Drawing Shear and Moment Diagrams*

[5]The conditions of equilibrium require that the sum of all moments on a beam be zero. However, the *moment* can be nonzero because only a portion of the beam is included in the analysis. Since that portion extends to the beam end in one direction only, moment is sometimes called *bending moment, resisting moment,* or *one-way moment.*

[6]If the beam is cantilevered with its built-in end at the left, the fixed-end moment will be unknown. In that case, the moment must be calculated to the right end of the beam.

Example 44.4

Draw the shear and bending moment diagrams for the following beam.

Solution

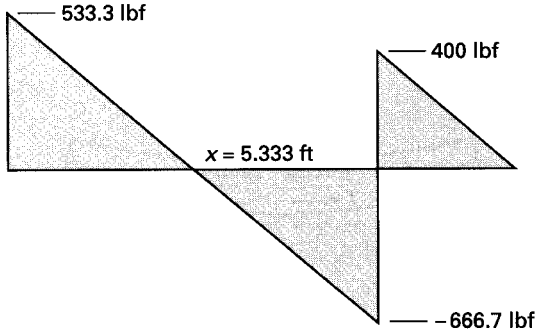
First, determine the reactions. The uniform load of $100x$ can be assumed to be concentrated at $x/2$.

$$R_r = \frac{\left(\frac{1}{2}\right)(16 \text{ ft})(16 \text{ ft})\left(100 \frac{\text{lbf}}{\text{ft}}\right)}{12 \text{ ft}} = 1066.7 \text{ lbf}$$

$$R_l = (16 \text{ ft})\left(100 \frac{\text{lbf}}{\text{ft}}\right) - R_r = 533.3 \text{ lbf}$$

The shear diagram starts at +533.3 at the left reaction but decreases linearly at the rate of 100 lbf/ft between the two reactions. Measuring x from the left end, the shear line goes through zero at

$$x = \frac{533.3 \text{ lbf}}{100 \frac{\text{lbf}}{\text{ft}}} = 5.333 \text{ ft}$$



The shear just to the left of the right reaction is

$$533.3 \text{ lbf} - (12 \text{ ft})\left(100 \frac{\text{lbf}}{\text{ft}}\right) = -666.7 \text{ lbf}$$

The shear just to the right of the right reaction is

$$-666.7 \text{ lbf} + R_r = +400 \text{ lbf}$$

To the right of the right reaction, the shear diagram decreases to zero at the same constant rate: 100 lbf/ft. This is sufficient information to draw the shear diagram.

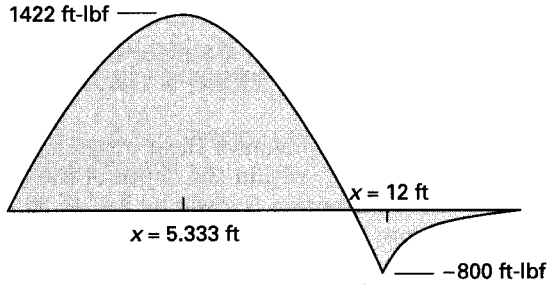
The left end is a free end, so the moment is zero. The bending moment at a distance x to the right of the left end has two parts. The left reaction of 533.3 lbf acts with moment arm x. The moment between the two reactions is

$$M_x = 533.3x - 100x\left(\frac{x}{2}\right)$$

This equation describes a parabolic section (curved upward) with a peak at $x = 5.333$ ft, where the shear is zero. The maximum moment is

$$M_{x=5.333} = (533.3 \text{ lbf})(5.333 \text{ ft}) - \left(50 \frac{\text{lbf}}{\text{ft}}\right)(5.333 \text{ ft})^2$$

$$= 1422.0 \text{ ft-lbf}$$



The moment at the right reaction (where $x = 12$ ft) is

$$M_{x=12} = (533.3 \text{ lbf})(12 \text{ ft}) - \left(50 \frac{\text{lbf}}{\text{ft}}\right)(12 \text{ ft})^2$$

$$= -800 \text{ ft-lbf}$$

The right end is a free end, so the moment is zero. The moment between the right reaction and the right end could be calculated by summing moments to the left end, but it is more convenient to sum moments to the right end. Measuring x from the right end, the moment is derived only from the uniform load.

$$M = 100x\left(\frac{x}{2}\right) = 50x^2$$

This is sufficient information to draw the moment diagram. Once the maximum moment is located, no attempt is made to determine the exact curvature. The point where $M = 0$ is of limited interest, and no attempt is made to determine the exact location.

Notice that the cross-sectional area of the beam was not needed in this example.

13. SHEAR STRESS IN BEAMS

Shear stress is generally not the limiting factor in most designs. However, it can control (or be limited by code) in wood and concrete beams and in thin tubes.

The average shear stress experienced at a point along the length of a beam depends on the shear, V, at that point and the area, A, of the beam. The shear can be found from the shear diagram.

$$\tau = \frac{V}{A} \qquad 44.28$$

In most cases, the entire area, A, of the beam is used in calculating the average shear stress. However, in flanged beam calculations it is assumed that only the web carries the average shear stress.[7] The flanges are not included in shear stress calculations.

$$\tau = \frac{V}{t_w d} \qquad 44.29$$

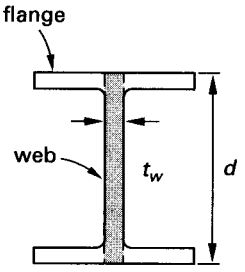


Figure 44.10 *Web of a Flanged Beam*

Figure 44.6 shows that for biaxial loading, identical shear stresses exist simultaneously in all four directions. One set of parallel shears (a couple) counteracts the rotational moment from the other set of parallel shears. The horizontal shear exists even when the loading is vertical (e.g., when a horizontal beam is loaded by a vertical force). For that reason, the term *horizontal shear* is sometimes used to distinguish it from the applied shear load.

The exact value of the horizontal shear stress is dependent on the location, y_1, within the depth of the beam. The shear stress distribution is given by Eq. 44.30. The shear stress is zero at the top and bottom surfaces of the beam and is maximum at the neutral axis (i.e., the center).

$$\tau_{y_1} = \frac{QV}{Ib} \qquad 44.30$$

In Eq. 44.30, V is the vertical shear at the point along the length of the beam where the shear stress is wanted. I is the beam's centroidal moment of inertia, and b is the width of the beam at the depth y_1 within the beam where the shear stress is wanted. Q is the *statical moment*, as defined by Eq. 44.31.

$$Q = \int_{y_1}^{c} y\,dA \qquad 44.31$$

[7]This is more than an assumption; it is a fact. There are several reasons the flanges do not contribute to shear resistance, including a non-uniform shear stress distribution in the flanges. This non-uniformity is too complex to be analyzed by elementary methods.

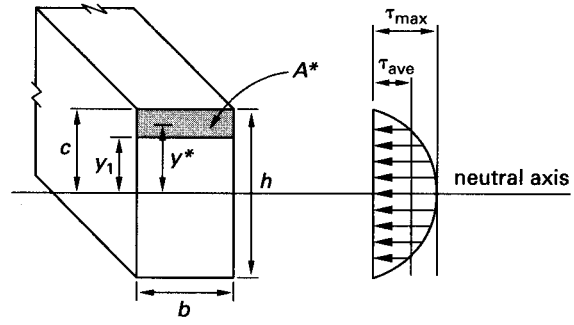

Figure 44.11 *Shear Stress Distribution Within a Rectangular Beam*

For rectangular beams, $dA = b\,dy$. Then, the statical moment of the area A^* above layer y_1 is equal to the product of the area and the distance from the centroidal axis to the centroid of the area.

$$Q = y^* A^* \qquad 44.32$$

Equation 44.33 calculates the maximum shear stress in a rectangular beam. It is 50% higher than the average shear stress.

$$\tau_{\text{max,rectangular}} = \frac{3V}{2A} = \frac{3V}{2bh} \qquad 44.33$$

For a beam with a circular cross section, the maximum shear stress is

$$\tau_{\text{max,circular}} = \frac{4V}{3A} = \frac{4V}{3\pi r^2} \qquad 44.34$$

For a hollow cylinder used as a beam, the maximum shear stress occurs at the plane of the neutral axis and is

$$\tau_{\text{max,hollow cylinder}} = \frac{2V}{A} \qquad 44.35$$

14. BENDING STRESS IN BEAMS

Normal stress occurs in a bending beam, as shown in Fig. 44.12, where the beam is acted upon by a *transverse force*. Although it is a normal stress, the term *bending stress* or *flexural stress* is used to indicate the source of the stress. The lower surface of the beam experiences tensile stress (which causes lengthening). The upper surface of the beam experiences compressive stress (which causes shortening). There is no normal stress along a horizontal plane passing through the centroid of the cross section, a plane known as the *neutral plane* or the *neutral axis*.

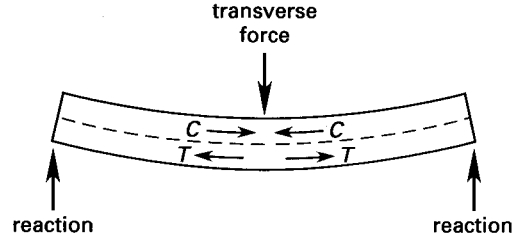

Figure 44.12 *Normal Stress Due to Bending*

Bending stress varies with location (depth) within the beam. It is zero at the neutral axis and increases linearly with distance from the neutral axis as predicted by Eq. 44.36.

$$\sigma_b = \frac{-My}{I_c} \qquad 44.36$$

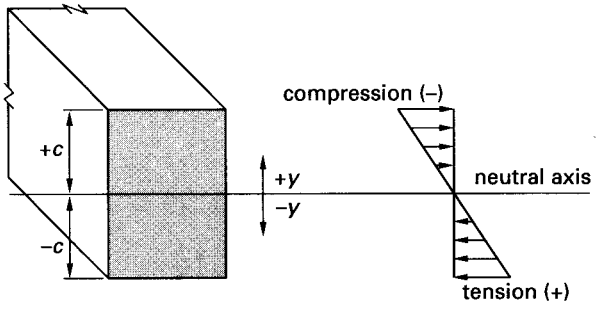

Figure 44.13 *Bending Stress Distribution in a Beam*

The bending moment, M, is used in Eq. 44.36. I_c is the centroidal moment of inertia of the beam's cross section. The negative sign in Eq. 44.36, required by the convention that compression is negative, is commonly omitted.

Since the maximum stress will govern the design, y can be set equal to c to obtain the *extreme fiber stress*. c is the distance from the neutral axis to the *extreme fiber* (i.e., the top or bottom surface most distant from the neutral axis).

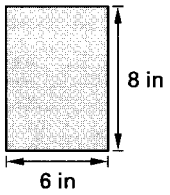
$$\sigma_{b,\max} = \frac{Mc}{I_c} \qquad 44.37$$

Equation 44.37 shows that the maximum bending stress will occur where the moment is maximum. The region immediately adjacent to the point of maximum bending moment is called the *dangerous section* of the beam. The dangerous section can be found from a bending moment or shear diagram.

For any given beam cross section, I_c and c are fixed. Therefore, these two terms can be combined into the *section modulus*, S.[8]

$$\sigma_{b,\max} = \frac{M}{S} \qquad 44.38$$

$$S = \frac{I_c}{c} \qquad 44.39$$



Since $c = h/2$, the section modulus of a rectangular $b \times h$ section ($I_c = bh^3/12$) is

$$S_{\text{rectangular}} = \frac{bh^2}{6} \qquad 44.40$$

Example 44.5

The beam in Ex. 44.4 has a 6 in × 8 in cross section. What are the maximum shear and bending stresses in the beam?

[8]The symbol Z is also commonly used for the section modulus.

Solution

The maximum shear (from the shear diagram) is 666.7 lbf. (The negative sign is disregarded.) From Eq. 44.33, the maximum shear stress in a rectangular beam is

$$\tau_{\max} = \frac{3V}{2A} = \frac{(3)(666.7\text{ lbf})}{(2)(6\text{ in})(8\text{ in})} = 20.8\text{ lbf/in}^2$$

The centroidal moment of inertia is

$$I_c = \frac{bh^3}{12} = \frac{(6\text{ in})(8\text{ in})^3}{12} = 256\text{ in}^4$$

The maximum bending moment (from the bending moment diagram) is 1422 ft-lbf. From Eq. 44.37, the maximum bending stress is

$$\sigma_{b,\max} = \frac{Mc}{I_c} = \frac{(1422\,\text{ft-lbf})\left(12\,\frac{\text{in}}{\text{ft}}\right)(4\,\text{in})}{256\,\text{in}^4} = 266.6\,\text{lbf/in}^2$$

15. STRAIN ENERGY DUE TO BENDING MOMENT

The elastic strain energy due to a bending moment stored in a beam is

$$U = \frac{1}{2EI}\int M^2(x)\,dx \qquad 44.41$$

The use of Eq. 44.41 is illustrated by Ex. 44.10.

16. ECCENTRIC LOADING OF AXIAL MEMBERS

If a load is applied through the centroid of a tension or compression member's cross section, the loading is said to be *axial loading* or *concentric loading*. *Eccentric loading* occurs when the load is not applied through the centroid.

If an axial member is loaded eccentrically, it will bend and experience bending stress in the same manner as a beam. Since the member experiences both axial stress and bending stress, it is known as a *beam-column*. In Fig. 44.14, e is known as the *eccentricity*.

Structural

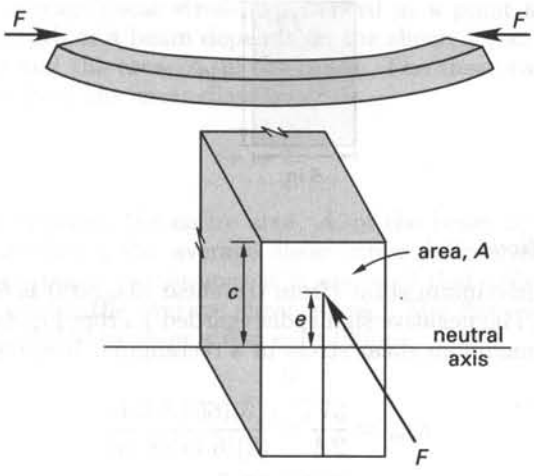


Figure 44.14 *Eccentric Loading of an Axial Member*

Both the axial stress and bending stress are normal stresses oriented in the same direction; therefore, simple addition can be used to combine them. Combined stress theory is not applicable. By convention, F is negative if the force compresses the member (as shown in Fig. 44.14).

$$\sigma_{\max,\min} = \frac{F}{A} \pm \frac{Mc}{I_c} \qquad 44.42$$

$$= \frac{F}{A} \pm \frac{Fec}{I_c} \qquad 44.43$$

If a pier or column (primarily designed as a compression member) is loaded with an eccentric compressive load, part of the section can still be placed in tension. Tension will exist when the Mc/I_c term in Eq. 44.42 is larger than the F/A term. It is particularly important to eliminate or severely limit tensile stresses in concrete and masonry piers, since these materials cannot support tension.

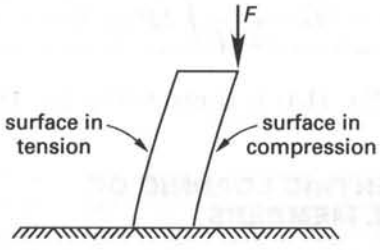

Figure 44.15 *Tension in a Pier*

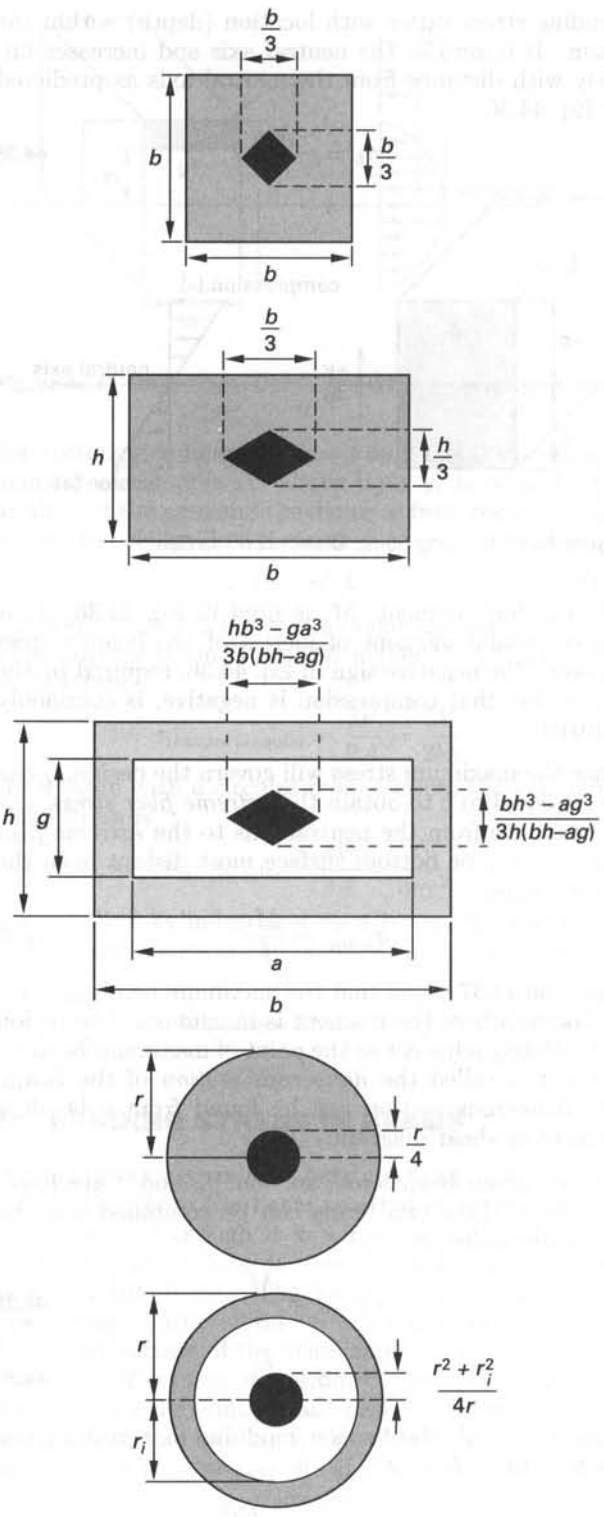
Regardless of the size of the load, there will be no tension as long as the eccentricity is low. In a rectangular member, the load must be kept within a rhombus-shaped area formed from the middle thirds of the centroidal axes. This area is known as the *core*, *kern*, or *kernel*. Figure 44.16 illustrates the kernel for other cross sections.



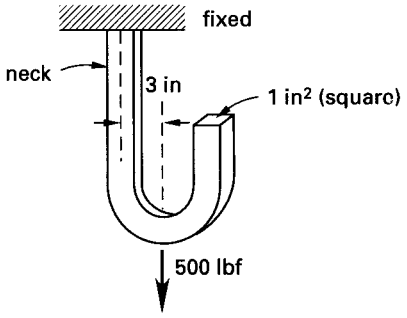


Figure 44.16 *Kerns of Common Cross Sections*

Example 44.6

A built-in hook with a cross section of 1 in × 1 in carries a load of 500 lbf, but the load is not in line with the centroidal axis of the hook's neck. What are the minimum stresses in the neck? Is the neck in tension everywhere?

Solution

The centroidal moment of inertia of a 1 in × 1 in section is

$$I_c = \frac{bh^3}{12} = \frac{(1\text{ in})(1\text{ in})^3}{12} = 0.0833\,\text{in}^4$$

The hook is eccentrically loaded with an eccentricity of 3 in. From Eq. 44.43, the total stress is the sum of the direct axial tension and the bending stress. As the hook bends to reduce the eccentricity, the inner face of the neck will receive a tensile bending stress. The outer face of the neck will receive a compressive bending stress.

$$\begin{aligned}\sigma_{\text{max,min}} &= \frac{F}{A} \pm \frac{Fec}{I} \\ &= \frac{500\text{ lbf}}{1\text{ in}^2} \pm \frac{(500\text{ lbf})(3\text{ in})(0.5\text{ in})}{0.0833\text{ in}^4} \\ &= 500\ \frac{\text{lbf}}{\text{in}^2} \pm 9000\ \frac{\text{lbf}}{\text{in}^2} \\ &= +9500\text{ lbf/in}^2,\ -8500\text{ lbf/in}^2\end{aligned}$$

The 500 lbf/in^2 direct stress is tensile, and the inner face experiences a total tensile stress of 9500 lbf/in^2. However, the compressive bending stress of 9000 lbf/in^2 counteracts the direct tensile stress, resulting in an 8500 lbf/in^2 compressive stress at the outer face of the neck.

17. BEAM DEFLECTION: DOUBLE INTEGRATION METHOD

The deflection and the slope of a loaded beam are related to the moment and shear by Eqs. 44.44 through 44.48.

$$y = \text{deflection} \qquad 44.44$$

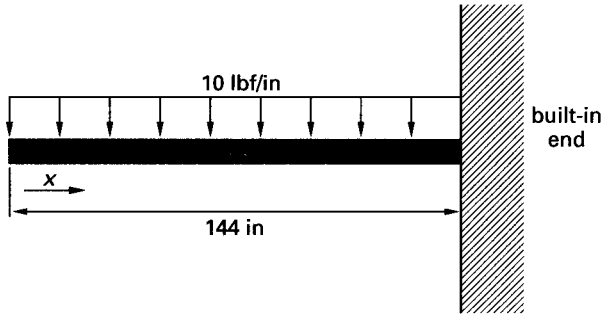
$$y' = \frac{dy}{dx} = \text{slope} \qquad 44.45$$

$$y'' = \frac{d^2y}{dx^2} = \frac{M(x)}{EI} \qquad 44.46$$

$$y''' = \frac{d^3y}{dx^3} = \frac{V(x)}{EI} \qquad 44.47$$

If the *moment function*, $M(x)$, is known for a section of the beam, the deflection at any point can be found from Eq. 44.48.

$$y = \frac{1}{EI}\int\left(\int M(x)\,dx\right)dx \qquad 44.48$$



In order to find the deflection, constants must be introduced during the integration process. These constants can be found from Table 44.3.

Table 44.3 *Beam Boundary Conditions*

end condition	y	y'	y''	V	M
simple support	0				0
built-in support	0	0			
free end			0	0	0
hinge					0

Example 44.7

Find the tip deflection of the beam shown. EI is 5×10^{10} lbf-in^2 everywhere.

Solution

The moment at any point x from the left end of the beam is

$$M(x) = -10x\left(\tfrac{1}{2}x\right) = -5x^2$$

This is negative by the left-hand rule convention. From Eq. 44.46,

$$y'' = \frac{M(x)}{EI}$$

$$EIy'' = M(x) = -5x^2$$

$$EIy' = \int -5x^2\,dx = -\tfrac{5}{3}x^3 + C_1$$

Since $y' = 0$ at a built-in support (Table 44.3) and $x = 144$ in at the built-in support,

$$0 = \left(-\tfrac{5}{3}\right)(144)^3 + C_1$$

$$C_1 = 4.98 \times 10^6$$

$$\begin{aligned}EIy &= \int\left(-\tfrac{5}{3}x^3 + 4.98\times10^6\right)dx \\ &= -\tfrac{5}{12}x^4 + (4.98\times10^6)x + C_2\end{aligned}$$

Again, $y = 0$ at $x = 144$, so $C_2 = -5.38 \times 10^8$. Therefore, the deflection as a function of x is

$$y = \left(\frac{1}{EI}\right)\left(\left(-\tfrac{5}{12}\right)x^4 + (4.98 \times 10^6)x - (5.38 \times 10^8)\right)$$

At the tip $x = 0$, so the deflection is

$$y_{\text{tip}} = \frac{-5.38 \times 10^8 \text{ in}^4}{5 \times 10^{10} \text{ in}^3} = -0.0108 \text{ in}$$

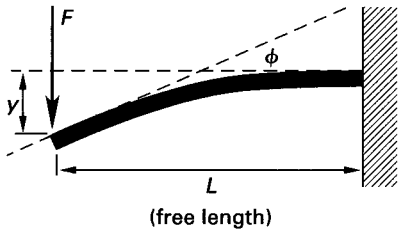
18. BEAM DEFLECTION: MOMENT AREA METHOD

The moment area method is a semigraphical technique that is applicable whenever slopes of deflection beams are not too great. This method is based on the following two theorems.

- *Theorem I:* The angle between tangents at any two points on the *elastic line* of a beam is equal to the area of the moment diagram between the two points divided by EI. That is,

$$\phi = \int \frac{M(x)\,dx}{EI} \qquad 44.49$$

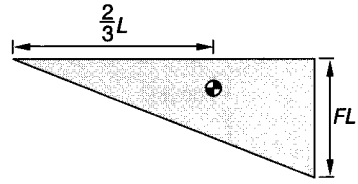
- *Theorem II:* One point's deflection away from the tangent of another point is equal to the *statical moment* of the bending moment between those two points divided by EI. That is,



$$y = \int \frac{xM(x)\,dx}{EI} \qquad 44.50$$

If EI is constant, the statical moment $\int xM(x)\,dx$ can be calculated as the product of the total moment diagram area times the distance from the point whose deflection is wanted to the centroid of the moment diagram.

If the moment diagram has positive and negative parts (areas above and below the zero line), the statical moment should be taken as the sum of two products, one for each part of the moment diagram.



Example 44.8

Find the deflection, y, and the angle, ϕ, at the free end of the cantilever beam shown. Neglect the beam weight.

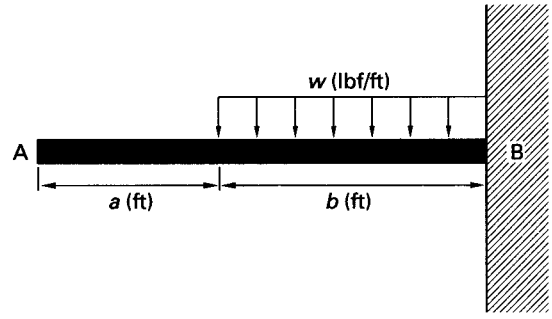
Solution

The deflection angle, ϕ, is the angle between the tangents at the free and built-in ends (Theorem I). The moment diagram is

The area of the moment diagram is

$$\tfrac{1}{2}(FL)(L) = \tfrac{1}{2}FL^2$$

From Eq. 44.49,

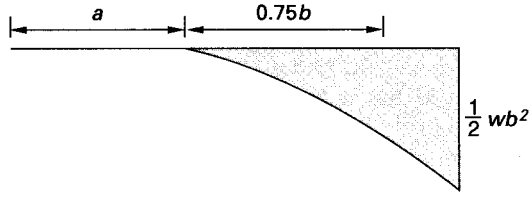


$$\phi = \frac{FL^2}{2EI}$$

From Eq. 44.50,

$$y = \left(\frac{FL^2}{2EI}\right)\left(\tfrac{2}{3}L\right) = \frac{FL^3}{3EI}$$

Example 44.9

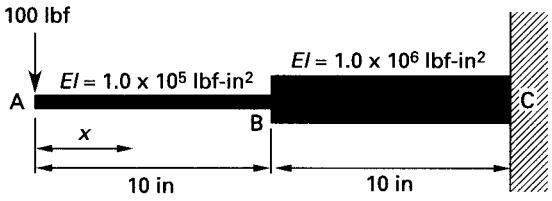


Find the deflection of the free end of the cantilever beam shown. Neglect the beam weight.

Solution

The distance from point A (where the deflection is wanted) to the centroid is $a + 0.75b$. The area of the moment diagram is $wb^3/6$. From Theorem II,

$$y = \left(\frac{wb^3}{6EI}\right)(a + 0.75b)$$



19. BEAM DEFLECTION: STRAIN ENERGY METHOD

The deflection at a point of load application can be found by the strain energy method. This method equates the external work to the total internal strain energy. Since work is a force moving through a distance (which in this case is the deflection), Eq. 44.51 holds true.

$$\tfrac{1}{2}Fy = \sum U \qquad 44.51$$

Example 44.10

Find the deflection at the tip of the stepped beam shown.

Solution

In section A–B, $M(x) = 100x$ in-lbf.

From Eq. 44.41,

$$U = \frac{1}{2EI}\int M^2(x)\,dx$$

$$= \frac{1}{(2)(1\times 10^5)}\int_0^{10}(100x)^2 = 16.67 \text{ in-lbf}$$

In section B–C, $M = 100x$.

$$U = \frac{1}{(2)(1\times 10^6)}\int_{10}^{20}(100x)^2 = 11.67 \text{ in-lbf}$$

Equating the internal work (U) and the external work,

$$\sum U = W$$

$$16.67 \text{ in-lbf} + 11.67 \text{ in-lbf} = \left(\tfrac{1}{2}\right)(100 \text{ lbf})y$$

$$y = 0.567 \text{ in}$$

20. BEAM DEFLECTION: CONJUGATE BEAM METHOD

The *conjugate beam method* changes a deflection problem into one of drawing moment diagrams. The method has the advantage of being able to handle beams of varying cross sections (e.g., stepped beams) and materials. It has the disadvantage of not easily being able to handle beams with two built-in ends. The following steps constitute the conjugate beam method.

step 1: Draw the moment diagram for the beam as it is actually loaded.

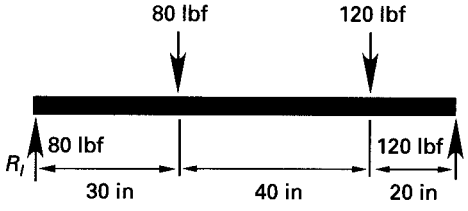
step 2: Construct the M/EI diagram by dividing the value of M at every point along the beam by EI at that point. If the beam is of constant cross section, EI will be constant, and the M/EI diagram will have the same shape as the moment diagram. However, if the beam cross section varies with x, I will change. In that case, the M/EI diagram will not look the same as the moment diagram.

step 3: Draw a conjugate beam of the same length as the original beam. The material and the cross-sectional area of this conjugate beam are not relevant.

(a) If the actual beam is simply supported at its ends, the conjugate beam will be simply supported at its ends.

(b) If the actual beam is simply supported away from its ends, the conjugate beam has hinges at the support points.

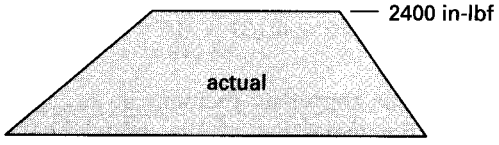
(c) If the actual beam has free ends, the conjugate beam has built-in ends.



(d) If the actual beam has built-in ends, the conjugate beam has free ends.

step 4: Load the conjugate beam with the M/EI diagram. Find the conjugate reactions by methods of statics. Use the superscript * to indicate conjugate parameters.

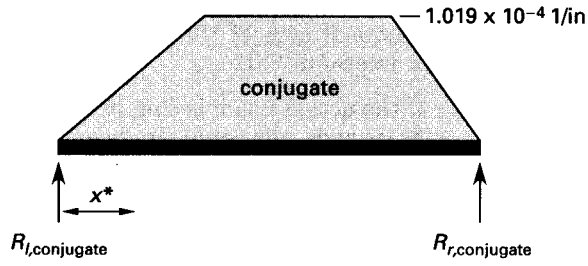
step 5: Find the conjugate moment at the point where the deflection is wanted. The deflection is numerically equal to the moment as calculated from the conjugate beam forces.



Example 44.11

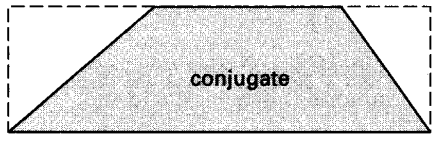
Find the deflections at the two load points. EI has a constant value of 2.356×10^7 lbf-in^2.

Solution



step 1: The moment diagram for the actual beam is

Structural



steps 2, 3, and 4: Since the beam cross section is constant, the conjugate load has the same shape as the original moment diagram. The peak load on the conjugate beam is

$$\frac{2400\text{ in-lbf}}{2.356 \times 10^7\text{ lbf-in}^2} = 1.019 \times 10^{-4}\text{ 1/in}$$

The conjugate reaction, $R_{l,\text{conjugate}}$, is found by the following method. The loading diagram is assumed to be made up of a rectangular load and two negative triangular loads. The area of the rectangular load (which has a centroid at $x_{\text{conjugate}} = 45$ in) is $(90\text{ in})(1.019 \times 10^{-4}\text{ 1/in}) = 9.171 \times 10^{-3}$.

Similarly, the area of the left triangle (which has a centroid at $x_{\text{conjugate}} = 10$ in) is $(1/2)(30\text{ in})(1.019 \times 10^{-4}\text{ 1/in}) = 1.529 \times 10^{-3}$. The area of the right triangle (which has a centroid at $x_{\text{conjugate}} = 83.33$ in) is $(1/2)(20\text{ in})(1.019 \times 10^{-4}\text{ 1/in}) = 1.019 \times 10^{-3}$.

$$\begin{aligned}\sum M_L^* &= (90\text{ in})R_{r,\text{conjugate}} + (1.019 \times 10^{-3}) \\ &\quad \times (83.3\text{ in}) \\ &\quad + (1.529 \times 10^{-3})(10\text{ in}) \\ &\quad - (9.171 \times 10^{-3})(45\text{ in}) \\ &= 0\end{aligned}$$

$$R_{r,\text{conjugate}} = 3.472 \times 10^{-3}$$

Then,

$$\begin{aligned}R_{l,\text{conjugate}} &= (9.171 - 1.019 \\ &\quad - 1.529 - 3.472) \times 10^{-3} \\ &= 3.151 \times 10^{-3}\end{aligned}$$

step 5: The conjugate moment at $x_{\text{conjugate}} = 30$ is the deflection of the actual beam at that point.

$$\begin{aligned}M_{\text{conjugate}} &= (3.151 \times 10^{-3})(30\text{ in}) \\ &\quad + (1.529 \times 10^{-3})(30\text{ in} - 10\text{ in}) \\ &\quad - (9.171 \times 10^{-3})\left(\frac{30\text{ in}}{90\text{ in}}\right)(15\text{ in}) \\ &= 7.926 \times 10^{-2}\text{ in}\end{aligned}$$

The conjugate moment (the deflection) at the right-most load is

$$\begin{aligned}M_{\text{conjugate}} &= (3.472 \times 10^{-3})(20\text{ in}) \\ &\quad + (1.019 \times 10^{-3})(13.3\text{ in}) \\ &\quad - (9.171 \times 10^{-3})\left(\frac{20\text{ in}}{90\text{ in}}\right)(10\text{ in}) \\ &= 6.261 \times 10^{-2}\text{ in}\end{aligned}$$

21. BEAM DEFLECTION: TABLE LOOK-UP METHOD

Appendix 44.A is a compilation of the most commonly used beam deflection formulas. These formulas should never need to be derived and should be used whenever possible. They are particularly useful in calculating deflections due to multiple loads using the principle of superposition.

The actual deflection of very *wide beams* (i.e., those whose widths are larger than 8 or 10 times the thickness) is less than that predicted by the equations in App. 44.A for elastic behavior. (This is particularly true for leaf springs.) The large width prevents lateral expansion and contraction of the beam material, reducing the deflection. For wide beams, the calculated deflection should be reduced by multiplying by $(1-\nu^2)$.

22. BEAM DEFLECTION: SUPERPOSITION

When multiple loads act simultaneously on a beam, all of the loads contribute to deflection. The principle of *superposition* permits the deflections at a point to be calculated as the sum of the deflections from each individual load acting singly.[9] This principle is valid as long as none of the deflections is excessive and all stresses are kept less than the yield point of the beam material.

23. INFLECTION POINTS

The *inflection point* (also known as a *point of contraflexure*) on a horizontal beam in elastic bending occurs where the curvature changes from concave up to concave down, or vice versa. There are three ways of determining the inflection point.

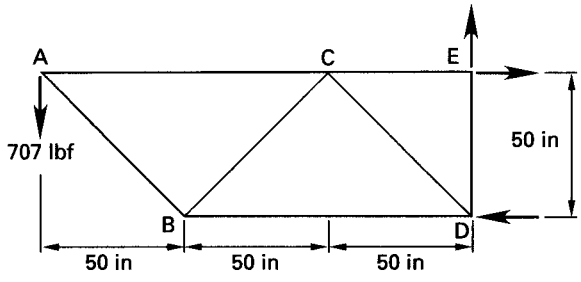
(1) If the elastic deflection equation, $y(x)$, is known, the inflection point can be found consistent with normal calculus methods (i.e., by determining the value of x for which $y''(x) = M(x) = 0$).

[9]The principle of superposition is not limited to deflections. It can also be used to calculate the shear and moment at a point and to draw the shear and moment diagrams.

(2) From Eq. 44.46, $y''(x) = M(x)/EI$. y'' is also the reciprocal of the *radius of curvature*, ρ, of the beam. Therefore,

$$y''(x) = \frac{1}{\rho(x)} = \frac{M(x)}{EI} \qquad 44.52$$

Since the flexural rigidity, EI, is always positive, the radius of curvature, $\rho(x)$, changes sign when the moment equation, $M(x)$, changes sign.



(3) If a shear diagram is known, the inflection point can sometimes be found by noting the point at which the positive and negative shear areas on either side of the point balance.

24. TRUSS DEFLECTION: STRAIN ENERGY METHOD

The deflection of a truss at the point of a single load application can be found by the *strain energy method* if all member forces are known. This method is illustrated by Ex. 44.12.

Example 44.12

Find the vertical deflection of point A under the external load of 707 lbf. $AE = 10^6$ lbf for all members. The internal forces have already been determined.

Solution

The length of member AB is $\sqrt{(50\text{ in})^2 + (50\text{ in})^2} = 70.7$ in. From Eq. 44.6, the internal strain energy in member AB is

$$U = \frac{F^2 L_o}{2AE} = \frac{(-1000\text{ lbf})^2(70.7\text{ in})}{(2)(10^6\text{ lbf})} = 35.4\text{ in-lbf}$$

Similarly, the energy in all members can be determined.

member	L (in)	F (lbf)	U (in-lbf)
AB	70.7	−1000	+35.4
BC	70.7	+1000	+35.4
AC	100	+707	+25.0
BD	100	−1414	+100.0
CD	70.7	−1000	+35.4
CE	50	+2121	+112.5
DE	50	+707	+12.5
			356.2

The work done by a constant force F moving through a distance y is Fy. In this case, the force increases with y. The average force is $\frac{1}{2}F$. The external work is $W_{\text{ext}} = \left(\frac{1}{2}\right)(707\text{ lbf})y$, so

$$\left(\tfrac{1}{2}\right)(707\text{ lbf})y = 356.2\text{ in-lbf}$$

$$y = 1\text{ in}$$

25. TRUSS DEFLECTION: VIRTUAL WORK METHOD

The *virtual work method* (also known as the *unit load method* and the *Hardy Cross method*) is an extension of the strain energy method.[10] It can be used to determine the deflection of any point on a truss.

step 1: Draw the truss twice.

step 2: On the first truss, place all the actual loads.

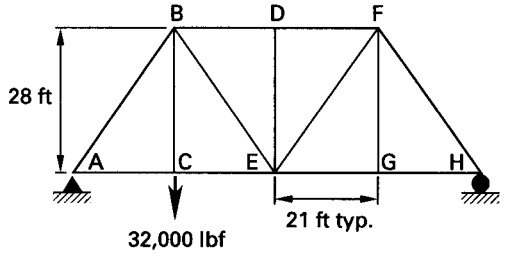
step 3: Find the forces, S, due to the actual applied loads in all the members.

step 4: On the second truss, place a dummy one-unit load in the direction of the desired displacement.

step 5: Find the forces, u, due to the one-unit dummy load in all members.

step 6: Find the desired displacement from Eq. 44.53. The summation is over all truss members that have nonzero forces in *both* trusses.

$$\delta = \sum \frac{SuL}{AE} \qquad 44.53$$

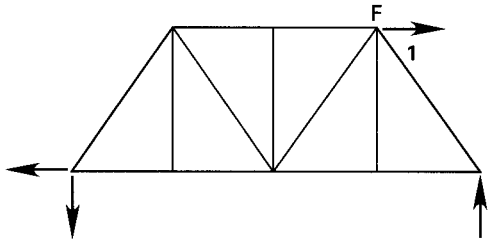


Example 44.13

What is the horizontal deflection of joint F on the truss shown? Use $E = 3 \times 10^7$ lbf/in^2. Joint A is restrained horizontally.

Solution

steps 1 and 2: Use the truss as drawn.



step 3: The forces in all the truss members are summarized in step 5.

[10]Not to be confused with the Hardy Cross method for determining flows in a piping network by way of iterative calculations.

Structural

step 4: Draw the truss and load it with a unit horizontal force at point F.

step 5: Find the forces, u, in all members of the second truss. These are summarized in the following table. Notice the sign convention: + for tension and − for compression.

member	S (lbf)	u (lbf)	L (ft)	A (in^2)	$\frac{SuL}{AE}$ (ft)
AB	−30,000	5/12	35	17.5	-8.33×10^{-4}
CB	32,000	0	28	14	0
EB	−10,000	−5/12	35	17.5	2.75×10^{-4}
ED	0	0	28	14	0
EF	10,000	5/12	35	17.5	2.78×10^{-4}
GF	0	0	28	14	0
HF	−10,000	−5/12	35	17.5	2.78×10^{-4}
BD	−12,000	1/2	21	10.5	-4.00×10^{-4}
DF	−12,000	1/2	21	10.5	-4.00×10^{-4}
AC	18,000	3/4	21	10.5	9.00×10^{-4}
CE	18,000	3/4	21	10.5	9.00×10^{-4}
EG	6000	1/4	21	10.5	1.00×10^{-4}
GH	6000	1/4	21	10.5	1.00×10^{-4}
					12.01×10^{-4}

Since 12.01×10^{-4} is positive, the deflection is in the direction of the dummy unit load. In this case, the deflection is to the right.

26. MODES OF BEAM FAILURE

Beams can fail in different ways, including excessive deflection, local buckling, lateral buckling, and rotation.

Excessive deflection occurs when a beam bends more than a permitted amount.[11] The deflection is elastic and no yielding occurs. For this reason, the failure mechanism is sometimes called *elastic failure*. Although the beam does not yield, the excessive deflection may cause cracks in plaster and sheetrock, misalignment of doors and windows, and occupant concern and lack of confidence in the structure.

Local buckling is an overload condition that occurs near large concentrated loads. Such locations include where a column frames into a supporting girder or a reaction point. *Vertical buckling* and *web crippling*, two types of local buckling, can be eliminated by use of *stiffeners*. Such stiffeners can be referred to as *intermediate stiffeners*, *bearing stiffeners*, *web stiffeners*, and *flange stiffeners*, depending on the location and technique of stiffening.

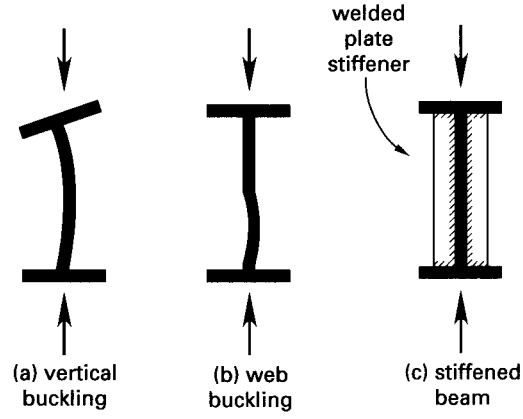


Figure 44.17 *Local Buckling and Stiffeners*

Lateral buckling, such as illustrated in Fig. 44.18, occurs when a long, unsupported member rolls out of its normal plane. To prevent lateral buckling, the beam's compression flange must be supported continuously or at frequent intervals along its length.

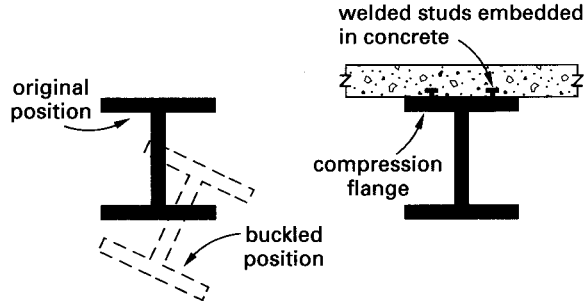

Figure 44.18 *Lateral Buckling and Flange Support*

Rotation is an inelastic (plastic) failure of the beam. When the bending stress at a point exceeds the strength of the beam material, the material yields. As the beam yields, its slope changes. Since the beam appears to be rotating at a hinge at the yield point, the term *plastic hinge* is used to describe the failure mechanism.

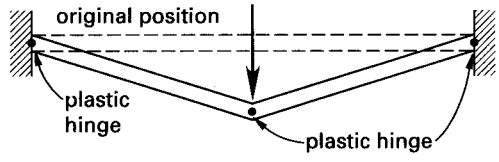

Figure 44.19 *Beam Failure by Rotation*

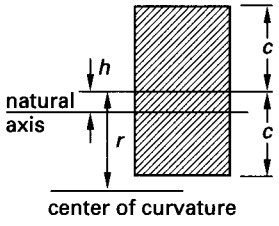
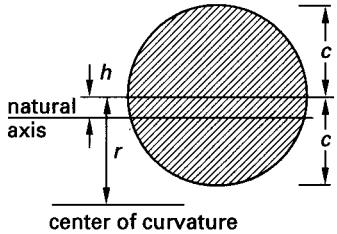
[11]The Uniform Building Code, as well as the steel, concrete, and timber codes, specifies maximum permitted deflections in terms of beam length.

27. CURVED BEAMS

Many members (e.g., hooks, chain links, clamps, and machine frames) have curved main axes. The distribution of bending stress in a curved beam is nonlinear. Compared to a straight beam, the stress at the inner radius is higher because the inner radius fibers are shorter. Conversely, the stress at the outer radius is lower because the outer radius fibers are longer. Also, the neutral axis is shifted from the center inward toward the center of curvature.



Since the process of finding the neutral axis and calculating the stress amplification is complex, tables and graphs are used for quick estimates and manual computations. The forms of these computational aids vary, but the straight-beam stress is generally multiplied by factors, K, to obtain the stresses at the extreme faces. The factor values depend on the beam cross section and radius of curvature.



$$\sigma_{\text{curved}} = K\sigma_{\text{straight}}$$

$$= \frac{KMc}{I}$$

Table 44.4 is typical of compilations for round and rectangular beams. Factors K_A and K_B are the multipliers for the inner (high stress) and outer (low stress) faces. The ratio h/r is the fractional distance that the neutral axis shifts inward toward the radius of curvature.

Table 44.4 *Curved Beam Correction Factors*

solid rectangular section	r/c	K_A	K_B	h/r
	1.2	2.89	0.57	0.305
	1.4	2.13	0.63	0.204
	1.6	1.79	0.67	0.149
	1.8	1.63	0.70	0.112
	2.0	1.52	0.73	0.90
	3.0	1.30	0.81	0.041
	4.0	1.20	0.85	0.021
	6.0	1.12	0.90	0.0093
	8.0	1.09	0.92	0.0052
	10.0	1.07	0.94	0.0033

solid circular section	r/c	K_A	K_B	h/r
	1.2	3.41	0.54	0.224
	1.4	2.40	0.60	0.151
	1.6	1.96	0.65	0.108
	1.8	1.75	0.68	0.084
	2.0	1.62	0.71	0.069
	3.0	1.33	0.79	0.03
	4.0	1.23	0.84	0.016
	6.0	1.14	0.89	0.007
	8.0	1.10	0.91	0.0039
	10.0	1.08	0.93	0.0025

28. COMPOSITE STRUCTURES

A *composite structure* is one in which two or more different materials are used. Each material carries part of an applied load. Examples of composite structures include steel-reinforced concrete and steel-plated timber beams.

Most simple composite structures can be analyzed using the *method of consistent deformations*, also known as the *area transformation method*. This method assumes that the strains are the same in both materials at the interface between them. Although the strains are the same, the stresses in the two adjacent materials are not equal, since stresses are proportional to the moduli of elasticity.

The following steps comprise an analysis method based on area transformation.

step 1: Determine the modulus of elasticity for each of the materials used in the structure.

step 2: For each of the materials used, calculate the *modular ratio*, n.

$$n = \frac{E}{E_{\text{weakest}}} \qquad 44.54$$

E_{weakest} is the smallest modulus of elasticity of any of the materials used in the composite structure.

step 3: For all of the materials except the weakest, multiply the actual material stress area by n. Consider this expanded *(transformed)* area to have the same composition as the weakest material.

step 4: If the structure is a tension or compression member, the distribution or placement of the transformed area is not important. Just assume that the transformed areas carry the axial load. For beams in bending, the transformed area can add to the width of the beam, but it cannot change the depth of the beam or the thickness of the reinforcement.

step 5: For compression or tension numbers, calculate the stresses in the weakest and stronger materials.

$$\sigma_{\text{weakest}} = \frac{F}{A_t} \qquad 44.55$$

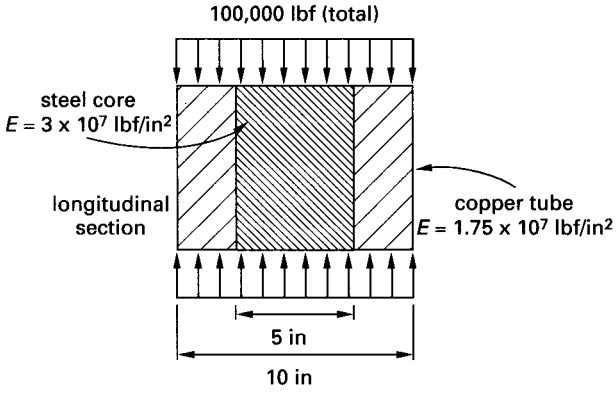
$$\sigma_{\text{stronger}} = \frac{nF}{A_t} \qquad 44.56$$

step 6: For beams in bending, proceed through step 9. Find the centroid of the transformed beam.

step 7: Find the centroidal moment of inertia of the transformed beam $I_{c,t}$.

step 8: Find $V_{\max}$ and $M_{\max}$ by inspection or from the shear and moment diagrams.

Structural



step 9: Calculate the stresses in the weakest and stronger materials.

$$\sigma_{\text{weakest}} = \frac{Mc_{\text{weakest}}}{I_{c,t}} \qquad 44.57$$

$$\sigma_{\text{stronger}} = \frac{nMc_{\text{stronger}}}{I_{c,t}} \qquad 44.58$$

Example 44.14

A short circular steel core is surrounded by a copper tube. The assemblage supports an axial compressive load of 100,000 lbf. The core and tube are well bonded, and the load is applied uniformly. Find the compressive stress in the inner steel core and the outer copper tube.

Solution

The moduli of elasticity are given in the illustration. From step 2, the modular ratio is

$$n = \frac{E_{\text{steel}}}{E_{\text{copper}}} = \frac{3 \times 10^7 \ \frac{\text{lbf}}{\text{in}^2}}{1.75 \times 10^7 \ \frac{\text{lbf}}{\text{in}^2}} = 1.714$$

The actual cross-sectional area of the steel is

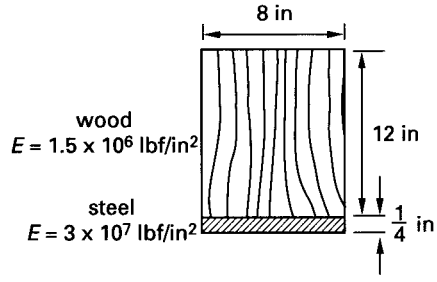
$$A_{\text{steel}} = \frac{\pi}{4}d^2 = \left(\frac{\pi}{4}\right)(5 \text{ in})^2 = 19.63 \text{ in}^2$$

The actual cross-sectional area of the copper is

$$A_{\text{copper}} = \frac{\pi}{4}\left(d_o^2 - d_i^2\right) = \left(\frac{\pi}{4}\right)\left((10 \text{ in})^2 - (5 \text{ in})^2\right) = 58.90 \text{ in}^2$$

The steel is the stronger material. Its area must be expanded to an equivalent area of copper. From step 3, the total transformed area is

$$A_t = A_{\text{copper}} + nA_{\text{steel}} = 58.90 \text{ in}^2 + (1.714)(19.63 \text{ in}^2) = 92.55 \text{ in}^2$$



Since the two pieces are well bonded and the load is applied uniformly, both pieces experience identical strains. From step 5, the compressive stresses are

$$\sigma_{\text{copper}} = \frac{F}{A_t} = \frac{-100{,}000 \text{ lbf}}{92.55 \text{ in}^2} = -1080 \text{ lbf/in}^2 \quad \text{[compression]}$$

$$\sigma_{\text{steel}} = \frac{nF}{A_t} = n\sigma_{\text{copper}} = (1.714)\left(-1080 \ \frac{\text{lbf}}{\text{in}^2}\right) = -1851 \text{ lbf/in}^2$$

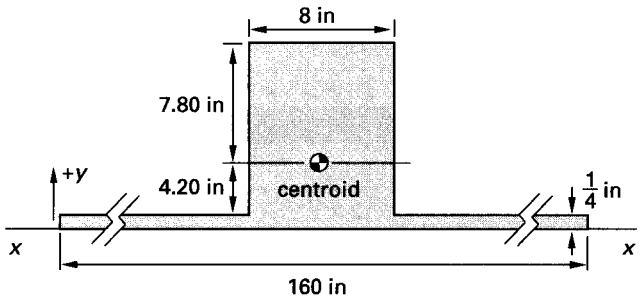
Example 44.15

At a particular point along the length of a steel-reinforced wood beam, the moment is 40,000 ft-lbf. Assume the steel reinforcement is lag-bolted to the wood at regular intervals along the beam. What is the maximum bending stress in the wood and steel?

Solution

The moduli of elasticity are given in the illustration. From step 2, the modular ratio is

$$n = \frac{E_{\text{steel}}}{E_{\text{wood}}} = \frac{3 \times 10^7 \ \frac{\text{lbf}}{\text{in}^2}}{1.5 \times 10^6 \ \frac{\text{lbf}}{\text{in}^2}} = 20$$



The actual cross-sectional area of the steel is

$$A_{\text{steel}} = (0.25 \text{ in})(8 \text{ in}) = 2 \text{ in}^2$$

The steel is the stronger material. Its area must be expanded to an equivalent area of wood. Since the depth of the beam and reinforcement cannot be increased (step 4), the width must increase. The width of the transformed steel plate is

$$b' = nb = (20)(8 \text{ in}) = 160 \text{ in}$$

The centroid of the transformed section is located 4.45 in from the horizontal axis. The centroidal moment of inertia of the transformed section is $I_{c,t} = 2211.5 \text{ in}^4$. (The calculations for centroidal location and moment of inertia are not presented here.)

Since the steel plate is bolted to the wood at regular intervals, both pieces experience the same strain. From step 9, the stresses in the wood and steel are

$$\sigma_{\text{max,wood}} = \frac{Mc_{\text{wood}}}{I}$$

$$= \frac{(40{,}000 \text{ ft-lbf})\left(12 \frac{\text{in}}{\text{ft}}\right)(7.8 \text{ in})}{2211.5 \text{ in}^4}$$

$$= 1693 \text{ lbf/in}^2$$

$$\sigma_{\text{max,steel}} = \frac{nMc_{\text{steel}}}{I}$$

$$= \frac{(20)(40{,}000 \text{ ft-lbf})\left(12 \frac{\text{in}}{\text{ft}}\right)(4.45 \text{ in})}{2211.5 \text{ in}^4}$$

$$= 19{,}317 \text{ lbf/in}^2$$

PRACTICE PROBLEMS

Elastic Deformation

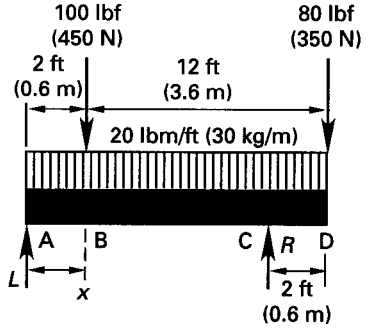
1. A 1 in (25 mm) diameter soft steel rod carries a tensile load of 15,000 lbf (67 kN). The elongation is 0.158 in (4 mm). The modulus of elasticity is 2.9×10^7 lbf/in^2 (200 GPa). What is the total length of the rod?

(A) 239.46 in (5.853 m)
(B) 239.93 in (5.857 m)
(C) 240.03 in (5.861 m)
(D) 240.07 in (5.865 m)

The answer is (D).

Thermal Deformation

2. A straight steel beam 200 ft (60 m) long is installed when the temperature is 40°F (4°C). It is supported in such a manner as to allow only 0.5 in (12 mm) longitudinal expansion. Lateral support is provided to prevent buckling. If the temperature increases to 110°F (43°C), what will be the compressive stress in the member?



(A) 3900 lbf/in^2 (28 MPa)
(B) 7400 lbf/in^2 (51 MPa)
(C) 9200 lbf/in^2 (67 MPa)
(D) 12,000 lbf/in^2 (88 MPa)

The answer is (B).

Shear and Moment Diagrams

3. A beam 25 ft long is simply supported at two points: at its left and 5 ft from its right end. A uniform load of 2 kips/ft extends over a 10 ft length starting from the left end. There is a concentrated 10 k load at the right end. Draw the shear and moment diagrams.

4. A beam 14 ft (4.2 m) long is supported at the left end and 2 ft (0.6 m) from the right end. The beam has a mass of 20 lbm/ft (30 kg/m). A 100 lbf (450 N) load is applied 2 ft (0.6 m) from the left end. An 80 lbf (350 N) load is applied at the right end.

(a) What is the maximum moment?

(A) 150 ft-lbf (200 N·m)
(B) 250 ft-lbf (340 N·m)
(C) 390 ft-lbf (520 N·m)
(D) 830 ft-lbf (1100 N·m)

The answer is (C).

(b) What is the maximum shear?

(A) 80 lbf (360 N)
(B) 120 lbf (530 N)
(C) 150 lbf (650 N)
(D) 190 lbf (830 N)

The answer is (D).

Structural

Stresses in Beams

5. The allowable stress in a steel beam is 20 ksi. The maximum moment carried by the beam is 1.5×10^5 ft-lbf. What is the required section modulus?

(A) 90 in^3
(B) 110 in^3
(C) 120 in^3
(D) 350 in^3

The answer is (A).

6. A simply supported beam 14 ft long carries a uniform load of 200 lbf/ft over its entire length. The beam has a width of 3.625 in and a depth of 7.625 in.

(a) What is the maximum bending stress?

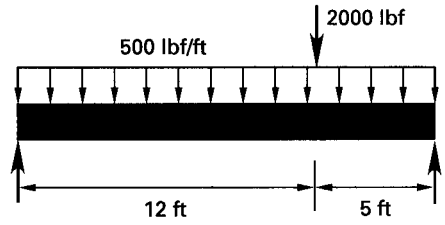
(A) 1700 lbf/in^2
(B) 2500 lbf/in^2
(C) 3700 lbf/in^2
(D) 9200 lbf/in^2

The answer is (A).

(b) What is the maximum shear stress?

(A) 38 lbf/in^2
(B) 76 lbf/in^2
(C) 150 lbf/in^2
(D) 300 lbf/in^2

The answer is (B).



Beam Deflections

7. A 40 ft long simply supported steel beam with a moment of inertia of I is reinforced along the central 20 ft, leaving the two 10 ft ends unreinforced. The moment of inertia of the reinforced sections is $2I$. A 20,000 lbf load is applied at midspan, 20 ft from each end. What is the deflection?

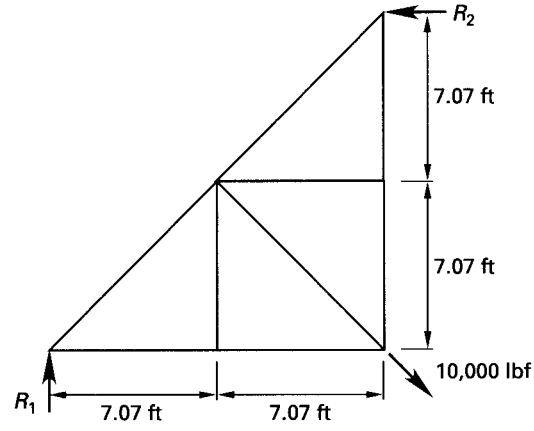
(A) $1.1 \times 10^6/EI$ ft
(B) $2.7 \times 10^6/EI$ ft
(C) $1.5 \times 10^7/EI$ ft
(D) $8.2 \times 10^7/EI$ ft

The answer is (C).

8. A 17 ft steel beam carries a uniform load of 500 lbf/ft over its entire length and a 2000 lbf concentrated load 5 ft from the right end, as shown. The beam is simply supported at each end. The centroidal moment of inertia of the cross section is 200 in^4. What is the midspan deflection?

(A) 0.05 in
(B) 0.20 in
(C) 0.40 in
(D) 0.70 in

The answer is (B).



9. A cantilever beam is 6 ft (1.8 m) in length. The cross section is 6 in wide by 4 in high (150 mm wide by 100 mm high). The modulus of elasticity is 1.5×10^6 psi (10 GPa). The beam is loaded by two concentrated forces: 200 lbf (900 N) located 1 ft (0.3 m) from the free end and 120 lbf (530 N) located 2 ft (0.6 m) from the free end. What is the tip deflection?

(A) 0.29 in (0.0084 m)
(B) 0.31 in (0.0090 m)
(C) 0.47 in (0.014 m)
(D) 0.55 in (0.015 m)

The answer is (D).

Truss Deflections

10. A steel truss with pinned joints is constructed as shown. Support R_1 is pinned. Support R_2 is a roller. The length:area ratio for each member is 50 in^{-1}. The modulus of elasticity of the steel is 2.9×10^7 lbf/in^2. What is the vertical deflection at the point where the 10,000 lbf load is applied?

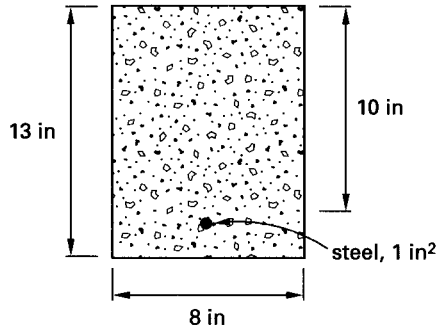
(A) 0.07 in
(B) 0.13 in
(C) 0.24 in
(D) 0.35 in

The answer is (A).

Composite Structures

11. A bimetallic spring is constructed of an aluminum strip with a 1/8 in by 1 1/2 in (3.2 mm by 38 mm) cross section bonded on top of a 1/16 in by 1 1/2 in (6.4 mm by 38 mm) steel strip. The modulus of elasticity of the aluminum is 10×10^6 lbf/in^2 (70 GPa). The modulus of elasticity of the steel is 30×10^6 lbf/in^2 (200 GPa). What is the equivalent, all-aluminum centroidal area moment of inertia of the cross section?

(A) 2.4×10^{-4} in^4 (190 mm^4)



(B) 5.2×10^{-4} in^4 (390 mm^4)

(C) 1.3×10^{-3} in^4 (550 mm^4)

(D) 2.6×10^{-3} in^4 (1100 mm^4)

The answer is (C).

12. The reinforced concrete beam illustrated is subjected to a maximum moment of 8125 ft-lbf. The total steel cross-sectional area is 1 in^2, assumed to be concentrated 10 in from the top surface. The modulus of elasticity of the concrete is 2×10^6 lbf/in^2, and the modulus of elasticity of the steel is 2.9×10^7 lbf/in^2. The bond between the steel and the concrete is perfect. The beam is balanced such that the concrete and steel fail simultaneously. The load-carrying contribution of concrete in tension is to be disregarded. Analyze the beam using the transformed area method.

(a) What is the maximum flexural stress in the concrete?

(A) 320 lbf/in^2

(B) 640 lbf/in^2

(C) 910 lbf/in^2

(D) 15,300 lbf/in^2

The answer is (B).

(b) What is the maximum flexural stress in the steel?

(A) 11,500 lbf/in^2

(B) 16,300 lbf/in^2

(C) 29,500 lbf/in^2

(D) 36,000 lbf/in^2

The answer is (A).

1. SLENDER COLUMNS

Very short compression members are known as *piers*. Long compression members are known as *columns*. Failure in piers occurs when the applied stress exceeds the yield strength of the material. However, very long columns fail by sideways *buckling* long before the compressive stress reaches the yield strength. Buckling failure is sudden, often without significant initial sideways bending. The load at which a column fails is known as the *critical load* or *Euler load*.

The *Euler load* is the theoretical maximum load that an initially straight column can support without buckling. For columns with frictionless or pinned ends, this load is given by Eq. 45.1.

$$F_e = \frac{\pi^2 EI}{L^2} = \frac{\pi^2 EA}{\left(\frac{L}{k}\right)^2} \qquad 45.1$$

The corresponding column stress is given by Eq. 45.2. This stress cannot exceed half of the compressive yield strength of the column material.

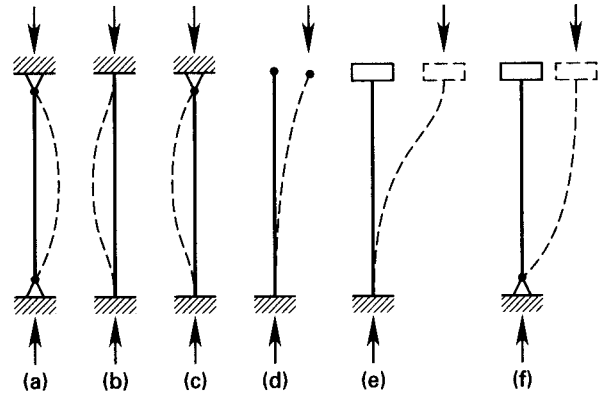
$$\sigma_e = \frac{F_e}{A} = \frac{\pi^2 E}{\left(\frac{L}{k}\right)^2} \qquad 45.2$$

The quantity L/k is known as the *slenderness ratio*. Long columns have high slenderness ratios. The smallest slenderness ratio for which Eq. 45.2 is valid is the *critical slenderness ratio*. Typical critical slenderness ratios range from 80 to 120. The critical slenderness ratio becomes smaller as the compressive yield strength increases.

L is the longest unbraced column length. If a column is braced against buckling at some point between its two ends, the column is known as a *braced column*, and L will be less than the full column height. Columns with rectangular cross sections have two radii of gyration, k_x and k_y, and therefore, will have two slenderness ratios. The smallest slenderness ratio will govern the design.

Columns do not always have frictionless or pinned ends. Often, a column will be fixed ("clamped," "built in," etc.) at its top and base. In such cases, the *effective length*, L', must be used in place of L in Eqs. 45.1 and 45.2.

$$L' = CL \qquad 45.3$$



$$\sigma_e = \frac{F_e}{A} = \frac{\pi^2 E}{\left(\frac{CL}{k}\right)^2} \qquad 45.4$$

C is the *end restraint coefficient*, which varies from 0.5 to 2.0 according to Table 45.1. For most real columns, the design values of C should be used since infinite stiffness of the supporting structure is not achievable.

Table 45.1 *Theoretical End Restraint Coefficients*

illus.	end conditions	C ideal	C recommended for design
(a)	both ends pinned	1	1.0*
(b)	both ends built in	0.5	0.65*–0.90
(c)	one end pinned, one end built in	0.707	0.80*–0.90
(d)	one end built in, one end free	2	2.0–2.1
(e)	one end built in, one end fixed against rotation but free	1	1.2*
(f)	one end pinned, one end fixed against rotation but free	2	2.0*

*AISC values

Euler's curve for columns, line BCD in Fig. 45.1, is generated by plotting the *Euler stress* (Eq. 45.2) versus the slenderness ratio. Since the material's compressive yield strength cannot be exceeded, a horizontal line AC is added to limit applications to the region below. Theoretically, members with slenderness ratios less than $(SR)_C$ could be treated as pure compression members. However, this is not done in practice.

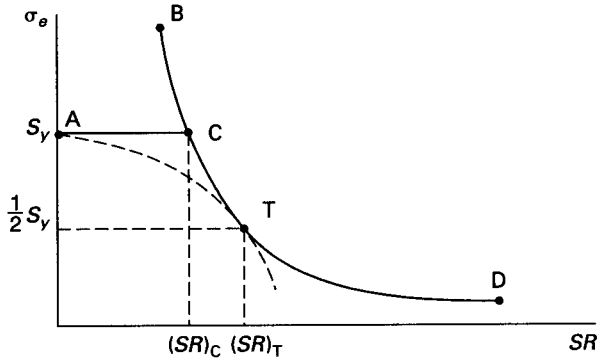


Figure 45.1 *Euler's Curve*

Defects in materials, errors in manufacturing, inabilities to achieve theoretical end conditions, and eccentricities frequently combine to cause column failures in the region around point C. Therefore, this region is excluded by designers.

The empirical procedure used to exclude the failure area is to draw a parabolic curve from point A through a tangent point T on the Euler curve at a stress of $^1/_2 S_y$. The corresponding value of the slenderness ratio of any end restraint coefficient, C, is

$$(SR)_{\mathrm{T}} = \sqrt{\frac{2\pi^2 CE}{S_y}} \qquad 45.5$$

Example 45.1

A steel member is used as an 8.5 ft long column. The ends are pinned. What is the maximum allowable compressive stress in order to have a factor of safety of 3.0? Use the following data for the column.

$$E = 2.9 \times 10^7 \text{ lbf/in}^2$$
$$S_{yt} = 36{,}000 \text{ lbf/in}^2$$
$$k = 0.569 \text{ in}$$

Solution

First, check the slenderness ratio to see if this is a long column.

$$\frac{L}{k} = \frac{(8.5 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{0.569 \text{ in}} = 179.3 \quad \text{[OK]}$$

From Eq. 45.2, the Euler stress is

$$\sigma_e = \frac{\pi^2 E}{\left(\frac{L}{k}\right)^2} = \frac{\pi^2 \left(2.9 \times 10^7 \frac{\text{lbf}}{\text{in}^2}\right)}{(179.3)^2}$$
$$= 8903 \text{ lbf/in}^2$$

Since 8903 lbf/in^2 is less than half of the yield strength of 36,000 lbf/in^2, the Euler formula is valid. The allowable working stress is

$$\sigma_a = \frac{\sigma_e}{\text{FS}} = \frac{8903 \frac{\text{lbf}}{\text{in}^2}}{3} = 2968 \text{ lbf/in}^2$$

2. INTERMEDIATE COLUMNS

Columns with slenderness ratios less than the critical slenderness ratio but that are too long to be piers are known as *intermediate columns*. The *parabolic formula* (also known as the *J. B. Johnson formula*) is used to describe the parabolic line between points A and T on Fig. 45.1. The critical stress is given by Eq. 45.6, where a and b are curve-fit constants.

$$\sigma_{\mathrm{cr}} = \frac{P_{\mathrm{cr}}}{A} = a - b\left(\frac{CL}{k}\right)^2 \qquad 45.6$$

It is commonly assumed that the stress at point A is S_y and the stress at point T is $S_y/2$. In that case, the parabolic formula becomes

$$\sigma_{\mathrm{cr}} = S_y - \left(\frac{1}{E}\right)\left(\frac{S_y}{2\pi}\right)^2\left(\frac{CL}{k}\right)^2 \qquad 45.7$$

3. ECCENTRICALLY LOADED COLUMNS

Accidental eccentricities are introduced during the course of normal manufacturing, so the load on real columns is rarely axial. The *secant formula* is one of the methods available for determining the critical column stress and critical load with eccentric loading.[1]

$$\sigma_{\max} = \sigma_{\text{ave}}(1 + \text{amplification factor})$$
$$= \left(\frac{F}{A}\right)\left(1 + \left(\frac{ec}{k^2}\right)\sec\left(\frac{\pi}{2}\sqrt{\frac{F}{F_e}}\right)\right)$$
$$= \left(\frac{F}{A}\right)\left(1 + \left(\frac{ec}{k^2}\right)\sec\left(\frac{L}{2k}\sqrt{\frac{F}{AE}}\right)\right)$$
$$= \left(\frac{F}{A}\right)\left(1 + \left(\frac{ec}{k^2}\right)\sec\phi\right) \qquad 45.8$$

$$\phi = \tfrac{1}{2}\left(\frac{L}{k}\right)\sqrt{\frac{F}{AE}} \qquad 45.9$$

For a given *eccentricity*, e, or eccentricity ratio, ec/k^2, and an assumed value of the buckling load, F, Eq. 45.9 is solved by trial and error for the slenderness ratio, L/k. Equations 45.8 and 45.9 converge quickly to the known L/k ratio when assumed values of F are substituted. (L/k is smaller when F is larger.)

4. THIN-WALLED CYLINDRICAL TANKS

In general, tanks under internal pressure experience circumferential, longitudinal, and radial stresses. If the wall thickness is small, the radial stress component is negligible and can be disregarded. A cylindrical tank is a *thin-walled tank* if its wall thickness-to-internal diameter ratio is less than approximately 0.1.[2]

$$\frac{t}{d_i} = \frac{t}{2r_i} < 0.1 \qquad \text{[thin-walled]} \qquad 45.10$$

The *hoop stress*, σ_h, also known as *circumferential stress* and *tangential stress*, for a cylindrical thin-walled tank

[1]The design of timber, steel, and reinforced concrete building columns is very code-intensive. None of the theoretical methods presented in this section is acceptable for building design.

[2]There is some confusion about the thin-wall/thick-wall criterion. This is because a cylinder is essentially thin-walled when $t/2r < 0.1$, but Lamé's solution is for thick-walled cylinders with $t/r > 0.1$. The latter (thick-wall) criterion should not be used to predict the applicability of the former (thin-wall) case.

Structural

under internal pressure is derived from the free-body diagram of a cylinder half.[3] Since the cylinder is assumed to be thin-walled, it is not important which radius (e.g., inner, mean, or outer) is used in Eq. 45.11. However, the inner radius is used by common convention.

$$\sigma_h = \frac{pr}{t} \qquad 45.11$$

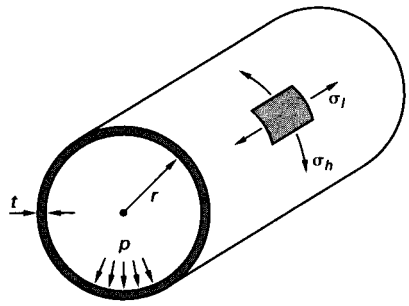

Figure 45.2 *Stresses in a Thin-Walled Tank*

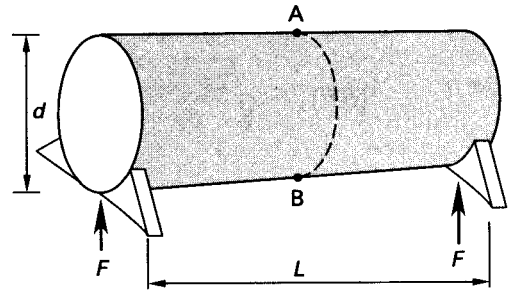
The axial forces on the ends of the cylindrical tank produce a stress, known as the *longitudinal stress* or *long stress*, σ_l, directed along the tank's longitudinal axis.

$$\sigma_l = \frac{pr}{2t} \qquad 45.12$$

Unless the tank is subject to torsion, there is no shear stress. Accordingly, the hoop and long stresses are the principal stresses. They do not combine into larger stresses. Their combined effect should be evaluated according to the appropriate failure theory.

The increase in length due to pressurization is easily determined from the longitudinal strain.



$$\begin{aligned}\Delta L &= L\epsilon_l \\ &= L\left(\frac{\sigma_l - \nu\sigma_h}{E}\right)\end{aligned} \qquad 45.13$$

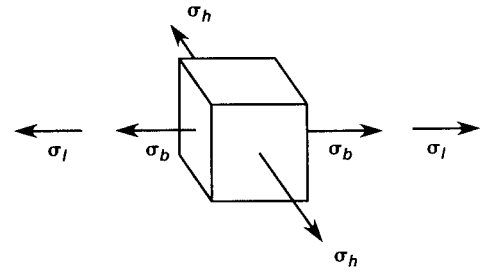
The increase in circumference (from which the radial increase can also be determined) due to pressurization is

$$\begin{aligned}\Delta C &= C\epsilon_h \\ &= \pi d_o\left(\frac{\sigma_h - \nu\sigma_l}{E}\right)\end{aligned} \qquad 45.14$$

Example 45.2

A thin-walled pressurized tank is supported at both ends, as shown. Points A and B are located midway between the supports and at the upper and lower surfaces, respectively. Evaluate the maximum stresses on the tank.

Solution



Since the tank is thin-walled, the radial stress is essentially zero. The hoop and longitudinal stresses are given by Eqs. 45.11 and 45.12, respectively. In addition, point A experiences a bending stress. The bending stress is

$$\sigma_b = \frac{Mc}{I}$$

$$c = \frac{d}{2}$$

$$M = \frac{FL}{2}$$

$$I = k^2A = \left(\frac{d}{2}\right)^2 \pi dt$$

The bending stress is compressive at point A and tensile at point B. At point B, the bending stress has the same sign (tensile) as the longitudinal stress, and these two stresses add to each other. There is no torsional stress, so the resultant normal stresses are the principal stresses.

$$\sigma_1 = \sigma_h$$

$$\sigma_2 = \sigma_l + \sigma_b$$

5. THICK-WALLED CYLINDERS

A thick-walled cylinder has a wall thickness-to-diameter ratio greater than 0.1. Figure 45.3 illustrates a thick-walled tank under both internal and external pressures.

[3]There is no simple way, including the more exact Lamé solutions, of evaluating theoretical stresses in thin-walled cylinders under external pressure, since failure is by collapse, not yielding. However, empirical equations exist for predicting the *collapsing pressure*.

In thick-walled tanks, radial stress is significant and cannot be disregarded. In *Lamé's solution*, a thick-walled cylinder is assumed to be made up of thin laminar rings. This method shows that the radial and circumferential stresses vary with location within the tank wall. (The term *circumferential stress* is preferred over *hoop stress* when dealing with thick-walled cylinders.) Compressive stresses are negative.

$$\sigma_c = \frac{r_i^2 p_i - r_o^2 p_o + \dfrac{(p_i - p_o)\, r_i^2 r_o^2}{r^2}}{r_o^2 - r_i^2} \qquad 45.15$$

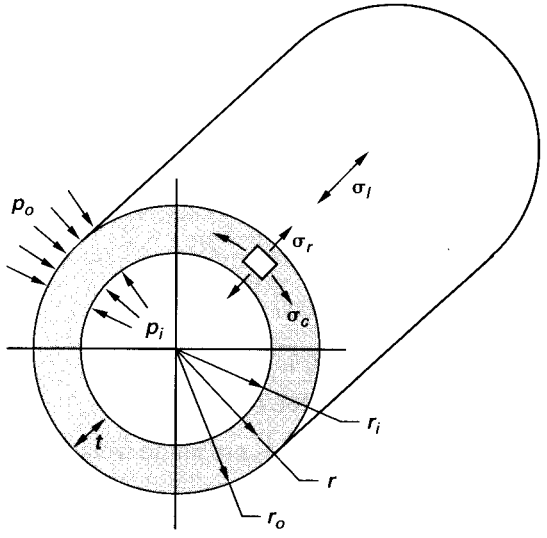


Figure 45.3 *Thick-Walled Cylinder*

$$\sigma_r = \frac{r_i^2 p_i - r_o^2 p_o - \dfrac{(p_i - p_o)\, r_i^2 r_o^2}{r^2}}{r_o^2 - r_i^2} \qquad 45.16$$

$$\sigma_l = \frac{p_i r_i^2}{r_o^2 - r_i^2} \qquad \left[\begin{array}{c} p_o \text{ does not act} \\ \text{longitudinally on the ends} \end{array}\right] \qquad 45.17$$

At every point in the cylinder, the circumferential, radial, and long stresses are the principal stresses. Unless an external torsional shear stress is added, it is not necessary to use the combined stress equations. Failure theories can be applied directly.

The cases of main interest are those of internal or external pressure only. The stress equations for these cases are summarized in Table 45.2. The maximum shear and normal stresses occur at the inner surface for both internal and external pressure.

Table 45.2 *Stresses in Thick-Walled Cylinders*[a]

stress	external pressure, p	internal pressure, p
$\sigma_{c,o}$	$\dfrac{-\left(r_o^2 + r_i^2\right) p}{r_o^2 - r_i^2}$	$\dfrac{2 r_i^2 p}{r_o^2 - r_i^2}$
$\sigma_{r,o}$	$-p$	0
$\sigma_{c,i}$	$\dfrac{-2 r_o^2 p}{r_o^2 - r_i^2}$	$\dfrac{\left(r_o^2 + r_i^2\right) p}{r_o^2 - r_i^2}$
$\sigma_{r,i}$	0	$-p$
$\tau_{\max}$	$\frac{1}{2}\sigma_{c,i}$	$\frac{1}{2}(\sigma_{c,i} + p)$

[a]Table 45.2 can be used with thin-walled cylinders. However, in most cases it will not be necessary to do so.

The *diametral strain* (which is the same as the *circumferential* and *radial strains*) is given by Eq. 45.18. Radial stresses are always compressive (hence they are negative), and algebraic signs must be observed with Eq. 45.18. Since the circumferential and radial stresses depend on location within the wall thickness, the strain can be evaluated at inner, outer, and any intermediate locations within the wall.

$$\epsilon = \frac{\Delta d}{d} = \frac{\Delta C}{C} = \frac{\Delta r}{r} = \frac{\sigma_c - \nu(\sigma_r + \sigma_l)}{E} \qquad 45.18$$

6. THIN-WALLED SPHERICAL TANKS

There is no unique axis in a spherical tank or in the spherical ends of a cylindrical tank. Therefore, the hoop and long stresses are identical.

$$\sigma = \frac{pr}{2t} \qquad 45.19$$

7. INTERFERENCE FITS

When assembling two pieces, interference fitting is often more economical than pinning, keying, or splining. The assembly operation can be performed in a hydraulic press, either with both pieces at room temperature or after heating the outer piece and cooling the inner piece. The former case is known as a *press fit* or *interference fit*; the latter as a *shrink fit*.

If two cylinders are pressed together, the pressure acting between them will expand the outer cylinder (placing it into tension) and will compress the inner cylinder. The *interference*, I, is the difference in dimensions between

Structural

the two cylinders. *Diametral interference* and *radial interference* are both used.[4]

$$\begin{aligned} I_{\text{diametral}} &= 2I_{\text{radial}} \\ &= d_{o,\text{inner}} - d_{i,\text{outer}} \\ &= |\Delta d_{o,\text{inner}}| + |\Delta d_{i,\text{outer}}| \end{aligned} \qquad 45.20$$

If the two cylinders have the same length, the thick-wall cylinder equations can be used. The materials used for the two cylinders do not need to be the same. Since there is no longitudinal stress from an interference fit and since the radial stress is negative, the strain from Eq. 45.18 is

$$\begin{aligned} \epsilon &= \frac{\Delta d}{d} = \frac{\Delta C}{C} = \frac{\Delta r}{r} \\ &= \frac{\sigma_c + \nu\sigma_r}{E} \end{aligned} \qquad 45.21$$

Equation 45.22 applies to the general case where both cylinders are hollow and have different moduli of elasticity and Poisson's ratios. The outer cylinder is designated as the *hub*; the inner cylinder is designated as the *shaft*. If the shaft is solid, use $r_{i,\text{shaft}} = 0$ in Eq. 45.22.

$$\begin{aligned} I_{\text{diametral}} &= 2I_{\text{radial}} \\ &= \left(\frac{2pr_{o,\text{shaft}}}{E_{\text{hub}}}\right)\left(\frac{r_{o,\text{hub}}^2 + r_{o,\text{shaft}}^2}{r_{o,\text{hub}}^2 - r_{o,\text{shaft}}^2} + \nu_{\text{hub}}\right) \\ &\quad + \left(\frac{2pr_{o,\text{shaft}}}{E_{\text{shaft}}}\right)\left(\frac{r_{o,\text{shaft}}^2 + r_{i,\text{shaft}}^2}{r_{o,\text{shaft}}^2 - r_{i,\text{shaft}}^2} - \nu_{\text{shaft}}\right) \end{aligned} \qquad 45.22$$

In the special case where the shaft is solid and is made from the same material as the hub, the diametral interference is given by Eq. 45.23.

$$\begin{aligned} I_{\text{diametral}} &= 2I_{\text{radial}} \\ &= \left(\frac{4pr_{\text{shaft}}}{E}\right)\left(\frac{1}{1 - \left(\frac{r_{\text{shaft}}}{r_{o,\text{hub}}}\right)^2}\right) \end{aligned} \qquad 45.23$$

The maximum assembly force required to overcome friction during a press-fitting operation is given by Eq. 45.24. The coefficient of friction is highly variable. Values in the range of 0.03 to 0.33 have been reported. This relationship is approximate because the coefficient of friction is not known with certainty and the assembly force affects the pressure, p, through Poisson's ratio.

$$F_{\max} = fN = 2\pi fpr_{\text{shaft}}L_{\text{interface}} \qquad 45.24$$

[4]Theoretically, the interference can be given to either the inner or outer cylinder, or it can be shared by both cylinders. However, in the case of a surface-hardened shaft with a standard diameter, the interference is usually all given to the disk. Otherwise, it may be necessary to machine the shaft and remove some of the hardened surface.

The maximum torque that the press-fitted hub can withstand or transmit is given by Eq. 45.25. This can be greater or less than the shaft's torsional shear capacity. Both values should be calculated.

$$T_{\max} = 2\pi fpr_{\text{shaft}}^2 L_{\text{interface}} \qquad 45.25$$

Most interference fits are designed to keep the contact pressure or the stress below a given value. Designs of interference fits limited by strength generally use the distortion energy failure criterion. That is, the maximum shear stress is compared with the shear strength determined from the failure theory.

Example 45.3

A steel cylinder has inner and outer diameters of 1.0 in and 2.0 in, respectively. The cylinder is pressurized internally to 10,000 lbf/in^2. The modulus of elasticity is 2.9×10^7 lbf/in^2, and Poisson's ratio is 0.3. What is the radial strain at the inside face?

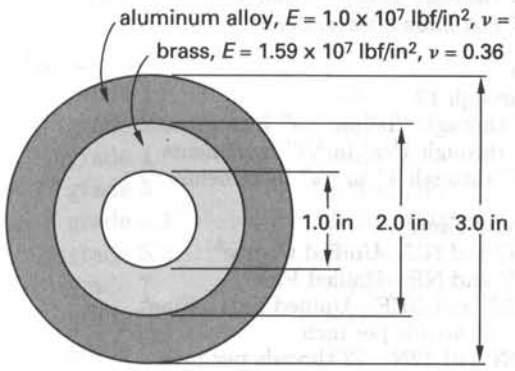
Solution

The longitudinal stress is

$$\begin{aligned} \sigma_l &= \frac{F}{A} = \frac{p\pi r_i^2}{\pi(r_o^2 - r_i^2)} \\ &= \frac{\left(10{,}000\ \frac{\text{lbf}}{\text{in}^2}\right)(0.5\ \text{in})^2}{(1.0\ \text{in})^2 - (0.5\ \text{in})^2} \\ &= 3333\ \text{lbf/in}^2 \end{aligned}$$

The stresses at the inner face are found from Table 45.2.

$$\begin{aligned} \sigma_{c,i} &= \frac{(r_o^2 + r_i^2)p}{r_o^2 - r_i^2} \\ &= \frac{((1.0\ \text{in})^2 + (0.5\ \text{in})^2)\left(10{,}000\ \frac{\text{lbf}}{\text{in}^2}\right)}{(1.0\ \text{in})^2 - (0.5\ \text{in})^2} \\ &= 16{,}667\ \text{lbf/in}^2 \\ \sigma_{r,i} &= -p = -10{,}000\ \text{lbf/in}^2 \end{aligned}$$



The circumferential stress increases the radial strain; the radial and longitudinal stresses decrease the radial strain. The radial strain is

$$\begin{aligned} \frac{\Delta r}{r} &= \frac{\sigma_{c,i} - \nu(\sigma_{r,i} + \sigma_l)}{E} \\ &= \frac{16{,}667\ \frac{\text{lbf}}{\text{in}^2} - (0.3)\left(-10{,}000\ \frac{\text{lbf}}{\text{in}^2} + 3333\ \frac{\text{lbf}}{\text{in}^2}\right)}{2.9 \times 10^7\ \frac{\text{lbf}}{\text{in}^2}} \\ &= 6.44 \times 10^{-4} \end{aligned}$$

Example 45.4

A hollow aluminum cylinder is pressed over a hollow brass cylinder as shown. Both cylinders are 2 in long. The interference is 0.004 in. The average coefficient of

friction during assembly is 0.25. (a) What is the maximum shear stress in the brass? (b) What initial disassembly force is required to separate the two cylinders?

Solution

(a) Work with the aluminum outer cylinder, which is under internal pressure.

$$\sigma_{c,i} = \frac{(r_o^2 + r_i^2)p}{r_o^2 - r_i^2}$$
$$= \frac{\left((1.5 \text{ in})^2 + (1.0 \text{ in})^2\right)p}{(1.5 \text{ in})^2 - (1.0 \text{ in})^2}$$
$$= 2.6p$$
$$\sigma_{r,i} = -p$$

From Eq. 45.18, the diametral strain is

$$\epsilon = \frac{\sigma_{c,i} - \nu(\sigma_{r,i} + \sigma_l)}{E}$$
$$= \frac{2.6p - (0.33)(-p)}{1.0 \times 10^7 \ \frac{\text{lbf}}{\text{in}^2}}$$
$$= 2.93 \times 10^{-7}p$$
$$\Delta d = \epsilon_d = (2.93 \times 10^{-7}p)(2.0 \text{ in})$$
$$= 5.86 \times 10^{-7}p$$

Now work with the brass inner cylinder, which is under external pressure. Use Table 45.2.

$$\sigma_{c,o} = \frac{-(r_o^2 + r_i^2)p}{r_o^2 - r_i^2}$$
$$= \frac{-\left((1.0 \text{ in})^2 + (0.5 \text{ in})^2\right)p}{(1.0 \text{ in})^2 - (0.5 \text{ in})^2}$$
$$= -1.667p$$
$$\sigma_{r,o} = -p$$

From Eq. 45.18, the diametral strain is

$$\epsilon = \frac{\sigma_{c,o} - \nu(\sigma_{r,o} + \sigma_l)}{E}$$
$$= \frac{-1.667p - (0.36)(-p)}{1.59 \times 10^7 \ \frac{\text{lbf}}{\text{in}^2}}$$
$$= -0.822 \times 10^{-7}p$$
$$\Delta d = \epsilon_d = (-0.822 \times 10^{-7}p)(2.0 \text{ in})$$
$$= -1.644 \times 10^{-7}p$$

The diametral interference is known to be 0.004 in. From Eq. 45.20,

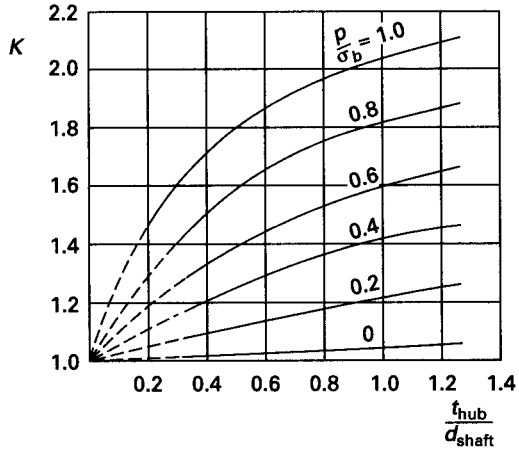
$$I_{\text{diametral}} = |\Delta d_{o,\text{inner}}| + |\Delta d_{i,\text{outer}}|$$
$$0.004 \text{ in} = 5.86 \times 10^{-7}p + |-1.644 \times 10^{-7}p|$$
$$p = 5330 \text{ lbf/in}^2$$

From Table 45.2, the circumferential stress at the inner face of the brass (under external pressure) is

$$\sigma_{c,i} = \frac{-2r_o^2 p}{r_o^2 - r_i^2}$$
$$= \frac{(-2)(1.0 \text{ in})^2 \left(5330 \ \frac{\text{lbf}}{\text{in}^2}\right)}{(1.0 \text{ in})^2 - (0.5 \text{ in})^2}$$
$$= -14{,}213 \text{ lbf/in}^2$$

Also from Table 45.2, the maximum shear stress is

$$\tau_{\max} = (0.5)\sigma_{c,i} = (0.5)\left(-14{,}213 \ \frac{\text{lbf}}{\text{in}^2}\right)$$
$$= -7107 \text{ lbf/in}^2$$



(b) The initial force necessary to disassemble the two cylinders is the same as the maximum assembly force. Use Eq. 45.24.

$$F_{\max} = 2\pi f p r_{\text{shaft}} t_{\text{hub}}$$
$$= (2\pi)(0.25)\left(5330 \ \frac{\text{lbf}}{\text{in}^2}\right)(1 \text{ in})(2 \text{ in})$$
$$= 16{,}745 \text{ lbf}$$

8. STRESS CONCENTRATIONS FOR PRESS-FITTED SHAFTS IN FLEXURE

When a shaft carrying a press-fitted hub (whose thickness is less than the shaft length) is loaded in flexure, there will be an increase in shaft bending stress in the vicinity of the inner hub edge. The fatigue life of the shaft can be seriously affected by this stress increase. The extent of the increase depends on the magnitude of the bending stress and the contact pressure and can be as high as 2.0 or more.

Some designs attempt to reduce the increase in shaft stress by grooving the disk (to allow the disk to flex). Other designs rely on various treatments to increase the fatigue strength of the shaft. For an unmodified simple press-fit, the stress concentration factor (to be applied to the bending stress calculated from Mc/I) is given by Fig. 45.4.

"Fatigue of Shafts at Fitted Members, with a Related Photoelastic Analysis," reproduced from *Transactions of the ASME*, Vol. 57, 1935, and Vol. 58, 1936, with permission of the American Society of Mechanical Engineers.

Figure 45.4 *Stress Concentration Factor for Press Fit*

9. BOLTS

There are three leading specifications for bolt thread families: ANSI, ISO metric, and DIN metric.[5] ANSI (essentially identical to SAE, ASTM, ISO-inch standard) is widely used in the United States. DIN (Deutches Institute für Normung) fasteners are widely available and broadly accepted.[6] ISO metric (the International Organization for Standardization, which first met in 1961) fasteners are used in large volume by U.S. car manufacturers. The CEN (European Committee for Standardization) standards promulgated by the European Community (EC) have essentially adopted the ISO standards.

An American National (Unified) thread is specified by the sequence of parameters S(×L)-N-F-A-(H-E), where S is the thread outside diameter (nominal size), L is the optional shank length, N is the number of threads per inch, F is the thread pitch family, A is the class (allowance), and H and E are the optional hand and engagement length designations. The letter R can be added to the thread pitch family to indicate that the thread roots are radiused (for better fatigue resistance). For example, a $^3/_8$ × 1-16UNC-2A bolt is $^3/_8$ in in diameter, 1 in in length, and has 16 Unified Coarse threads per inch rolled with a class 2A accuracy.[7] A UNRC bolt would be identical except for radiused roots. Table 45.3 lists some (but not all) values for these parameters.

Table 45.3 *Representative American National (Unified) Bolt Thread Designations*[a]

S: Size
1 through 12
$^1/_4$″ through $^9/_{16}$″ in $^1/_{16}$″ increments
$^5/_8$″ through $1^1/_2$″ in $^1/_8$″ increments
$1^3/_4$″ through 4″ in $^1/_4$″ increments

F: Thread Family
UNC and NC—Unified Coarse[b]
UNF and NF—Unified Fine[b]
UNEF and NEF—Unified Extra Fine[c]
8N—8 threads per inch
12UN and 12N—12 threads per inch
16UN and 16N—16 threads per inch
UN, UNS, and NS—special series

A: Allowance (A—external threads, B—internal threads)[d]
1A and 1B—liberal allowance for ease of assembly with dirty or damaged threads
2A and 2B—normal production allowance (sufficient for plating)
3A and 3B—close tolerance work with no allowance

H: Hand
blank—right-hand thread
LH—left-hand thread

[a]In addition to fastener thread families, there are other special-use threads such as Acme, stub, square, buttress, and worm series.
[b]Previously known as United States Standard or American Standard.
[c]The UNEF series is the same as the SAE (Society of Automotive Engineers) fine series.
[d]Allowance classes 2 and 3 (without the A and B designation) were used prior to industry transition to the Unified classes.

The *grade* of a bolt indicates the fastener material and is marked on the bolt cap.[8] In this regard, the marking depends on whether an SAE grade or ASTM designation is used. The minimum *proof load* (i.e., the maximum load the bolt can support without acquiring a permanent set) increases with the grade. The *proof strength* is the proof load divided by the tensile stress area. Table 45.4 lists how the caps of the bolts are marked to distinguish among the major grades.[9] If a bolt is manufactured in the United States, its cap must also show the logo or mark of the manufacturer.

A metric thread is specified by an M or MJ and a diameter and a pitch in millimeters, in that order. Thus, M10 × 1.5 is a thread having a nominal major diameter of 10 mm and a pitch of 1.5 mm. The MJ series have rounded root fillets and larger minor diameters.

[5]Other fastener families include the Italian UNI, Swiss VSM, Japanese JIS, and United Kingdom's BS series.
[6]To add to the confusion, many DIN standards are identical to ISO standards, with only slight differences in the tolerance ranges. However, the standards are not interchangeable in every case.
[7]Threads are generally rolled, not cut, into a bolt.
[8]The *type* of a structural bolt should not be confused with the *grade* of a structural rivet.
[9]Optional markings can also be used.

Table 45.4 *Selected Bolt Grades and Designations*

Head markings on metric bolts indicate their *property class* and correspond to the approximate tensile strength in MPa/100. For example, a bolt marked 8.8 would correspond to a medium carbon, quenched and tempered bolt with an approximate tensile strength of 880 MPa. (The minimum of the tensile strength range for property class 8.8 is 830 MPa.)

10. RIVET AND BOLT CONNECTIONS

Figure 45.5 illustrates a tension *lap joint* connection using rivet or bolt connectors.[10] Unless the plate material is very thick, the effects of eccentricity are disregarded. A connection of this type can fail in shear, tension, or bearing. A common design procedure is to determine the number of connectors based on shear stress and then to check the bearing and tensile stresses.

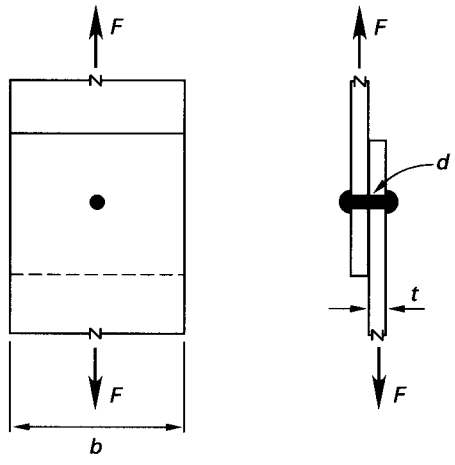

Figure 45.5 *Tension Lap Joint*

[10]Rivets are no longer used in building construction, but they are still extensively used in manufacturing.

One of the failure modes is shearing of the connectors. In the case of *single shear*, each connector supports its proportionate share of the load. In *double shear*, each connector has two shear planes, and the stress per connector is halved.[11] The shear stress in a cylindrical connector is

$$\tau = \frac{F}{\frac{\pi}{4}d^2} \qquad 45.26$$

The number of required connectors, as determined by shear, is

$$n = \frac{\tau}{\text{allowable shear stress}} \qquad 45.27$$

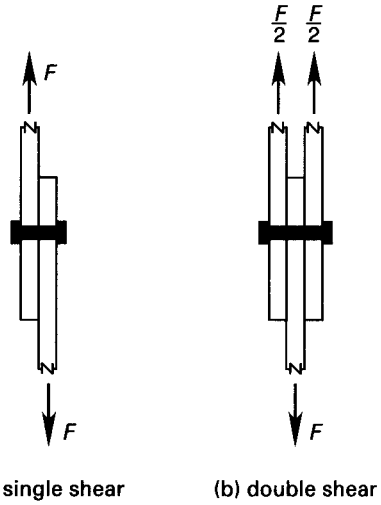

Figure 45.6 *Single and Double Shear*

The plate can fail in tension. If there are n connector holes of diameter d in a line across the width, b, of the plate, the cross-sectional area in the plate remaining to resist the tension is

$$A_t = t(b - nd) \qquad 45.28$$

The number of connectors across the plate width must be chosen to keep the tensile stress less than the allowable stress. The maximum tensile stress in the plate will be

$$\sigma_t = \frac{F}{A_t} \qquad 45.29$$

The plate can also fail by *bearing* (i.e., crushing). The number of connectors must be chosen to keep the actual *bearing stress* below the allowable bearing stress. For one connector, the bearing stress in the plate is

$$\sigma_p = \frac{F}{dt} \qquad 45.30$$

$$n = \frac{\sigma_p}{\text{allowable bearing stress}} \qquad 45.31$$

[11]"Double shear" is not the same as "double rivet" or "double butt." *Double shear* means that there are two shear planes in one rivet. *Double rivet* means that there are two rivets along the force path. *Double butt* refers to the use of two backing plates (i.e., "scabs") used on either side to make a tension connection between two plates. Similarly, *single butt* refers to the use of a single backing plate to make a tension connection between two plates.

The plate can also fail by shear tear-out, as illustrated in Fig. 45.7. The shear stress is

$$\tau = \frac{F}{2A} = \frac{F}{2t\left(L - \frac{d}{2}\right)} \qquad 45.32$$

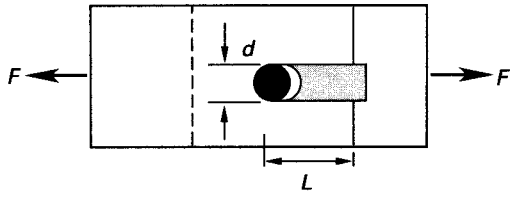

Figure 45.7 *Shear Tear-Out*

The *joint efficiency* is the ratio of the strength of the joint divided by the strength of a solid (i.e., unpunched or undrilled) plate.

11. BOLT PRELOAD

Consider the ungasketed connection shown in Fig. 45.8. The load varies from $F_{\min}$ to $F_{\max}$. If the bolt is initially snug but without initial tension, the force in the bolt also will vary from $F_{\min}$ to $F_{\max}$. If the bolt is tightened so that there is an initial *preload force*, F_i, greater than $F_{\max}$ in addition to the applied load, the bolt will be placed in tension and the parts held together will be in compression.[12] When a load is applied, the bolt tension will increase even more, but the compression in the parts will decrease.

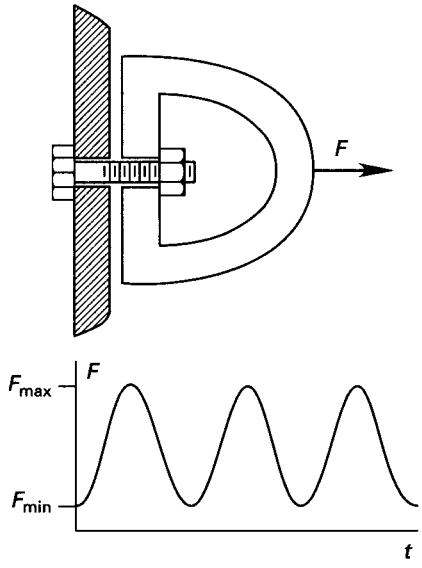

Figure 45.8 *Bolted Tension Joint with Varying Load*

[12]If the initial preload force is less than $F_{\max}$, the bolt will once again carry the entire load.

The amount of compression in the parts will vary as the applied load varies. Thus, the clamped members will carry some of the applied load, since this varying load has to "uncompress" the clamped part as well as lengthen the bolt. The net result is the reduction of the variation of the force in the bolt. The initial tension produces a larger mean stress, but the overall result is the reduction of the alternating stress. Thus, preloading is an effective method of reducing the alternating stress in bolted tension connections.

It is convenient to define the *spring constant*, k, of the bolt. The *grip*, L, is the thickness of the parts being connected by the bolt (not the bolt length). It is common to use the nominal diameter of the bolt, disregarding the reduction due to threading.

$$k_{\text{bolt}} = \frac{F}{\Delta L} = \frac{A_{\text{bolt}} E_{\text{bolt}}}{L_{\text{bolt}}} \qquad 45.33$$

The actual spring constant for a bolted part, k_{part}, is difficult to determine if the clamped area is not small and well defined. The only accurate way to determine the stiffness of a part in a bolted joint is through experimentation. If the clamped parts are flat plates, various theories can be used to calculate the effective load-bearing areas of the flanges, but doing so is a laborious process.

One simple rule of thumb is that the bolt force spreads out to three times the bolt-hole diameter. Of course, the hole diameter needs to be considered (i.e., needs to be subtracted) in calculating the effective force area. If the modulus of elasticity is the same for the bolt and the clamped parts, using this rule of thumb, the larger area results in the parts being eight times stiffer than the bolts.

$$k_{\text{parts}} = \frac{A_{e,\text{parts}} E_{\text{parts}}}{L_{\text{parts}}} \qquad 45.34$$

If the clamped parts have different moduli of elasticity, including if a gasket constitutes one of the layers compressed by the bolt, the composite spring constant can be found from Eq. 45.35.[13]

$$\frac{1}{k_{\text{parts,composite}}} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} + \cdots \qquad 45.35$$

The bolt and the clamped parts all carry parts of the applied load.

$$F_{\text{bolt}} = F_i + \frac{k_{\text{bolt}} F_{\text{applied}}}{k_{\text{bolt}} + k_{\text{parts}}} \qquad 45.36$$

$$F_{\text{parts}} = \frac{k_{\text{parts}} F_{\text{applied}}}{k_{\text{bolt}} + k_{\text{parts}}} - F_i \qquad 45.37$$

[13]If a soft washer or gasket is used, its spring constant can control Eq. 45.35.

O-ring (metal and elastomeric) seals permit metal-to-metal contact and affect the effective spring constant of the parts very little. However, the seal force tends to separate bolted parts and must be added to the applied force. The seal force can be obtained from the seal deflection and seal stiffness or from manufacturer's literature.

For static loading, recommended amounts of preloading often are specified as a percentage of the *proof strength* (or *proof load*) in psi.[14] For bolts, the proof load is slightly less than the yield strength. Traditionally, preload has been specified conservatively as 75% of proof for reusable connectors and 90% of proof for one-use connectors.[15] Connectors with some ductility can safely be used beyond the yield point, and 100% is now in widespread use.[16] When understood, advantages of preloading to 100% of proof load often outweigh the disadvantages.[17]

If the applied load varies, the forces in the bolt and parts will also vary. In that case, the preload must be determined from an analysis of the Goodman line.

Tightening of a tension bolt will induce a torsional stress in the bolt.[18] Where the bolt is to be locked in place, the torsional stress can be removed without greatly affecting the preload by slightly backing off the bolt. If the bolt is subject to cyclic loading, the bolt will probably slip back by itself, and it is reasonable to neglect the effects of torsion in the bolt altogether. (This is the reason that well-designed connections allow for a loss of 5 to 10% of the initial preload during routine use.)

Stress concentrations at the beginning of the threaded section are significant in cyclic loading.[19] To avoid a reduction in fatigue life, the alternating stress used in the Goodman line should be multiplied by an appropriate stress concentration factor, K. For fasteners with rolled threads, an average factor of 2.2 for SAE grades 0 to 2 (metric grades 3.6 to 5.8) is appropriate. For SAE grades 4 to 8 (metric grades 6.6 to 10.9), an average factor of 3.0 is appropriate. Stress concentration factors for the fillet under the bolt head are different, but lower than these values. Stress concentration factors for cut threads are much higher.

The stress in a bolt depends on its load-carrying area. This area is typically obtained from a table of bolt properties. The effects of threads usually are ignored, so the area is based on the major (nominal) diameter.

$$\sigma_{\text{bolt}} = \frac{KF}{A} \qquad 45.38$$

12. BOLT TORQUE TO OBTAIN PRELOAD

During assembly, the preload tension is not monitored directly. Rather, the torque required to tighten the bolt is used to determine when the proper preload has been reached. Methods of obtaining the required preload include the standard torque wrench, the *run-of-the-nut method* (e.g., turning the bolt some specific angle past snugging torque), and computerized automatic assembly.

The standard manual torque wrench does not provide precise, reliable preloads, since the fraction of the torque going into bolt tension is variable.[20] Torque-, angle-, and time-monitoring equipment, usually part of an automated assembly operation, is essential to obtaining precise preloads on a consistent basis. It automatically applies the snugging torque and specified rotation, then checks the results with torque and rotation sensors. The computer warns of out-of-spec conditions.

The *Maney formula* is a simple relationship between the initial bolt tension, F_i, and the installation torque, T. The *torque coefficient*, K_T (also known as the *bolt torque factor* and the *nut factor*) used in Eq. 45.40 depends mainly on the coefficient of friction, f. The torque coefficient for lubricated bolts generally varies from 0.15 to 0.20, and a value of 0.2 is commonly used.[21] With antiseize lubrication, it can drop as low as 0.12. (The torque coefficient is not the same as the coefficient of friction.)

$$T = K_T d_{\text{bolt}} F_i \qquad 45.39$$

$$K_T = \frac{f_c r_c}{d_{\text{bolt}}} + \left(\frac{r_t}{d_{\text{bolt}}}\right)\left(\frac{\tan\theta + f_t \sec\alpha}{1 - f_t \tan\theta \sec\alpha}\right) \qquad 45.40$$

$$\tan\theta = \frac{\text{lead per revolution}}{2\pi r_t} \qquad 45.41$$

f_c is the coefficient of friction at the collar (fastener bearing face). r_c is the mean collar radius (i.e., the effective radius of action of the friction forces on the

[14]This is referred to as a "rule of thumb" specification, because a mathematical analysis is not performed to determine the best preload.

[15]Some U.S. military specifications call for 80% of proof load in tension fasteners and only 30% for shear fasteners. The object of keeping the stresses below yielding is to be able to reuse the bolts.

[16]Even under normal elastic loading of a bolt, local plastic deformation occurs in the bolt-head fillet and thread roots. Since the stress-strain curve is nearly flat at the yield point, a small amount of elongation into the plastic region does not increase the stress or tension in the bolt.

[17]The disadvantages are: (a) Field maintenance probably won't be possible, as manually running up bolts to 100% proof will result in many broken bolts. (b) Bolts should not be reused, as some will have yielded. (c) The highest-strength bolts do not exhibit much plastic elongation and ordinarily should not be run up to 100% proof load.

[18]An argument for the conservative 75% of proof load preload limit is that the residual torsional stress will increase the bolt stress to 90% or higher anyway, and the additional 10% needed to bring the preload up to 100% probably won't improve economic performance much.

[19]Stress concentrations are frequently neglected for static loading.

[20]Even with good lubrication, about 50% of the torque goes into overcoming friction between the head and collar/flange, another 40% is load in thread friction, and only the remaining 10% goes into tensioning the connector.

[21]With a coefficient of friction of 0.15, the torque coefficient is approximately 0.20 for most bolt sizes, regardless of whether the threads are coarse or fine.

bearing face). r_t is the effective radius of action of the frictional forces on the thread surfaces. Similarly, f_t is the coefficient of friction between the thread contact surfaces. θ is the *lead angle*, also known as the *helix thread angle*. α is the thread half angle (30° for UNF threads). $d_{t,m}$ is the mean thread diameter, and N is the number of threads per inch.

13. FILLET WELDS

The common *fillet weld* is shown in Fig. 45.9. Such welds are used to connect one plate to another. The applied load, F, is assumed to be carried in shear by the *effective weld throat*. The *effective throat size*, t_e, is related to the weld size, y, by Eq. 45.42.

$$t_e = 0.707y \tag{45.42}$$

Neglecting any increased stresses due to eccentricity, the shear stress in a fillet lap weld is

$$\tau = \frac{F}{bt_e} \tag{45.43}$$

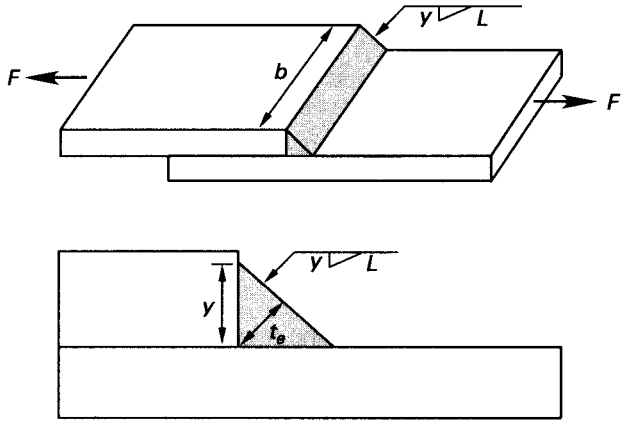

Figure 45.9 *Fillet Lap Weld and Symbol*

Weld (filler) metal should have a strength equal to or greater than the base material. Properties of filler metals are readily available from their manufacturers and, for standard rated welding rod, from engineering handbooks.

14. CIRCULAR SHAFT DESIGN

Shear stress occurs when a shaft is placed in torsion. The shear stress at the outer surface of a bar of radius r, which is torsionally loaded by a torque, T, is

$$\tau = G\phi = \frac{Tr}{J} \tag{45.44}$$

The total strain energy due to torsion is

$$U = \frac{T^2L}{2GJ} \tag{45.45}$$

J is the shaft's polar moment of inertia. For a solid round shaft,

$$J = \frac{\pi r^4}{2} = \frac{\pi d^4}{32} \tag{45.46}$$

For a hollow round shaft,

$$J = \frac{\pi}{2}\left(r_o^4 - r_i^4\right) \tag{45.47}$$

If a shaft of length L carries a torque T, the angle of twist (in radians) will be

$$\phi = \frac{\tau}{G} = \frac{TL}{GJ} \tag{45.48}$$

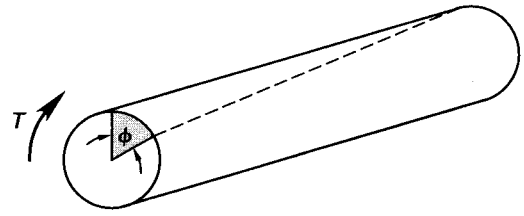

Figure 45.10 *Torsional Deflection of a Circular Shaft*

G is the *shear modulus*. For steel, it is approximately equal to 11.5×10^6 lbf/in^2 (8.0×10^4 MPa). The shear modulus also can be calculated from the modulus of elasticity.

$$G = \frac{E}{2(1+\nu)} \tag{45.49}$$

The torque, T, carried by a shaft spinning at n revolutions per minute is related to the transmitted horsepower.

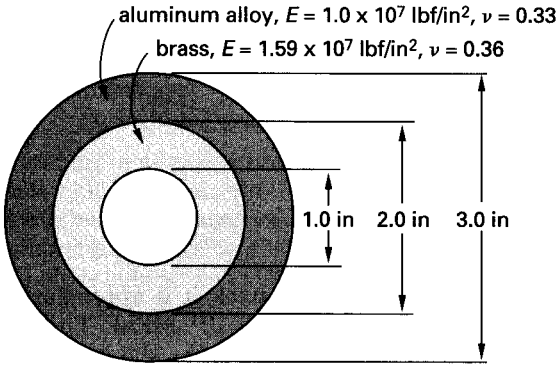
$$T_{\text{in-lbf}} = \frac{(63{,}025)(\text{horsepower})}{n_{\text{rpm}}} \tag{45.50}$$

If a statically loaded shaft without axial loading experiences a bending stress, $\sigma_x = Mc/I$ (i.e., is loaded in flexure), in addition to torsional shear stress, $\tau = Tr/J$, the maximum shear stress from the combined stress theory is

$$\tau_{\max} = \sqrt{\left(\frac{\sigma_x}{2}\right)^2 + \tau^2} \tag{45.51}$$

$$\tau_{\max} = \frac{16}{\pi d^3}\sqrt{M^2 + T^2} \tag{45.52}$$

The equivalent normal stress from the distortion energy theory is



$$\sigma' = \frac{16}{\pi d^3}\sqrt{4M^2 + 3T^2} \tag{45.53}$$

The diameter can be determined by setting the shear and normal stresses equal to the maximum allowable shear (as calculated from the maximum shear stress theory, $S_y/2(\text{FS})$, or from the distortion energy theory, $\sqrt{3}S_y/2(\text{FS})$, and normal stresses, respectively).

Equations 45.51 and 45.52 should not be used with dynamically loaded shafts (i.e., those that are turning). Fatigue design of shafts should be designed according to a specific code (e.g., ANSI or ASME) or should use a fatigue analysis (e.g., Goodman, Soderberg, or Gerber).

Example 45.5

The press-fitted aluminum alloy-brass cylinder described in Ex. 45.4 is used as a shaft. The press fit is adequate to maintain nonslipping contact between the two materials. The shaft carries a steady torque of 24,000 in-lbf. There is no bending stress. What is the maximum torsional shear stress in the (a) aluminum and (b) brass?

Solution

The stronger material (as determined from the shear modulus, G) should be converted to an equivalent area of the weaker material.

For the aluminum, from Eq. 45.49,

$$\begin{aligned} G_{\text{aluminum}} &= \frac{E}{2(1+\nu)} \\ &= \frac{1.0 \times 10^7 \ \frac{\text{lbf}}{\text{in}^2}}{(2)(1+0.33)} \\ &= 3.76 \times 10^6 \ \text{lbf/in}^2 \end{aligned}$$

For the brass, from Eq. 45.49,

$$\begin{aligned} G_{\text{brass}} &= \frac{E}{2(1+\nu)} \\ &= \frac{1.59 \times 10^7 \ \frac{\text{lbf}}{\text{in}^2}}{(2)(1+0.36)} \\ &= 5.85 \times 10^6 \ \text{lbf/in}^2 \end{aligned}$$

The brass is the stronger material. The modular shear ratio is

$$\begin{aligned} n &= \frac{G_{\text{brass}}}{G_{\text{aluminum}}} \\ &= \frac{5.85 \times 10^6 \ \frac{\text{lbf}}{\text{in}^2}}{3.76 \times 10^6 \ \frac{\text{lbf}}{\text{in}^2}} \\ &= 1.56 \end{aligned}$$

The polar moment of inertia of the aluminum is

$$\begin{aligned} J_{\text{aluminum}} &= \frac{\pi}{2}(r_o^4 - r_i^4) \\ &= \left(\frac{\pi}{2}\right)\left((1.5 \text{ in})^4 - (1.0 \text{ in})^4\right) \\ &= 6.38 \text{ in}^4 \end{aligned}$$

The equivalent polar moment of inertia of the brass is

$$\begin{aligned} J_{\text{brass}} &= n\left(\frac{\pi}{2}\right)(r_o^4 - r_i^4) \\ &= (1.56)\left(\frac{\pi}{2}\right)\left((1.0 \text{ in})^4 - (0.5 \text{ in})^4\right) \\ &= 2.30 \text{ in}^4 \end{aligned}$$

The total equivalent polar moment of inertia is

$$\begin{aligned} J_{\text{total}} &= J_{\text{aluminum}} + J_{\text{brass}} \\ &= 6.38 \text{ in}^4 + 2.30 \text{ in}^4 = 8.68 \text{ in}^4 \end{aligned}$$

(a) The maximum torsional shear stress in the aluminum occurs at the outer edge. Use Eq. 45.57.

$$\begin{aligned} \tau &= \frac{Tr}{J} = \frac{(24{,}000 \text{ in-lbf})(1.5 \text{ in})}{8.68 \text{ in}^4} \\ &= 4147 \text{ lbf/in}^2 \end{aligned}$$

(b) The maximum torsional shear stress in the brass is

$$\begin{aligned} \tau &= \frac{nTr}{J} = \frac{(1.56)(24{,}000 \text{ in-lbf})(0.5 \text{ in})}{8.68 \text{ in}^4} \\ &= 2157 \text{ lbf/in}^2 \end{aligned}$$

15. TORSION IN THIN-WALLED, NONCIRCULAR SHELLS

Shear stress due to torsion in a thin-walled, noncircular shell (also known as a *closed box*) acts around the perimeter of the shell, as shown in Fig. 45.11. The shear stress, τ, is given by Eq. 45.54. A is the area enclosed by the centerline of the shell.

$$\tau = \frac{T}{2At} \qquad 45.54$$

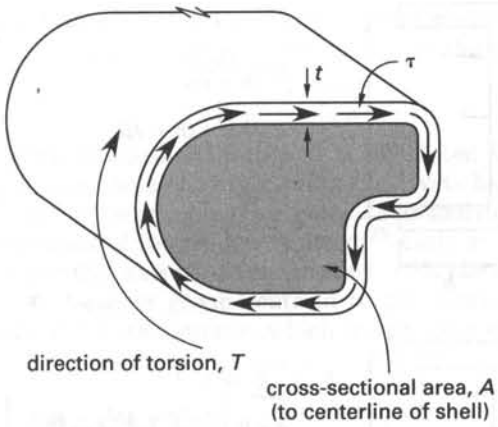


Figure 45.11 *Torsion in Thin-Walled Shells*

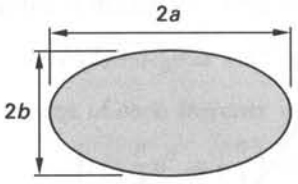
The shear stress at any point is not proportional to the distance from the centroid of the cross section. Rather, the *shear flow*, q, around the shell is constant, regardless of whether the wall thickness is constant or variable.[22] The shear flow is the shear per-unit length of the centerline path.[23] At any point where the shell thickness is t,

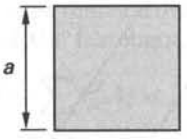
$$q = \tau t = \frac{T}{2A} \quad [\text{constant}] \qquad 45.55$$

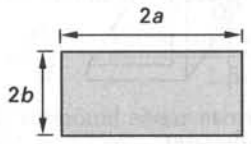
When the wall thickness, t, is constant, the angular twist depends on the perimeter, p, of the shell as measured along the centerline of the shell wall.

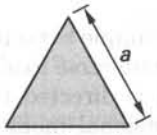
$$\phi = \frac{TLp}{4A^2tG} \qquad 45.56$$

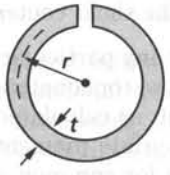
16. TORSION IN SOLID, NONCIRCULAR MEMBERS











When a noncircular solid member is placed in torsion, the shear stress is not proportional to the distance from the centroid of the cross section. The maximum shear usually occurs close to the point on the surface that is nearest the centroid.

Shear stress, τ, and angular deflection, ϕ, due to torsion are functions of the cross-sectional shape. They cannot be specified by simple formulas that apply to all sections. Table 45.6 lists the governing equations for several basic cross sections. These formulas have been derived by dividing the member into several concentric thin-walled closed shells and summing the torsional strength, T, provided by each shell.

[22]The concept of shear flow can also be applied to a regular beam in bending, although there is little to be gained by doing so. Removing the dimension b in the general beam shear stress equation, $q = VQ/I$.

[23]Shear flow is not analogous to magnetic flux or other similar quantities because the shear flow path does not need to be complete (i.e., does not need to return to its starting point).

Table 45.6 *Torsion in Solid, Noncircular Shapes*

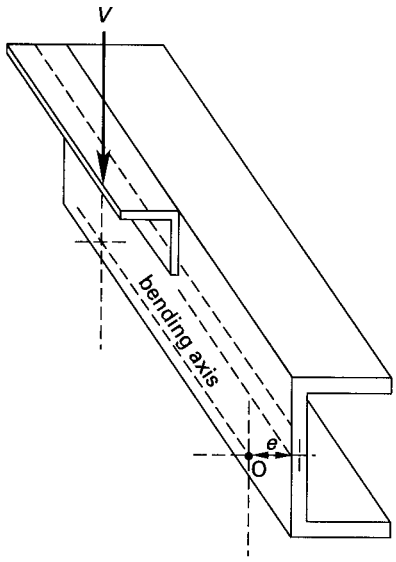
cross section	K in formula $\phi = TL/KG$	τ (max)
 ellipse	$\frac{\pi a^3 b^3}{a^2 + b^2}$	$\frac{2T}{\pi ab^2}$ (at ends of minor axis)
 square	$0.1406a^4$	$\frac{T}{0.208a^3}$ (at midpoint of each side)
 rectangle	*	$\frac{T(3a + 1.8b)}{8a^2b^2}$ (at midpoint of each longer side)
 equilateral triangle	$\frac{a^4\sqrt{3}}{80}$	$\frac{20T}{a^3}$ (at midpoint of each side)
 slotted tube	$\frac{2\pi r t^3}{3}$	$\frac{T(6\pi r + 1.8t)}{4\pi^2 r^2 t^2}$ (along both edges remote from ends)

$$*ab^3\left(\frac{16}{3} - \left(\frac{3.36b}{a}\right)\left(1 - \frac{b^4}{12a^4}\right)\right)$$

17. SHEAR CENTER FOR BEAMS

A beam with a symmetrical cross section supporting a transverse force that is offset from the longitudinal centroidal axis will be acted upon by a torsional moment, and the beam will tend to "roll" about a longitudinal axis known as the *bending axis* or *torsional axis*. For solid, symmetrical cross sections, this bending axis passes through the centroid of the cross section. However, for an asymmetrical beam (e.g., a channel beam on its side), the bending axis passes through the *shear*

center (*torsional center* or *center of twist*), not the centroid. The shear center is a point that does not experience rotation (i.e., is a point about which all other points rotate) when the beam is in torsion.



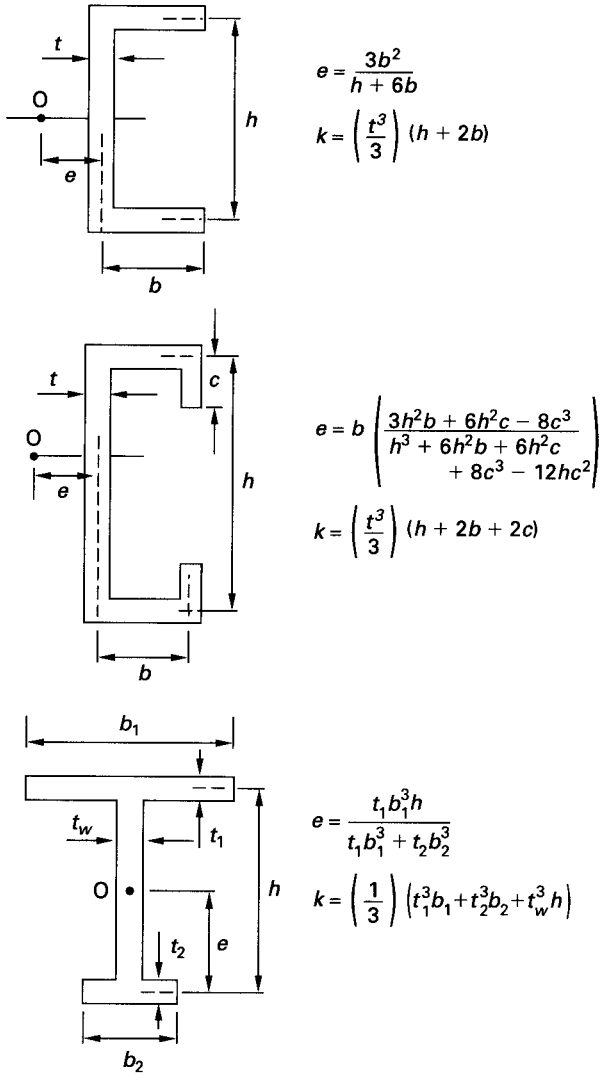


Figure 45.12 *Channel Beam in Pure Bending (shear resultant, V, directed through shear center, O)*

For beams with transverse loading, simple bending without torsion can only occur if the transverse load (*shear resultant* or *shear force of action*) is directed through the shear center. Otherwise, a torsional moment calculated as the product of the shear resultant and the torsional eccentricity will cause the beam to twist. The *torsional eccentricity* is the distance between the line of action of the shear resultant and the shear center.

The location of the shear center for any particular beam geometry is determined by setting the torsional moment equal to the shear resisting moment, as calculated from the total shear flow and the appropriate moment arm. In practice, however, shear centers for common shapes are located in tables similar to Fig. 45.13.

[a]Distance e from shear center, O, measured from the reference point shown. Distance e is not the torsional eccentricity.

Figure 45.13 *Shear Centers of Selected Thin-Walled Open Sections*[a]

18. ECCENTRICALLY LOADED BOLTED CONNECTIONS

An eccentrically loaded connection is illustrated in Fig. 45.14. The bracket's natural tendency is to rotate about the centroid of the connector group. The shear stress in the connectors includes both the direct vertical shear and the torsional shear stress. The sum of these shear stresses is limited by the shear strength of the critical connector, which in turn determines the capacity of the connection.[24]

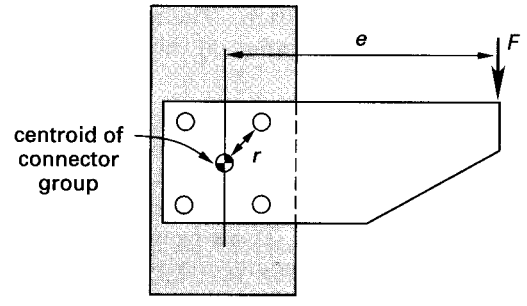

Figure 45.14 *Eccentrically Loaded Connection*

Analysis of an eccentric connection is similar to the analysis of a shaft under torsion. The shaft torque, T, is analogous to the moment, Fe, on the connection. The shaft's radius corresponds to the distance from the centroid of the fastener group to the *critical fastener*. The

[24]This type of analysis is known as an *elastic analysis* of the connection. Although it is traditional, it tends to understate the capacity of the connection.

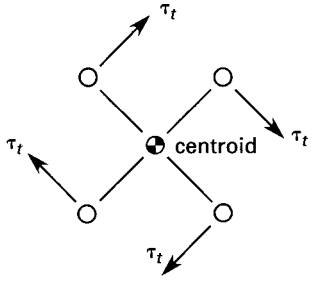
critical fastener is the one for which the vector sum of the vertical and torsional shear stresses is the greatest.

$$\tau = \frac{Tr}{J} = \frac{Fer}{J} \qquad 45.57$$

The polar moment of inertia, J, is calculated from the parallel axis theorem. Since bolts and rivets have little resistance to twisting in their holes, their individual polar moments of inertia are omitted.[25] Only r^2A terms in the parallel axis theorem are used. r_i is the distance from the fastener group centroid to the centroid (i.e., center) of the ith fastener, which has an area of A_i.

$$J = \sum_i r_i^2 A_i \qquad 45.58$$

The torsional shear stress is directed perpendicularly to a line between each fastener and the connector group centroid. The direction of the shear stress is the same as the rotation of the connection.



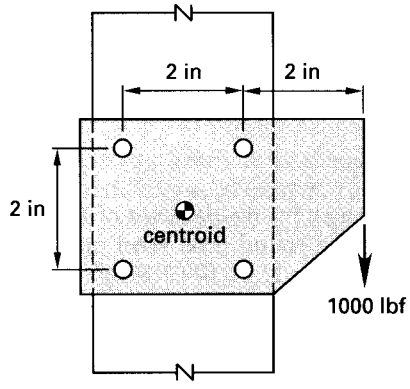


Figure 45.15 *Direction of Torsional Shear Stress*

Once the torsional shear stress has been determined in the critical fastener, it is added in a vector sum to the direct vertical shear stress. The direction of the vertical shear stress is the same as that of the applied force.

$$\tau_v = \frac{F}{nA} \qquad 45.59$$

Example 45.6

All fasteners used in the bracket shown have a nominal 1/2 in diameter. What is the stress in the most critical fastener?

[25]In spot-welded and welded stud connections, the torsional resistance of each connector can be considered.

Solution

Since the fastener group is symmetrical, the centroid is centered within the four fasteners. This makes the eccentricity of the load equal to 3 in. Each fastener is located a distance r from the centroid, where

$$r = \sqrt{x^2 + y^2} = \sqrt{(1\text{ in})^2 + (1\text{ in})^2} = 1.414\text{ in}$$

The area of each fastener is

$$A_i = \frac{\pi}{4}d^2 = \left(\frac{\pi}{4}\right)(0.5\text{ in})^2 = 0.1963\text{ in}^2$$

Using the parallel axis theorem for polar moments of inertia, and disregarding the individual torsional resistances of the fasteners,

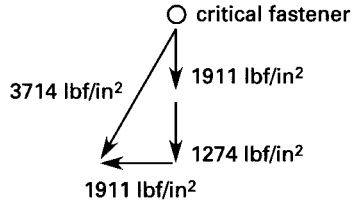
$$J = \sum_i r_i^2 A_i = (4)\left((1.414\text{ in})^2(0.1963\text{ in}^2)\right)$$
$$= 1.570\text{ in}^4$$

The torsional shear stress on each fastener is

$$\tau_t = \frac{Fer}{J} = \frac{(1000\text{ lbf})(3\text{ in})(1.414\text{ in})}{1.570\text{ in}^4} = 2702\text{ lbf/in}^2$$

Each torsional shear stress can be resolved into a horizontal shear stress, τ_{tx}, and a vertical shear stress, τ_{ty}. Both of these components are equal to

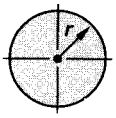
$$\tau_{tx} = \tau_{ty} = \frac{\sqrt{2}\left(2702\ \frac{\text{lbf}}{\text{in}^2}\right)}{2} = 1911\text{ lbf/in}^2$$

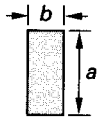


The direct vertical shear downward is

$$\tau_v = \frac{F}{nA} = \frac{1000\text{ lbf}}{(4)(0.1963\text{ in}^2)}$$
$$= 1274\text{ lbf/in}^2$$

The two right fasteners have vertical downward components of torsional shear stress. The direct vertical shear is also downward. These downward components add, making both right fasteners critical.





The total stress in each of these fasteners is

$$\tau = \sqrt{\tau_{tx}^2 + (\tau_{ty} + \tau_v)^2}$$
$$= \sqrt{\left(1911\ \frac{\text{lbf}}{\text{in}^2}\right)^2 + \left(1911\ \frac{\text{lbf}}{\text{in}^2} + 1274\ \frac{\text{lbf}}{\text{in}^2}\right)^2}$$
$$= 3714\text{ lbf/in}^2$$

19. ECCENTRICALLY LOADED WELDED CONNECTIONS

The traditional elastic analysis of an eccentrically loaded welded connection is virtually the same as for a bolted connection, with the additional complication of having to determine the polar moment of inertia of the welds.[26] This can be done either by taking the welds as lines or by assuming each weld has an arbitrary thickness, t. After finding the centroid of the weld group, the rectangular moments of inertia of the individual welds are taken about that centroid using the parallel axis theorem. These rectangular moments of inertia are added to determine the polar moment of inertia. This laborious process can be shortened by use of App. 45.A.

The torsional shear stress, calculated from Mr/J (where r is the distance from the centroid of the weld group to the most distant weld point), is added to the direct shear to determine the maximum shear stress at the critical weld point.

[26]Steel building design does not use an elastic analysis to design eccentric brackets, either bolted or welded. The design methodology is highly proceduralized and codified.

20. FLAT PLATES

Flat plates under uniform pressure are separated into two edge-support conditions: simply supported and built-in edges.[27] Commonly accepted working equations are summarized in Table 45.7. It is assumed that (a) the plates are of "medium" thickness (meaning that the thickness is equal to or less than one-fourth of the minimum dimension of the plate), (b) the pressure is no more than will produce a maximum deflection less than or equal to one-half of the thickness, (c) the plates are constructed of isotropic, elastic material, and (d) the stress does not exceed the yield strength.

Example 45.7

A steel pipe with an inside diameter of 10 in (254 mm) is capped by welding round mild steel plates on its ends. The allowable stress is 11,100 lbf/in^2 (77 MPa). The internal gage pressure in the pipe is maintained at 500 lbf/in^2 (3.5 MPa). What plate thickness is required?

[27]Fixed-edge conditions are theoretical and are seldom achieved in practice. Considering this fact and other simplifying assumptions that are made to justify the use of Table 45.7, a value of $\nu = 0.3$ can be used without loss of generality.

SI Solution

A fixed edge approximates the welded edges of the plate. From Table 45.7, the maximum bending stress is

$$\sigma_{\max} = \frac{3pr^2}{4t^2}$$

$$t = \sqrt{\frac{3pr^2}{4\sigma_{\max}}}$$

$$= \sqrt{\frac{(3)(3.5\ \text{MPa})\left(\frac{254\ \text{mm}}{2}\right)^2}{(4)(77\ \text{MPa})}}$$

$$= 23.4\ \text{mm}$$

Customary U.S. Solution

A fixed edge approximates the welded edges of the plate. From Table 45.7, the maximum bending stress is

$$\sigma_{\max} = \frac{3pr^2}{4t^2}$$

$$t = \sqrt{\frac{3pr^2}{4\sigma_{\max}}}$$

$$= \sqrt{\frac{(3)\left(500\ \frac{\text{lbf}}{\text{in}^2}\right)\left(\frac{10\ \text{in}}{2}\right)^2}{(4)\left(11{,}100\ \frac{\text{lbf}}{\text{in}^2}\right)}}$$

$$= 0.919\ \text{in}$$

21. SPRINGS

An *ideal spring* is assumed to be perfectly elastic within its working range. The deflection is assumed to follow *Hooke's law*.[28] The *spring constant*, k, is also known as the *stiffness, spring rate, scale,* and *k-value*.[29]

$$F = k\delta \qquad 45.60$$

$$k = \frac{F_1 - F_2}{\delta_1 - \delta_2} \qquad 45.61$$

A spring stores energy when it is compressed or extended. By the *work-energy principle*, the energy storage is equal to the work required to displace the spring.

[28]A spring can be perfectly elastic even though it does not follow Hooke's law. The deviation from proportionality, if any, occurs at very high loads. The difference in theoretical and actual spring forces is known as the *straight-line error.*

[29]Another unfortunate name for the spring constant, k, that is occasionally encountered is the *spring index.* This is not the same as the spring index, C, used in helical coil spring design. The units will determine which meaning is intended.

The potential energy of a spring whose ends have been displaced a total distance δ is

$$\Delta E_p = \tfrac{1}{2}k\delta^2 \qquad 45.62$$

If a mass, m, is dropped from height h onto a spring, the compression, δ, can be found by equating the change in potential energy to the energy storage.

$$mg(h+\delta) = \tfrac{1}{2}k\delta^2 \quad \text{[SI]} \qquad 45.63(a)$$

$$m\left(\frac{g}{g_c}\right)(h+\delta) = \tfrac{1}{2}k\delta^2 \quad \text{[U.S.]} \qquad 45.63(b)$$

Within the elastic region, this energy can be recovered by restoring the spring to its original unstressed condition. It is assumed that there is no permanent set, and no energy is lost through external friction or *hysteresis* (internal friction) when the spring returns to its original length.[30]

The entire applied load is felt by each spring in a series of springs linked end-to-end. The *equivalent (composite) spring constant* for springs in series is

$$\frac{1}{k_{\text{eq}}} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} + \cdots \qquad 45.64$$

Springs in parallel (e.g., concentric springs) share the applied load. The equivalent spring constant for springs in parallel is

$$k_{\text{eq}} = k_1 + k_2 + k_3 + \cdots \qquad 45.65$$

22. WIRE ROPE

Wire rope is constructed by first winding individual *wires* into *strands* and then winding the strands into rope. Wire rope is specified by its diameter and numbers of strands and wires. The most common *hoisting cable* is 6×19, consisting of six strands of 19 wires each, wound around a core. This configuration is sometimes referred to as "standard wire rope." Other common configurations are 6×7 (stiff *transmission* or *haulage rope*), 8×19 (extra-flexible hoisting rope), and the abrasion-resistant 6×37. The diameter and area of a wire rope are based on the circle that just encloses the rope.

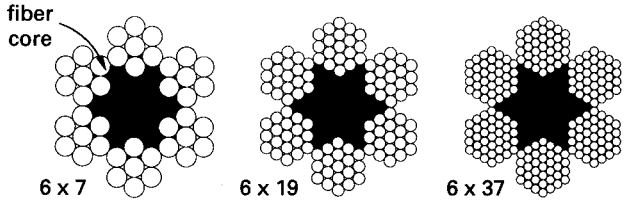

Figure 45.16 *Wire Rope Cross Sections*

[30]There is essentially no hysteresis in properly formed compression, extension, or open-wound helical torsion springs.

Structural

Wire rope can be obtained in a variety of materials and cross sections. In the past, wire ropes were available in iron, cast steel, traction steel (TS), mild plow steel (MPS), and plow steel (PS) grades. Modern wire ropes are generally available only in improved plow steel (IPS) and extra-improved plow steel (EIP) grades.[31] *Monitor* and *blue center steels* are essentially the same as improved plow steel.

Table 45.8 *Minimum Strengths of Wire Materials*

material	ultimate strength, $S_{ut,w}$ (ksi)
iron	65
cast steel	140
extra-strong cast steel	160
plow steel	175–210
improved plow steel	200–240
extra-improved plow steel	240–280

(Multiply ksi by 0.00689 to obtain MPa.)

In Table 45.9, the ultimate strength, $S_{ut,r}$, is the ultimate tensile load that the rope can carry without breaking. This is different from the ultimate strength, $S_{ut,w}$, of each wire given in Table 45.8. The rope's tensile strength will be only 80 to 95% of the combined tensile strengths of the individual wires. The modulus of elasticity for steel ropes is more a function of how the rope is constructed than the type of steel used. (See Table 45.10.)

While manufacturer's data should be relied on whenever possible, general properties of 6 × 19 wire rope are given in Table 45.9.

Table 45.9 *Properties of 6 × 19 Steel Wire Rope (improved plow steel, fiber core)*

diameter		mass		tensile strength[a,b], $S_{ut,r}$	
in	(mm)	lbm/ft	(kg/m)	tons[c]	(tonnes)
1/4	(6.4)	0.11	(0.16)	2.74	(2.49)
3/8	(9.5)	0.24	(0.35)	6.10	(5.53)
1/2	(13)	0.42	(0.63)	10.7	(9.71)
5/8	(16)	0.66	(0.98)	16.7	(15.1)
7/8	(22)	1.29	(1.92)	32.2	(29.2)
1 1/8	(29)	2.13	(3.17)	52.6	(47.7)
1 3/8	(35)	3.18	(4.73)	77.7	(70.5)
1 5/8	(42)	4.44	(6.61)	107	(97.1)
1 7/8	(48)	5.91	(8.80)	141	(128)
2 1/8	(54)	7.59	(11.3)	179	(162)
2 3/8	(60)	9.48	(14.1)	222	(201)
2 5/8	(67)	11.6	(17.3)	268	(243)

[a]Add 7 1/2% for wire ropes with steel cores.
[b]Deduct 10% for galvanized wire ropes.
[c]tons of 2000 pounds

[31]The term "plow steel" is somewhat traditional, as hard-drawn AISI 1070 or AISI 1080 might actually be used.

The central core can be of natural (e.g., hemp) or synthetic fibers or, for higher-temperature use, steel strands or cable. Core designations are FC for *fiber core*, IWRC for *independent wire rope core*, and WSC for *wire-strand core*. Wire rope is protected against corrosion by lubrication carried in the saturated fiber core. Steel-cored ropes are approximately 7.5% stronger than fiber-cored ropes.

Structural rope, structural strand, and *aircraft cabling* are similar in design to wire rope but are intended for permanent installation in bridges and aircraft, respectively. Structural rope and strand are galvanized to prevent corrosion, while aircraft cable is usually manufactured from corrosion-resistant steel.[32,33] Galvanized ropes should not be used for hoisting, as the galvanized coating will be worn off. Structural rope and strand have a nominal tensile strength of 220 ksi (1.5 GPa) and a modulus of elasticity of approximately 20,000 ksi (140 GPa) for diameters between 3/8 and 4 in (0.95 and 10.2 cm).

The most common winding is *regular lay* in which the wires are wound in one direction and the strands are wound around the core in the opposite direction. Regular lay ropes do not readily kink or unwind. Wires and strands in *lang lay* ropes are wound in the same direction, resulting in a wear-resistant rope that is more prone to unwinding. Lang lay ropes should not be used to support loads that are held in free suspension.

In addition to considering the primary tensile dead load, the significant effects of bending and sheave-bearing pressure must be considered when selecting wire rope. Self-weight may also be a factor for long cables. Appropriate dynamic factors should be applied to allow for acceleration, deceleration, and impacts, or the acceleration forces. In general for hoisting and hauling, the working load should not exceed 20% of the breaking strength (i.e., a minimum factor of safety of 5 should be used).[34]

If d_w is the nominal wire diameter in inches,[35] d_r is the nominal wire rope diameter in inches, and d_{sh} is the sheave diameter in inches, the stress from bending around a drum or sheave is given by Eq. 45.66. E_w is the modulus of elasticity of the wire material (approximately 3×10^7 psi (207 GPa for steel), not the rope's modulus of elasticity, though the latter is widely used in this calculation.[36]

$$\sigma_{\text{bending}} = \frac{d_w E_w}{d_{sh}} \qquad 45.66$$

[32]Manufacture of structural rope and strand in the United States are in accordance with ASTM A603 and ASTM A586, respectively.
[33]Galvanizing usually reduces the strength of wire rope by approximately 10%.
[34]Factors of safety are much higher and may be as high as 8 to 12 for elevators and hoists carrying passengers.
[35]For 6 × 19 standard wire rope, the outer wires are typically 1/13 to 1/16 of the rope diameter. For 6 × 7 haulage rope, the ratio is approximately 1/9.
[36]Although E in Eq. 45.66 is often referred to as "the modulus of elasticity of the wire rope," it is understood that E is actually the modulus of elasticity of the wire rope material.

To reduce stress and eliminate permanent set in wire ropes, the diameter of the sheave should be kept as large as is practical, ideally 45 to 90 times the rope diameter. Alternatively, the minimum diameter of the sheave or drum may be stated as 400 times the diameter of the individual outer wires in the rope.[37] Table 45.10 lists minimum diameters for specific rope types.

Table 45.10 *Typical Characteristics of Steel Wire Rope*

configuration	mass (lbm/ft)	area (in^2)	minimum sheave diameter	modulus of elasticity (psi)
6×7	$1.50d_r^2$	$0.380d_r^2$	$42\text{–}72d_r$	14×10^6
6×19	$1.60d_r^2$	$0.404d_r^2$	$30\text{–}45d_r$	12×10^6
6×37	$1.55d_r^2$	$0.404d_r^2$	$18\text{–}27d_r$	11×10^6
8×19	$1.45d_r^2$	$0.352d_r^2$	$21\text{–}31d_r$	10×10^6

(Multiply lbm/ft by 1.49 to obtain kg/m.)
(Multiply in^2 by 6.45 to obtain cm^2.)
(Multiply psi by 6.9×10^{-6} to obtain GPa.)

To prevent wear and fatigue of the sheave or drum, the radial bearing pressure should be kept as low as possible. Actual maximum bearing pressures are highly dependent on the sheave material, type of rope, and application. For 6×19 wire ropes, the acceptable bearing pressure can be as low as 500 psi (3.5 MPa) for cast-iron sheaves and as high as 2500 psi (17 MPa) for alloy steel sheaves. The approximate bearing pressure of the wire rope on the sheave or drum depends on the tensile force in the rope and is given by Eq. 45.67.

$$p_{\text{bearing}} = \frac{2F_t}{d_r d_{\text{sh}}} \qquad 45.67$$

Fatigue failure in wire rope can be avoided by keeping the ratio $p_{\text{bearing}}/S_{ut,w}$ below approximately 0.014 for 6×19 wire rope.[38] ($S_{ut,w}$ is the ultimate tensile strength of the wire material, not of the rope.)

PRACTICE PROBLEMS

Note: Unless instructed otherwise in a problem, use the following properties:

steel: $E = 30 \times 10^6$ lbf/in^2 (20×10^4 MPa)
$G = 11.5 \times 10^6$ lbf/in^2 (8.0×10^4 MPa)
$\alpha = 6.5 \times 10^{-6}$ 1/°F (1.2×10^{-5} 1/°C)
$\nu = 0.3$

[37] For elevators and mine hoists, the sheave-to-wire diameter ratio may be as high as 1000.
[38] A maximum ratio of 0.001 is often quoted for wire rope regardless of configuration.

Columns

1. A structural steel member 50 ft (15 m) long is used as a long column to support 75,000 lbf (330 kN). Both ends are built-in, and there are no intermediate supports. A factor of safety of 2.5 is used. What is the required moment of inertia?

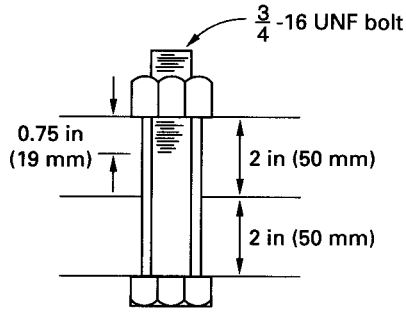
(A) 67 in^4 (2.8×10^{-5} m^4)
(B) 96 in^4 (4.0×10^{-5} m^4)
(C) 130 in^4 (5.6×10^{-5} m^4)
(D) 190 in^4 (8.0×10^{-5} m^4)

The answer is (B).

2. A long steel column with a yield strength of 36,000 lbf/in^2 (250 MPa) has pinned ends. The column is 25 ft (7.5 m) long and has a cross-sectional area of 25.6 in^2 (165 cm^2), a centroidal moment of inertia of 350 in^4 (14,600 cm^2), and a distance from the neutral axis to the extreme fiber of 7 in (180 mm). It carries an axial concentric load of 100,000 lbf (440 kN) and an eccentric load of 150,000 lbf (660 kN) located 3.33 in (80 mm) from the longitudinal axial axis. Use the secant formula to determine the stress factor of safety.

(A) 1.6
(B) 2.1
(C) 2.4
(D) 3.0

The answer is (A).



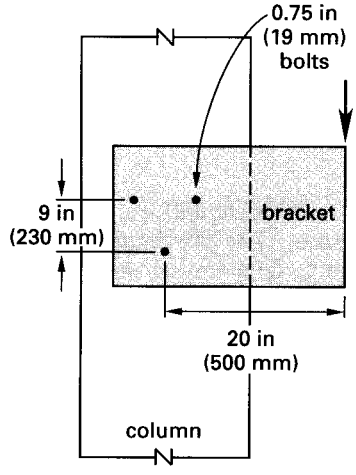
3. A 4 in × 4 in (nominal size) timber post is used to support a sign. The post's modulus of elasticity is 1.5×10^6 lbf/in^2. One end of the post is embedded in a deep concrete base. The other end supports a sign 9 ft above the ground. Neglect torsion and wind effects. What is the Euler load sign weight that will cause failure by buckling?

(A) 2700 lbf
(B) 3200 lbf
(C) 4000 lbf
(D) 5500 lbf

The answer is (C).

Bolts

4. A 3/4-16 UNF steel bolt is used without washers to clamp two rigid steel plates, each 2 in (50 mm) thick. 0.75 in (19 mm) of the threaded section of the bolt remains under the nut. The nut has six threads. The nut is tightened until the stress in the bolt body is 40,000 lbf/in^2 (280 MPa). The bolt's modulus of elasticity is 2.9×10^7 lbf/in^2 (200 GPa). How much does the bolt stretch?

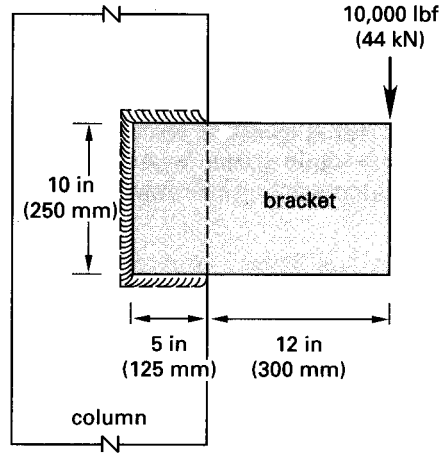


(A) 0.006 in (0.15 mm)
(B) 0.012 in (0.30 mm)
(C) 0.024 in (0.60 mm)
(D) 0.048 in (1.2 mm)

The answer is (A).

Eccentrically Loaded Bolted Connections

5. The bracket shown is attached to a column with three 0.75 in (19 mm) bolts arranged in an equilateral triangular layout. A force is applied with a moment arm of 20 in (500 mm) measured to the centroid of the bolt group. The maximum shear stress in the bolts is limited to 15,000 lbf/in^2 (100 MPa). What is the maximum force that the connection can support?

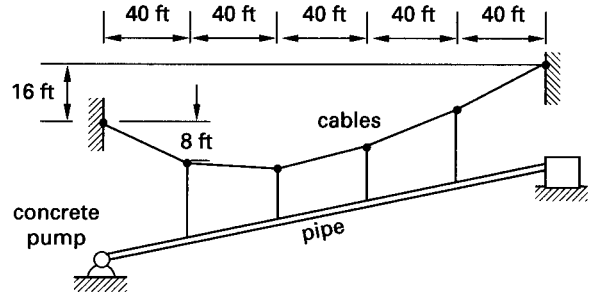


(A) 700 lbf (3.1 kN)
(B) 1200 lbf (5.3 kN)
(C) 2400 lbf (11 kN)
(D) 4700 lbf (20 kN)

The answer is (D).

Eccentrically Loaded Welded Connections

6. A fillet weld is used to secure a steel bracket to a column. The bracket supports a 10,000 lbf (44 kN) force applied 12 in (300 mm) from the face of the column, as shown. The maximum shear stress in the weld material is 8000 lbf/in^2 (55 MPa). What size fillet weld is required?



(A) 3/8 in (9.5 mm)
(B) 1/2 in (13 mm)
(C) 5/8 in (16 mm)
(D) 3/4 in (19 mm)

The answer is (B).

Wire Rope

7. (*Time limit: one hour*) Wet concrete is mixed at a point that is separated from the pour location by a deep, 200 ft wide ravine. It is decided to use a 1/2 in steel cable and a series of 1/2 in steel cable hangers to support a 6 in schedule-40 steel pipe. The cables are 6 × 19 standard hoisting rope with a mass of 0.4 lbm/ft and a breaking strength of 11 tons. The pipe can be assumed to be completely filled with concrete. The cabling geometry is as illustrated. Horizontal restraint is infinite, and the impulse effects of periodic pump stroke pulsations are to be neglected. The vertical wire rope hangers remain vertical. The two pipe ends are supported. Use a tensile factor of safety of 5, and consider a 50% loss of strength at cable connections. What is the factor of safety in the cable?

(A) 0.15
(B) 1.5
(C) 1.9
(D) 2.4

The answer is (A).

1. INTRODUCTION TO INDETERMINATE STATICS

A structure that is *statically indeterminate* is one for which the equations of statics are not sufficient to determine all reactions, moments, and internal forces. Additional formulas involving deflection are required to completely determine these variables.

Although there are many configurations of statically indeterminate structures, this chapter is primarily concerned with beams on more than two supports, trusses with more members than are required for rigidity, and miscellaneous composite structures.

2. DEGREE OF INDETERMINACY

The *degree of indeterminacy* (*degree of redundancy*) is equal to the number of reactions or members that would have to be removed in order to make the structure statically determinate. For example, a two-span beam on three simple supports is indeterminate (redundant) to the first degree. The degree of indeterminacy of a pin-connected truss is given by Eq. 46.1.

$$\text{degree of indeterminacy} = 3 + \text{no. of members} - \left(2 \times \text{no. of joints}\right) \quad \textit{46.1}$$

3. INDETERMINATE BEAMS

Three common configurations of beams can easily be recognized as being statically indeterminate. These are the *continuous beam*, *propped cantilever beam*, and *fixed-end beam* illustrated in Fig. 46.1.

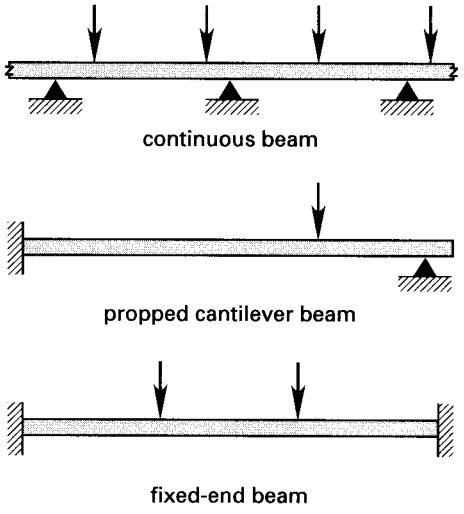

Figure 46.1 *Types of Indeterminate Beams*

4. REVIEW OF ELASTIC DEFORMATION[1]

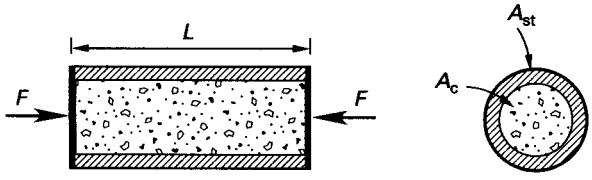
When an axial force, F, acts on an object with length L, cross-sectional area A, and modulus of elasticity E, the deformation[2] is

$$\delta = \frac{FL}{AE} \quad \textit{46.2}$$

[1]This subject is covered in greater detail in Chap. 44.
[2]The terms *deformation* and *elongation* are often used interchangeably in this context.

Structural

When an object with initial length L_o and coefficient of thermal expansion α experiences a temperature change of ΔT degrees, the deformation is



$$\delta = \alpha L_o \Delta T \qquad 46.3$$

5. CONSISTENT DEFORMATION METHOD

The *consistent deformation method*, also known as the *compatibility method*, is one of the methods of solving indeterminate problems. This method is simple to learn and to apply. First, geometry is used to develop a relationship between the deflections of two different members (or for one member at two locations) in the structure. Then, the deflection equations for the two different members at a common point are written and equated, since the deformations must be the same at a common point. This method is illustrated by the following examples.

Example 46.1

A pile is constructed of concrete with a steel jacket. What are the forces in the steel and concrete if a load F is applied? Assume the end caps are rigid and the steel-concrete bond is perfect.

Solution

Let F_c and F_{st} be the loads carried by the concrete and steel, respectively. Then,

$$F_c + F_{st} = F$$

The deformation of the steel is given by Eq. 46.2.

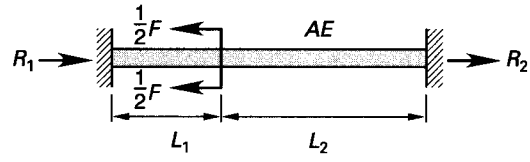
$$\delta_{st} = \frac{F_{st}L}{A_{st}E_{st}}$$

Similarly, the deflection of the concrete is

$$\delta_c = \frac{F_cL}{A_cE_c}$$

But, $\delta_c = \delta_{st}$ since the bonding is perfect. Therefore,

$$\frac{F_cL}{A_cE_c} - \frac{F_{st}L}{A_{st}E_{st}} = 0$$



The first and last equations are solved simultaneously for F_c and F_{st}.

$$F_c = \frac{F}{1 + \dfrac{A_{st}E_{st}}{A_cE_c}}$$

$$F_{st} = \frac{F}{1 + \dfrac{A_cE_c}{A_{st}E_{st}}}$$

Example 46.2

A uniform bar is clamped at both ends and the axial load applied near one of the supports. What are the reactions?

Solution

The first required equation is

$$R_1 + R_2 = F$$

The shortening of section 1 due to the reaction R_1 is

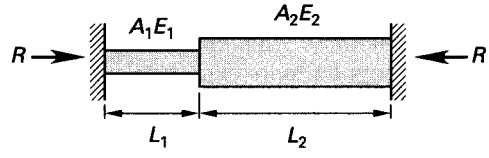
$$\delta_1 = \frac{-R_1L_1}{AE}$$

The elongation of section 2 due to the reaction R_2 is

$$\delta_2 = \frac{R_2L_2}{AE}$$

However, the bar is continuous, so $\delta_1 = -\delta_2$. Therefore,

$$R_1L_1 = R_2L_2$$



The first and last equations are solved simultaneously to find R_1 and R_2.

$$R_1 = \frac{F}{1 + \dfrac{L_1}{L_2}}$$

$$R_2 = \frac{F}{1 + \dfrac{L_2}{L_1}}$$

Example 46.3

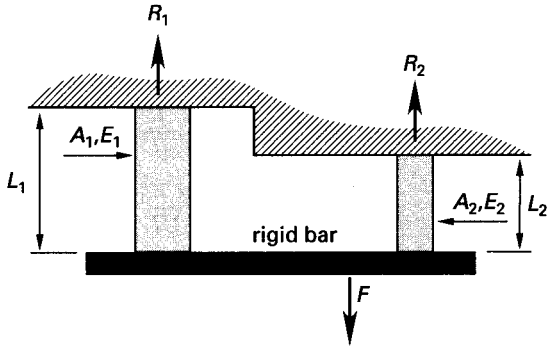
The non-uniform bar shown is clamped at both ends. What are the reactions if a temperature change of ΔT is experienced?

Solution

The thermal deformations of sections 1 and 2 can be calculated directly. Use Eq. 46.3.

$$\delta_1 = \alpha_1 L_1 \Delta T$$
$$\delta_2 = \alpha_2 L_2 \Delta T$$

The total deformation is $\delta = \delta_1 + \delta_2$. However, the deformation can also be calculated from the principles of mechanics.



$$\delta = \frac{RL_1}{A_1 E_1} + \frac{RL_2}{A_2 E_2}$$

These equations can be solved directly for R.

$$R = \frac{(\alpha_1 L_1 + \alpha_2 L_2)\Delta T}{\frac{L_1}{A_1 E_1} + \frac{L_2}{A_2 E_2}}$$

Example 46.4

The beam shown is supported by dissimilar members. What are the forces in the members? Assume the bar is rigid and remains horizontal.[3] The beam's mass is insignificant.

Solution

The required equilibrium condition is

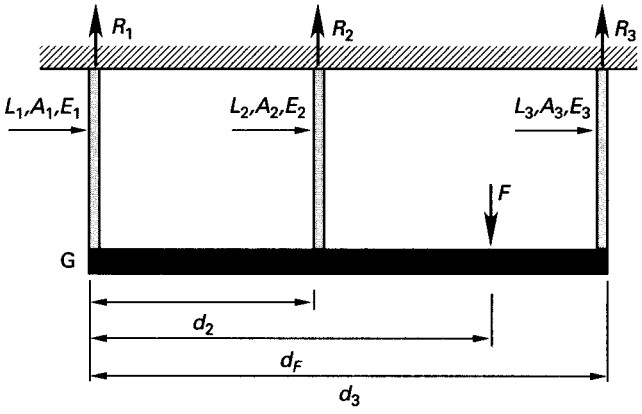
$$R_1 + R_2 = F$$

The elongations of the two tension members are

$$\delta_1 = \frac{R_1 L_1}{A_1 E_1}$$
$$\delta_2 = \frac{R_2 L_2}{A_2 E_2}$$

Since the horizontal bar remains horizontal, $\delta_1 = \delta_2$.

$$\frac{R_1 L_1}{A_1 E_1} = \frac{R_2 L_2}{A_2 E_2}$$



[3]This example is easily solved by summing moments about a point on the horizontal beam.

The first and last equations are solved simultaneously to find R_1 and R_2.

$$R_1 = \frac{F}{1 + \frac{L_1 A_2 E_2}{L_2 A_1 E_1}}$$
$$R_2 = \frac{F}{1 + \frac{L_2 A_1 E_1}{L_1 A_2 E_2}}$$

Example 46.5

The beam shown is supported by dissimilar members. The bar is rigid but is not constrained to remain horizontal. The beam's mass is insignificant. Develop the simultaneous equations needed to determine the reactions in the vertical members.

Solution

The forces in the supports are R_1, R_2, and R_3. Any of these may be tensile (positive) or compressive (negative).

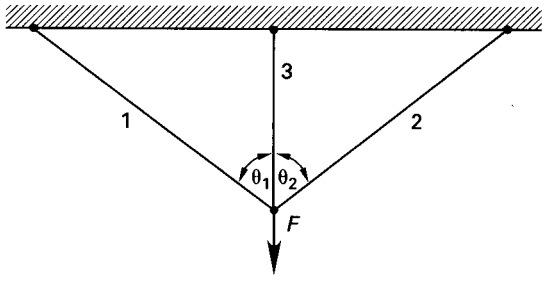
$$R_1 + R_2 + R_3 = F$$

The changes in length are given by Eq. 46.2.

$$\delta_1 = \frac{R_1 L_1}{A_1 E_1}$$
$$\delta_2 = \frac{R_2 L_2}{A_2 E_2}$$
$$\delta_3 = \frac{R_3 L_3}{A_3 E_3}$$

Since the bar is rigid, the deflections will be proportional to the distance from point G.

$$\delta_2 = \delta_1 + \left(\frac{d_2}{d_3}\right)(\delta_3 - \delta_1)$$



Moments can be summed about point G to give a third equation.

$$M_G = R_3 d_3 + R_2 d_2 - F d_F = 0$$

Structural

Example 46.6

A load is supported by three tension members. Develop the simultaneous equations needed to find the forces in the three members.

Solution

The equilibrium requirement is

$$F_{1y} + F_3 + F_{2y} = F$$
$$F_1 \cos\theta_1 + F_3 + F_2 \cos\theta_2 = F$$

Assuming the elongations are small compared to the member lengths, the angles θ_1 and θ_2 are unchanged. Then,

$$\frac{F_1 L_1 \cos\theta_1}{A_1 E_1} = \frac{F_3 L_3}{A_3 E_3} = \frac{F_2 L_2 \cos\theta_2}{A_2 E_2}$$

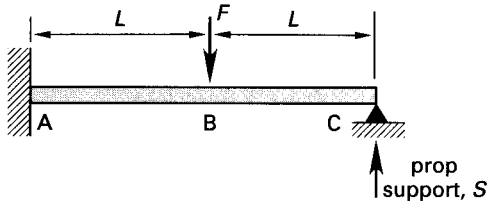
These equations can be solved simultaneously to find F_1, F_2, and F_3. (It may be necessary to work with the x-components of the deflections in order to find a third equation.)

6. SUPERPOSITION METHOD

Two-span (three-support) beams and propped cantilevers are indeterminate to the first degree. Their reactions can be determined from a variation of the consistent deformation procedure known as the *superposition method*.[4] This method requires finding the deflection with one or more supports removed and then satisfying the known conditions.

step 1: Remove enough redundant supports to reduce the structure to a statically determinate condition.

step 2: Calculate the deflections at the previous locations of redundant supports. Use consistent sign conventions.



step 3: Apply each redundant support as a load, and find the deflections at the redundant support points as functions of the redundant support forces.

step 4: Use superposition to combine (i.e., add) the deflections due to the actual loads and the redundant support loads. The total deflections must agree with the known deflections (usually zero) at the redundant support points.

[4]Superposition can also be used with higher-order indeterminate problems. However, the simultaneous equations that must be solved may make superposition unattractive for manual calculations.

Example 46.7

A propped cantilever is loaded by a concentrated force at midspan. Determine the reaction, S, at the prop.

Solution

Start by removing the unknown prop reaction at point C. The cantilever beam is then statically determinate. The deflection and slope at point B can be found or derived from the beam equations. Use App. 44.A.

$$\text{deflection:}\quad \delta_B = \frac{-FL^3}{3EI}$$

$$\text{slope:}\quad y'_B = \frac{-FL^2}{2EI}$$

The slope remains constant to the right of point B. Therefore, the deflection at point C due to the load at point B is

$$\delta_{C,F} = \delta_B + y'_B L$$
$$= \frac{-5FL^3}{6EI}$$

The upward deflection at the cantilever tip due to the prop support, S, alone is given by App. 44.A.

$$\delta_{C,S} = \frac{S(2L)^3}{3EI} = \frac{8SL^3}{3EI}$$

Now, it is known that the actual deflection at point C is zero (the boundary condition). Therefore, the prop support, S, can be determined as a function of the applied load.

$$\delta_{C,S} + \delta_{C,F} = 0$$
$$\frac{8SL^3}{3EI} - \frac{5FL^3}{6EI} = 0$$
$$S = \frac{5F}{16}$$

7. THREE-MOMENT EQUATION

A *continuous beam* has two or more spans (i.e., three or more supports) and is statically indeterminate. The *three-moment equation* is a method of determining the reactions on continuous beams. It relates the moments at any three adjacent supports. The three-moment method can be used with a two-span beam to directly find all three reactions.

When a beam has more than two spans, the equation must be used with three adjacent supports at a time, starting with a support whose moment is known. (The moment is known to be zero at a simply supported end. For a cantilever end, the moment depends only on the loads on the cantilever portion.)

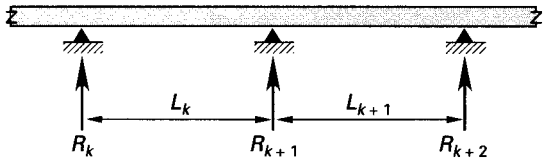


Figure 46.2 *Portion of a Continuous Beam*

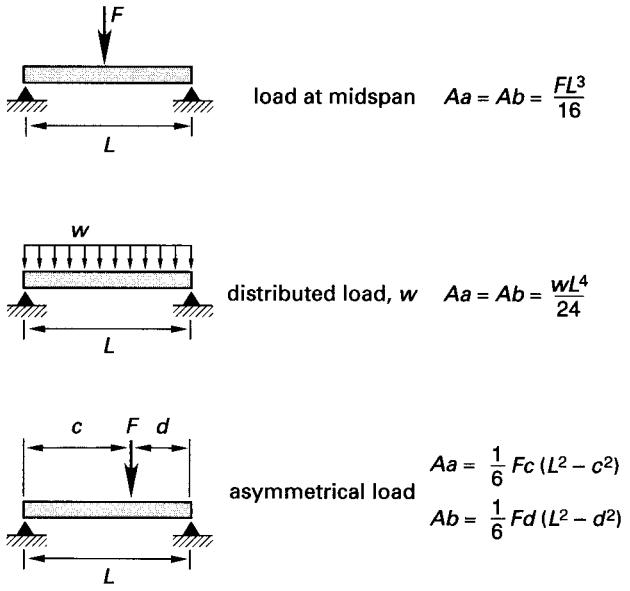
In its most general form, the three-moment equation is applicable to beams with non-uniform cross sections. In Eq. 46.4, I_k is the moment of inertia of span k.

$$\frac{M_k L_k}{I_k} + (2M_{k+1})\left(\frac{L_k}{I_k} + \frac{L_{k+1}}{I_{k+1}}\right) + \frac{M_{k+2}L_{k+1}}{I_{k+1}} = -6\left(\frac{A_k a}{I_k L_k} + \frac{A_{k+1} b}{I_{k+1} L_{k+1}}\right) \quad 46.4$$

Equation 46.4 uses the following special nomenclature.

- a distance from the left support to the centroid of the moment diagram on the left span
- b distance from the right support to the centroid of the moment diagram on the right span
- I_k the moment of inertia of the open span between supports k and $k+1$
- L_k length of the span between supports k and $k+1$
- M_k bending moment at support k
- A_k area of moment diagram between supports k and $k+1$, assuming that the span is simply and independently supported

The products Aa and Ab are known as *first moments of the areas*. It is convenient to derive simplified expressions for Aa and Ab for commonly encountered configurations. Several are presented in Fig. 46.3.



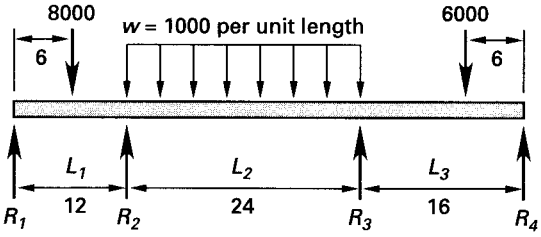


Figure 46.3 *Simplified Three-Moment Equation Terms*

For beams with uniform cross sections, the moment of inertia terms can be eliminated.

$$M_k L_k + (2M_{k+1})(L_k + L_{k+1}) + M_{k+2}L_{k+1} = -6\left(\frac{A_k a}{L_k} + \frac{A_{k+1} b}{L_{k+1}}\right) \quad 46.5$$

Example 46.8

Find the four reactions supporting the beam.

Solution

Spans 1 and 2:

Since the three-moment method can be applied to only two spans at a time, work first with the left and middle spans (spans 1 and 2).

From Fig. 46.3, the quantities $A_1 a$ and $A_2 b$ are

$$A_1 a = \frac{FL^3}{16} = \frac{(8000)(12)^3}{16} = 864{,}000$$

$$A_2 b = \frac{wL^4}{24} = \frac{(1000)(24)^4}{24} = 13{,}824{,}000$$

Structural

Since the left end of the beam is simply supported, M_1 is zero. Therefore, the three-moment equation (Eq. 46.5) becomes

$$(2M_2)(L_1 + L_2) + M_3L_2 = -6\left(\frac{A_1a}{L_1} + \frac{A_2b}{L_2}\right)$$

$$(2M_2)(12 + 24) + M_3(24) = (-6)\left(\frac{864{,}000}{12} + \frac{13{,}824{,}000}{24}\right)$$

After simplification,

$$3M_2 + M_3 = -162{,}000$$

Spans 2 and 3:

From the previous calculations,

$$A_2a = A_2b = 13{,}824{,}000$$

From Fig. 46.3 for the third span,

$$\begin{aligned} A_3b &= \tfrac{1}{6}Fd(L^2 - d^2) \\ &= \left(\tfrac{1}{6}\right)(6000)(6)\left((16)^2 - (6)^2\right) \\ &= 1{,}320{,}000 \end{aligned}$$

Since the right end is simply supported, $M_4 = 0$ and the three-moment equation is

$$M_2L_2 + (2M_3)(L_2 + L_3) = -6\left(\frac{A_2a}{L_2} + \frac{A_3b}{L_3}\right)$$

$$M_2(24) + (2M_3)(24 + 16) = (-6)\left(\frac{13{,}824{,}000}{24} + \frac{1{,}320{,}000}{16}\right)$$

After simplifying,

$$0.3M_2 + M_3 = -49{,}388$$

There are two equations in two unknowns (M_2 and M_3). A simultaneous solution yields

$$M_2 = -41{,}708$$
$$M_3 = -36{,}875$$

Finding reactions:

M_2 can be written in terms of the loads and reactions to the left of support 2. Assuming clockwise moments are positive,

$$M_2 = 12R_1 - (6)(8000) = -41{,}708$$
$$R_1 = 524.3$$

Now that R_1 is known, moments can be taken from support 3 to the left.

$$\begin{aligned} M_3 &= (36)(524.3) + 24R_2 - (30)(8000) - (12)(24{,}000) \\ &= -36{,}875 \end{aligned}$$
$$R_2 = 19{,}677.1$$

Similarly, R_4 and R_3 can be determined by working from the right end to the left. Assuming counterclockwise moments are positive,

$$M_3 = 16R_4 - (10)(6000) = -36{,}875$$
$$R_4 = 1445.3$$
$$\begin{aligned} M_2 &= (40)(1445) + 24R_3 - (34)(6000) - (12)(24{,}000) \\ &= -41{,}708 \end{aligned}$$
$$R_3 = 16{,}353.3$$

Check:

It is a good idea to check for equilibrium in the vertical direction.

$$\begin{aligned} \sum \text{loads} &= 8000 + 24{,}000 + 6000 \\ &= 38{,}000 \end{aligned}$$
$$\begin{aligned} \sum \text{reactions} &= 524.3 + 19{,}677.1 + 1445.3 + 16{,}353.3 \\ &= 38{,}000 \end{aligned}$$

(*Alternative solution:* $R_1 = 4000; R_2 = 16{,}000; R_3 = 14{,}250; R_4 = 3750.$)

8. FIXED-END MOMENTS

When the end of a beam is constrained against rotation, it is said to be a *fixed end* (also known as a *built-in end*). The ends of fixed-end beams are constrained to remain horizontal. Cantilever beams have a single fixed end. Some beams, as illustrated in Fig. 46.1, have two fixed ends and are known as *fixed-end beams*.[5]

Fixed-end beams are inherently indeterminate. To reduce the work required to find end moments and reactions, tables and books of fixed-end moments are often used. (See App. 47.A.)

9. INDETERMINATE TRUSSES

It is possible to manually calculate the forces in all members of an indeterminate truss. However, due to the time required, it is preferable to limit such manual calculations to trusses that are indeterminate to the first degree. The following *dummy unit load method* can be used to solve trusses with a single redundant member.

step 1: Draw the truss twice. Omit the redundant member on both trusses. (There may be a choice of redundant members.)

step 2: Load the first truss (which is now determinate) with the actual loads.

step 3: Calculate the forces, S, in all of the members. Assign a positive sign to tensile forces.

[5]The definition is loose. The term *fixed-end beam* can also be used to mean any indeterminate beam with at least one built-in end (e.g., a propped cantilever).

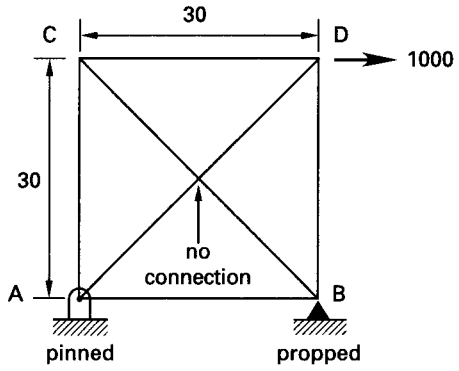
step 4: Load the second truss with two unit forces acting collinearly toward each other along the line of the redundant member.

step 5: Calculate the force, u, in each of the members.

step 6: Calculate the force in the redundant member from Eq. 46.6.

$$S_{\text{redundant}} = \frac{-\sum\left(\frac{SuL}{AE}\right)}{\sum\left(\frac{u^2L}{AE}\right)} \qquad 46.6$$

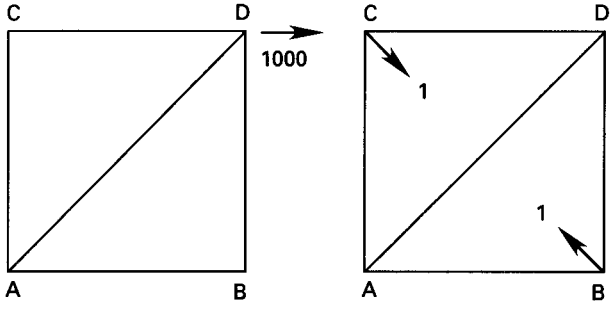
If AE is the same for all members,



$$S_{\text{redundant}} = \frac{-\sum SuL}{\sum u^2L} \qquad 46.7$$

The true force in member j of the truss is

$$F_{j,\text{true}} = S_j + S_{\text{redundant}}\, u_j \qquad 46.8$$



Example 46.9

Find the force in members BC and BD. $AE = 1$ for all members except for CB, which is 2, and AD, which is 1.5.

Solution

The two trusses are shown appropriately loaded.

member	L	AE	S	u	$\frac{SuL}{AE}$	$\frac{u^2L}{AE}$
AB	30	1	0	−0.707 (C)	0	15
BD	30	1	−1000 (C)	−0.707	21,210	15
DC	30	1	0	−0.707	0	15
CA	30	1	0	−0.707	0	15
CB	42.43	2	0	1.0	0	21.22
AD	42.43	1.5	1414 (T)	1.0	39,997	28.29
					61,207	109.51

From Eq. 46.6,

$$S_{\text{BC}} = \frac{-61{,}207}{109.51} = -558.9 \text{ (C)}$$

From Eq. 46.8,

$$F_{\text{BD,true}} = -1000 + (-558.9)(-0.707) = -604.9 \text{ (C)}$$

10. INFLUENCE DIAGRAMS

Shear, moment, and reaction influence diagrams (influence lines) can be drawn for any point on a beam or truss. This is a necessary first step in the evaluation of stresses induced by moving loads. It is important to realize, however, that the influence diagram applies only to one point on the beam or truss.

Influence Diagrams for Beam Reactions

In a typical problem, the load is fixed in position and the reactions do not change. If a load is allowed to move across a beam, the reactions will vary. An influence diagram can be used to investigate the value of a chosen reaction as the load position varies.

To make the influence diagram as general in application as possible, the load is taken as 1 lbf. As an example, consider a 20 ft, simply supported beam and determine the effect on the left reaction of moving a 1 lbf load across the beam.

If the load is directly over the right reaction ($x = 0$), the left reaction will not carry any load. Therefore, the ordinate of the influence diagram is zero at that point. (Even though the right reaction supports 1 lbf, this influence diagram is being drawn for one point only—the left reaction.) Similarly, if the load is directly over the left reaction ($x = L$), the ordinate of the influence diagram will be 1. Basic statics can be used to complete the rest of the diagram, as shown in Fig. 46.4.

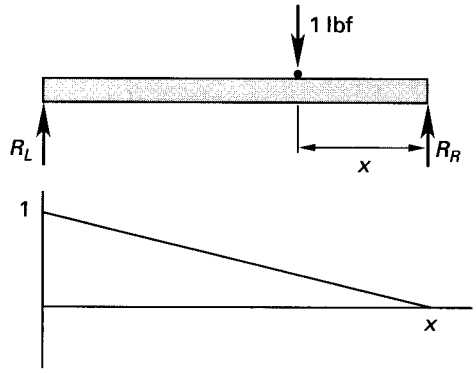


Figure 46.4 *Influence Diagram for Reaction of Simple Beam*

Use this rudimentary example of an influence diagram to calculate the left reaction for any placement of any load (not just 1 lbf loads) by multiplying the actual load by the ordinate of the influence diagram.

$$R_L = P \times \text{ordinate} \qquad 46.9$$

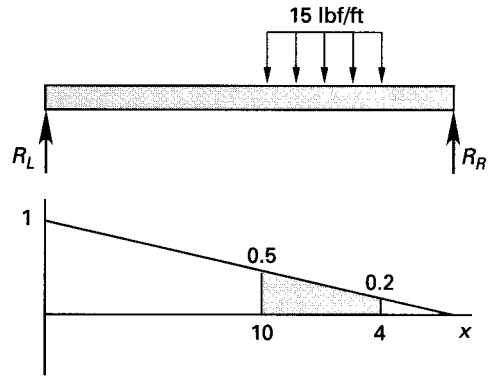
Even though the influence diagram was drawn for a point load, it can still be used when the beam carries a uniformly distributed load. In the case of a uniform load of w distributed over the beam from x_1 to x_2, the left reaction can be calculated from Eq. 46.10.

$$\begin{aligned} R_L &= \int_{x_1}^{x_2} (w \times \text{ordinate})dx \\ &= w \times \text{area under curve} \end{aligned} \qquad 46.10$$

Example 46.10

A 500 lbf load is placed 15 ft from the right end of a 20 ft, simply supported beam. Use the influence diagram to determine the left reaction.

Solution



Since the influence line increases linearly from 0 to 1, the ordinate is the ratio of position to length. That is, the ordinate is $15/20 = 0.75$. The left reaction is

$$R_L = (0.75)(500 \text{ lbf}) = 375 \text{ lbf}$$

Example 46.11

A uniform load of 15 lbf/ft is distributed between $x = 4$ and $x = 10$ along a 20 ft, simply supported beam. What is the left reaction?

Solution

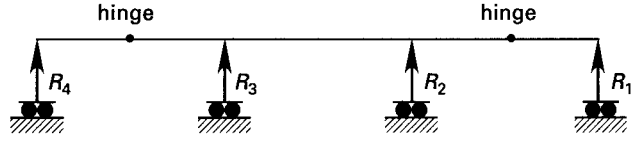
From Eq. 46.10, the left reaction can be calculated from the area under the influence diagram between the limits of loading.

$$\text{area} = \left(\tfrac{1}{2}\right)(10 \text{ ft})(0.5) - \left(\tfrac{1}{2}\right)(4 \text{ ft})(0.2) = 2.1 \text{ ft}$$

The left reaction is

$$R_L = \left(15 \frac{\text{lbf}}{\text{ft}}\right)(2.1 \text{ ft}) = 31.5 \text{ lbf}$$

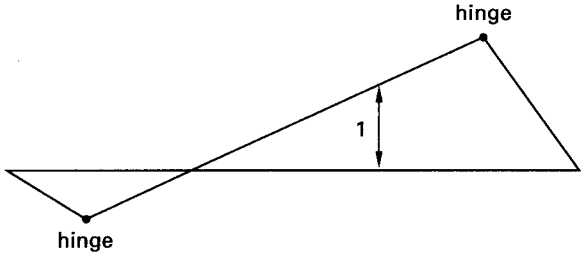
Finding Reaction Influence Diagrams Graphically



Since the reaction will always have a value of 1 when the unit load is directly over the reaction and since the reaction is always directly proportional to the distance x, the reaction influence diagram can be easily determined from the following steps.

step 1: Remove the support being investigated.

step 2: Displace (lift) the beam upward a distance of one unit at the support point. The resulting beam shape will be the shape of the reaction influence diagram.



Example 46.12

What is the approximate shape of the reaction influence diagram for reaction 2?

Solution

Pushing up at reaction 2 such that the deflection is one unit results in the shown shape.

Influence Diagrams for Beam Shears

A shear influence diagram (not the same as a shear diagram) illustrates the effect on the shear at a particular point in the beam of moving a load along the beam's length. As an illustration, consider point A along the simply supported beam of length 20.

In all cases, principles of statics can be used to calculate the shear at point A as the sum of loads and reactions on the beam from point A to the left end. (With the appropriate sign convention, summation to the right end could be used as well.) If the unit load is placed between the right end ($x = 0$) and point A, the shear at point A will consist only of the left reaction, since there are no other loads between point A and the left end. From the reaction influence diagram, the left reaction varies linearly. At $x = 12$, the location of point A, the shear is $V = R_L = 12/20 = 0.6$.

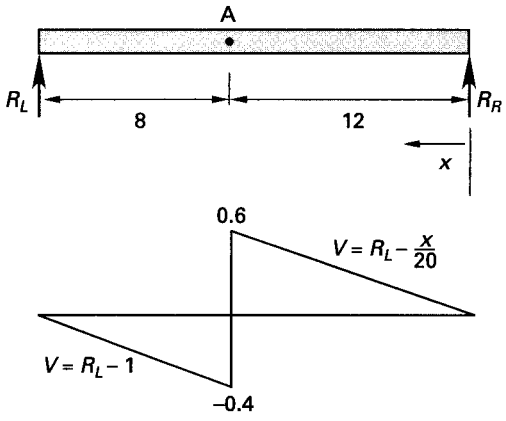


Figure 46.5 *Shear Influence Diagram for Simple Beam*

When the unit load is between point A and the left end, the shear at point A is the sum of the left reaction (upward and positive) and the unit load itself (downward and negative). Therefore, $V = R_L - 1$. At $x = 12$, the shear is $V = 0.6 - 1 = -0.4$.

Figure 46.5 is the shear influence diagram. In the diagram, notice that the shear goes through a reversal of 1. It is also helpful to note that the slopes of the two inclined sections are the same.

Shear influence diagrams are used in the same manner as reaction influence diagrams. The shear at point A for any position of the load can be calculated by multiplying the ordinate of the diagram by the actual load. Distributed loads are found by multiplying the uniform load by the area under the diagram between the limits of loading. If the loading extends over positive and negative parts of the curve, the sign of the area is considered when performing the final summation.

If it is necessary to determine the distribution of loading that will produce the maximum shear at a point whose influence diagram is available, the load should be positioned in order to maximize the area under the diagram.[6] This can be done by "covering" either all of the positive area or all of the negative area.[7]

Shear Influence Diagrams by Virtual Displacement

A difficulty in drawing shear influence diagrams for continuous beams on more than two supports is finding the reactions. The method of *virtual displacement* or *virtual work* can be used to find the influence diagram without going through that step.

step 1: Replace the point being investigated (i.e., point A) with an imaginary link with unit length. (It may be necessary to think of the link as having a length of 1 ft, but the link does not add to or subtract from any length of the beam.) If the point being investigated is a reaction, place a hinge at that point and lift the hinge upward a unit distance.

step 2: Push the two ends of the beam (with the link somewhere in between) toward each other a very small amount until the linkage is vertical. The distance between supports does not change, but the linkage allows the beam sections to assume a slope. The sections to the left and right of the linkage displace δ_1 and δ_2, respectively, from their equilibrium positions. The slope of both sections is the same. Points of support remain in contact with the beam.

step 3: Determine the ratio of δ_1 and δ_2. Since the slope on the two sections is the same, the longer section will have the larger deflection. If $L = a + b$ is the length of the beam, the relationships between the deflections can be determined from Eqs. 46.11 through 46.13.

$$\delta_1 + \delta_2 = 1$$

$$\frac{\delta_1}{\delta_2} = \frac{a}{b} \qquad 46.11$$

$$\delta_1 = \left(\frac{a}{L}\right)\delta \qquad 46.12$$

[6] If the *minimum shear* is requested, the maximum negative shear is implied. The minimum shear is not zero in most cases.

[7] Usually, the dead load is assumed to extend over the entire length of the beam. The uniform live loads are distributed in any way that will cause the maximum shear.

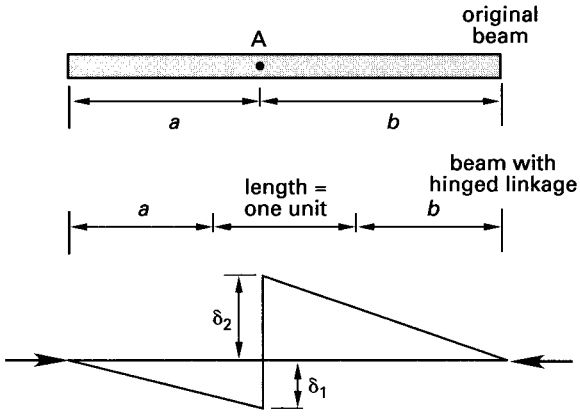

Figure 46.6 *Virtual Beam Displacements*

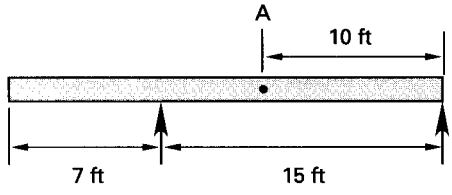
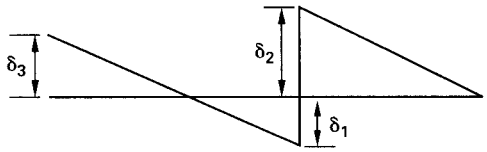
$$\delta_2 = \left(\frac{b}{L}\right)\delta \qquad 46.13$$



Since $\delta = \delta_1 + \delta_2$ was chosen as one, Eqs. 46.12 and 46.13 really give the relative proportions of the unit link that extend below and above the reference line in Fig. 46.6.

Knowing that the total shear reversal through point A is one unit and that the slopes are the same, the relative proportions of the reversal below and above the line will determine the shape of the displaced beam. The shape of the influence diagram is the shape taken on by the beam.

step 4: As required, use equations of straight lines to obtain the shear influence ordinate as a function of position along the beam.



Example 46.13

For the simply supported beam shown, draw the shear influence diagram for a point 10 ft from the right end.

Solution

If a unit link is placed at point A and the beam ends are pushed together, the following shape will result. Notice that the beam must remain in contact with the points of support, and that the two slopes are the same.

The overhanging 7 ft of beam do not change the shape of the shear influence diagram between the supports. The deflections can be evaluated assuming a 15 ft long beam.

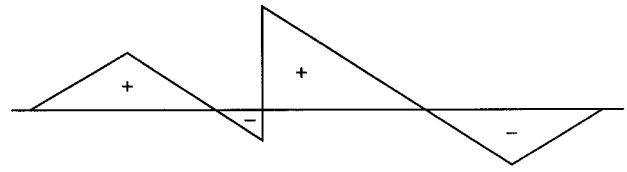
$$\delta_1 = \frac{5\text{ ft}}{15\text{ ft}} = 0.33$$

$$\delta_2 = \frac{10\text{ ft}}{15\text{ ft}} = 0.67$$

The slope in both sections of the beam is the same. This slope can be used to calculate δ_3.

$$m = \frac{\delta_1}{a} = \frac{0.33}{5\text{ ft}} = 0.066\ 1/\text{ft}$$

$$\delta_3 = (7\text{ ft})\left(0.066\ \frac{1}{\text{ft}}\right) = 0.46$$



Example 46.14

Where should a uniformly distributed load be placed on the following beam to maximize the shear at section A?

Solution

Using the principle of virtual displacement, the following shear influence diagram results by inspection. (It is not necessary to calculate the relative displacements to answer this question. It is only necessary to identify the positive and negative parts of the influence diagram.)

To maximize the shear, the uniform load should be distributed either over all positive or all negative sections of the influence diagram.

Moment Influence Diagrams by Virtual Displacement

A moment influence diagram (not the same as a moment diagram) gives the moment at a particular point for any location of a unit load. The method of virtual displacement can be used in this situation to simplify finding the moment influence diagram.

step 1: Replace the point being investigated (i.e., point A) with an imaginary hinge.

step 2: Rotate the beam one unit rotation by applying equal but opposite moments to each of the two beam sections. Except where the

point being investigated is at a support, this unit rotation can be achieved simply by "pushing up" on the beam at the hinge point.

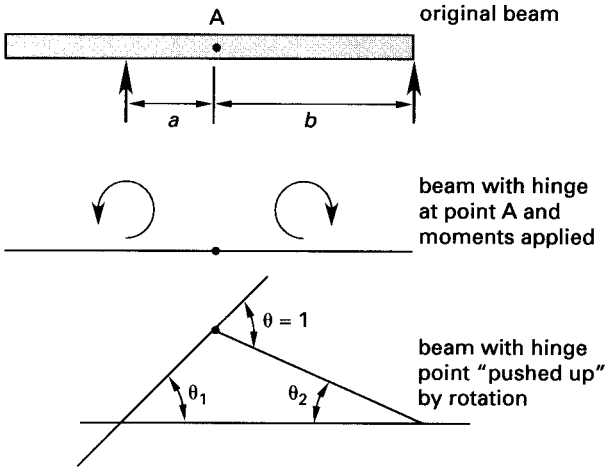


Figure 46.7 *Moment Influence Diagram by Virtual Displacement*

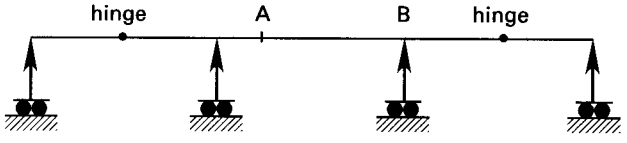
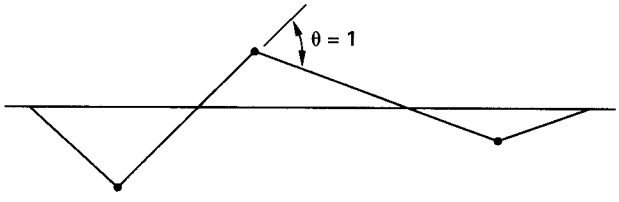
step 3: The angles made by the sections on either side of the hinge will be proportional to the lengths of the opposite sections. (Since the angle is small for a virtual displacement, the angle and its tangent, or slope, are the same.)



$$\theta_1 = \frac{b}{L} \qquad 46.14$$

$$\theta_2 = \frac{a}{L} \qquad 46.15$$

$$L = a + b \qquad 46.16$$



Example 46.15

What are the approximate shapes of the moment influence diagrams for points A and B on the beam shown?

Solution

By placing an imaginary hinge at point A and rotating the two adjacent sections of the beam, the following shape results.

The moment influence diagram for point B is found by placing an imaginary hinge at point B and applying a rotating moment. Since the beam must remain in contact with all supports, and since there is no hinge between the two middle supports, the moment influence diagram must be horizontal in that region.

Shear Influence Diagrams on Cross-Beam Decks

When girder-type construction is used to construct a road or bridge deck, the loads will not be applied directly to the girder. Rather, the loads will be transmitted to the girder at panel points from cross beams. Figure 46.8 shows a typical construction detail involving girders and cross beams.

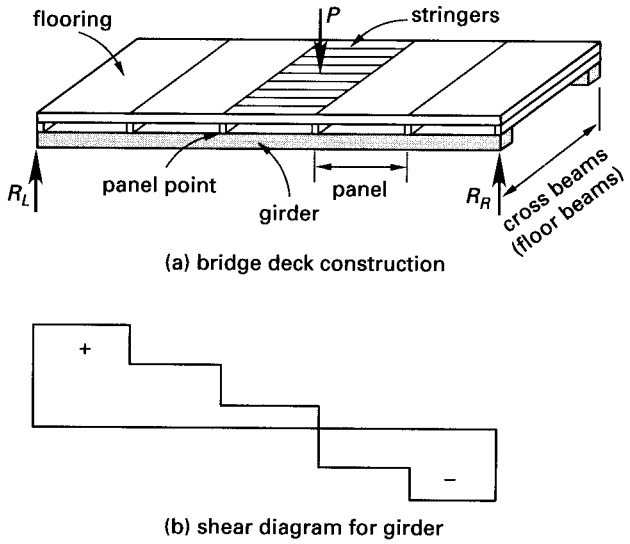


Figure 46.8 *Cross-Beam Decking*

A load applied to the deck stringers will be transmitted to the girder only at the panel points. Because the girder experiences a series of concentrated loads, the shear between panel points is horizontal. Since the shear is always constant between panel points, we speak of *panel shear* rather than shear at a point. Accordingly, shear influence diagrams are drawn for a panel, not for a point. Moment influence diagrams are similarly drawn for a panel.

Influence Diagrams on Cross-Beam Decks

Shear and moment influence diagrams for girders with cross beams are identical to simple beams, except for the panel being investigated. Once the influence diagram has been drawn for the simple beam, the influence diagram ordinates at the ends of the panel being investigated are connected to obtain the influence diagram for the girder. This is illustrated in Fig. 46.9.

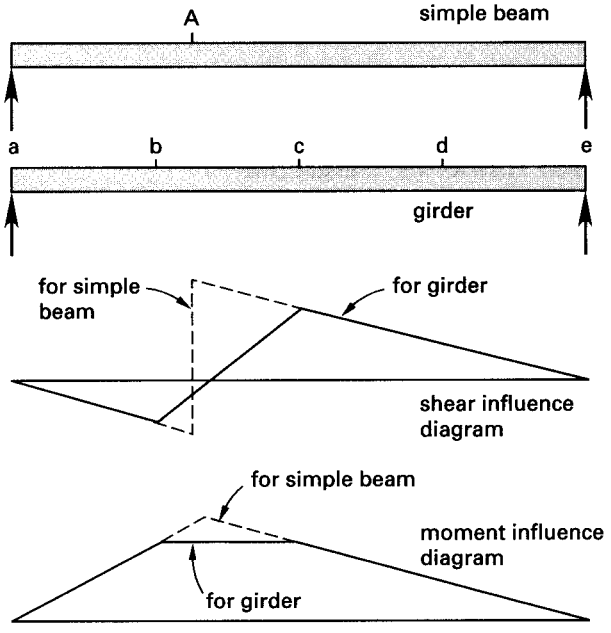

Figure 46.9 *Comparison of Influence Diagrams for Simple Beams and Girders (Panel bc)*

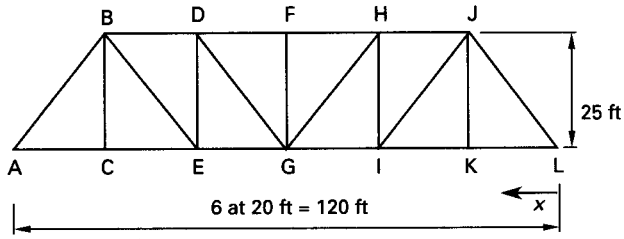
Influence Diagrams for Truss Members



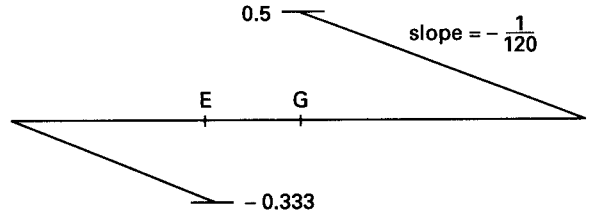
Since members in trusses are initially assumed to be axial members, they cannot carry shears or moments. Therefore, shear and moment influence diagrams do not exist for truss members. However, it is possible to obtain an influence diagram showing the variation in axial force in a given truss member as the load varies in position.

There are two general cases for finding forces in truss members. The force in a horizontal truss member is proportional to the moment across the member's panel. The force in an inclined truss member is proportional to the shear across that member's panel.

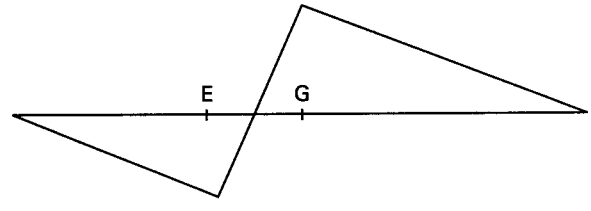
So, even though we may only want the axis load in a truss member, it is still necessary to construct the shear and moment influence diagrams for the entire truss in order to determine the applications of loading on the truss that produce the maximum shear and moment across the member's panel.

Example 46.16

Draw the influence diagram for vertical shear in panel DF of the through truss shown. What is the maximum force in member DG if a 1000 lbf load moves across the truss?

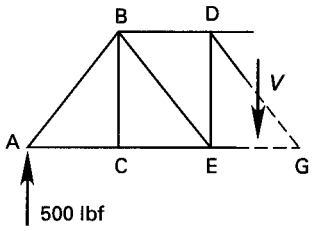


Solution



Allow a unit load to move from joint L to joint G along the lower chords. If the unit vertical load is at a distance x from point L, the right reaction will be $+\left(1-(x/120)\right)$. The unit load itself has a value of -1, so the shear at distance x is just $-x/120$.

Allow a unit load to move from joint A to joint E along the lower chords. If the unit load is a distance x from point L, the left reaction will be $x/120$, and the shear at distance x will be $(x/120) - 1$.



These two lines can be graphed.

The influence line is completed by connecting the two lines as shown. Therefore, the maximum shear in panel DF will occur when a load is at point G on the truss.

If the 1000 lbf load is at point G, the two reactions at points A and L will each be 500 lbf. The cut-and-sum method can be used to calculate the force in member DG simply by evaluating the vertical forces on the free-body to the left of point G.

For equilibrium to occur, V must be 500. This vertical shear is entirely carried by member DG. The length of member DG is

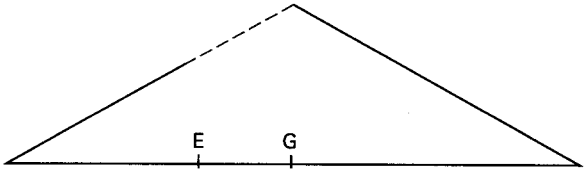
$$\sqrt{(20\text{ ft})^2 + (25\text{ ft})^2} = 32\text{ ft}$$

The force in member DG is

$$\left(\frac{32\text{ ft}}{25\text{ ft}}\right) 500\text{ lbf} = 640\text{ lbf}$$

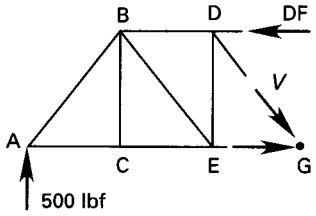
Example 46.17

Draw the moment influence diagram for panel DF on the truss shown in Ex. 46.16. What is the maximum force in member DF if a 1000 lbf load moves across the truss?



Solution

The left reaction is $x/120$ where x is the distance from the unit load to the right end. If the unit load is to the right of point G, the moment can be found by summing moments from point G to the left. The moment is $(x/120)(60) = 0.5x$.



If the unit load is to the left of point E, the moment will again be found by summing moments about point G.

$$\left(\frac{x}{120}\right)(60) - (1)(x - 60) = 60 - 0.5x$$

These two lines can be graphed. The moment for a unit load between points E and G is obtained by connecting the two end points of the lines derived above. Therefore, the maximum moment in panel DF will occur when the load is at point G on the truss.

If the 1000 lbf load is at point G, the two reactions at points A and L will each be 500 lbf. The method of sections can be used to calculate the force in member DF by taking moments about joint G.

$$\sum M_G\text{: } (500\text{ lbf})(60\text{ ft}) - (\text{DF})(25\text{ ft}) = 0$$

$$\text{DF} = 1200\text{ lbf}$$

11. MOVING LOADS ON BEAMS

Global Maximum Moment Anywhere on Beam

If a beam supports a single moving load, the maximum bending and shearing stresses at any point can be found by drawing the moment and shear influence diagrams for that point. Once the positions of maximum moment and maximum shear are known, the stress at the point in question can be found from Mc/I.

If a simply supported beam carries a set of moving loads (which remain equidistant as they travel across the beam), the following procedure can be used to find the *dominant load*. (The dominant load is the one that occurs directly over the point of maximum moment.)

step 1: Calculate and locate the resultant of the load group.

step 2: Assume that one of the loads is dominant. Place the group on the beam such that the distance from one support to the assumed dominant load is equal to the distance from the other support to the resultant of the load group.

step 3: Check to see that all loads are on the span and that the shear changes sign under the assumed dominant load. If the shear does not change sign under the assumed dominant load, the maximum moment may occur when only some of the load group is on the beam. If it does change sign, calculate the bending moment under the assumed dominant load.

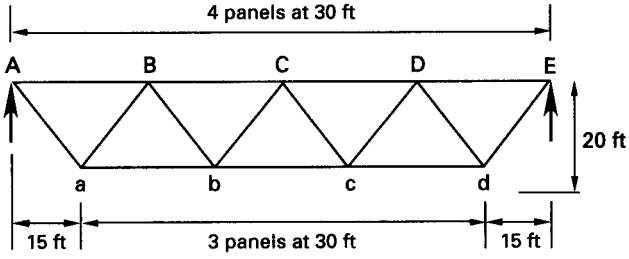
step 4: Repeat steps 2 and 3, assuming that the other loads are dominant.

step 5: Find the maximum shear by placing the load group such that the resultant is a minimum distance from a support.

Placement of Load Group to Maximize Local Moment

In the design of specific members or connections, it is necessary to place the load group in a position that will maximize the load on those members or connections.

Structural



The procedure for finding these positions of local maximum loadings is different from the global maximum procedures.

The solution to the problem of local maximization is somewhat trial-and-error oriented. It is aided by use of the influence diagram. In general, the variable being evaluated (reaction, shear, or moment) is maximum when one of the wheels is at the location or section of interest.

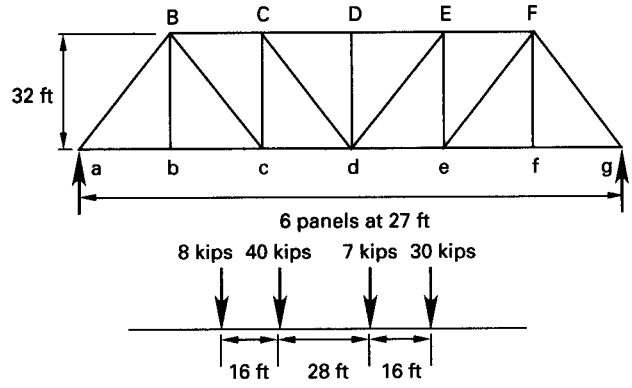
When there are only two or three wheels in the load group, the various alternatives can be simply evaluated by using the influence diagram for the variable being evaluated. When there are many loads in the load group (e.g., a train loading), it may be advantageous to use heuristic rules for predicting the dominant wheel.

PRACTICE PROBLEMS

1. The truss shown carries a moving uniform live load of 2 kips/ft and a moving concentrated live load of 15 kips.

(a) What is the maximum force in member Bb?

(A) 40 kips
(B) 51 kips
(C) 59 kips
(D) 73 kips

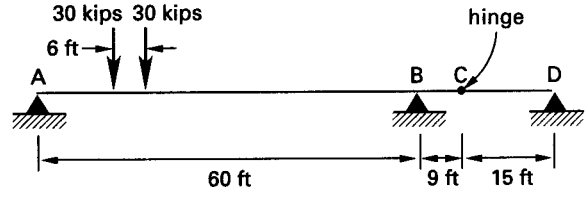


The answer is (C).

(b) What is the maximum force in member BC?

(A) 15 kips
(B) 80 kips
(C) 95 kips
(D) 170 kips

The answer is (D).



2. The truss shown carried a group of four live loads along its bottom chord. What is the maximum force in member CD?

(A) 34 kips
(B) 82 kips
(C) 180 kips
(D) 220 kips

The answer is (B).

3. A moving load consisting of two 30 kip forces separated by a constant 6 ft travels over a two-span bridge. The bridge has an interior expansion joint that can be considered to be an ideal hinge.

(a) What is the maximum moment at point B?

(A) 250 ft-kips
(B) 310 ft-kips
(C) 380 ft-kips
(D) 430 ft-kips

The answer is (D).

(b) What is the maximum reaction at point B?

(A) 30 kips
(B) 60 kips
(C) 66 kips
(D) 90 kips

The answer is (C).

v	shear, or due to shear

1. INTRODUCTION TO STRUCTURAL ANALYSIS

Structural analysis determines the reactions, internal forces, stresses, and deformations induced in a structure by loading. While loading from external forces is the most common situation, stress and deformation can also be caused by internal temperature changes and settling of foundations.

Prior to widespread use of computers in engineering design and analysis, various exact and approximate methods of manual analysis were developed for specific types of structures. While these traditional manual methods continue to be useful, the need for a variety of specialized techniques has been reduced significantly. This chapter concentrates on the manual techniques that remain most relevant in present-day structural analysis.

Structural analysis is categorized as either *static* or *dynamic*, depending on the need to evaluate inertial forces caused by acceleration. A *static analysis* does not consider inertial forces. In a *dynamic analysis*, the various forces and deformations are determined as functions of time. While computer analysis has enhanced the application of dynamic analysis in certain areas (e.g., earthquake loading), most structures continue to be designed using static analyses based on the maximum expected dynamic loads. This chapter is limited to a review of several common methods of structural analysis used for static loading.

Structural analysis can also be categorized on the basis of the level of refinement that is incorporated. *Linear elastic first-order analysis* is used to evaluate the majority of structures built today. The basic assumptions are that (a) the structure is perfectly linear and elastic in behavior, and (b) deformations can be neglected. The principle of *proportionality* is assumed to hold, so changing all of the loads by a certain percentage results in an equal percentage change in all of the internal forces, reactions, and deflections.

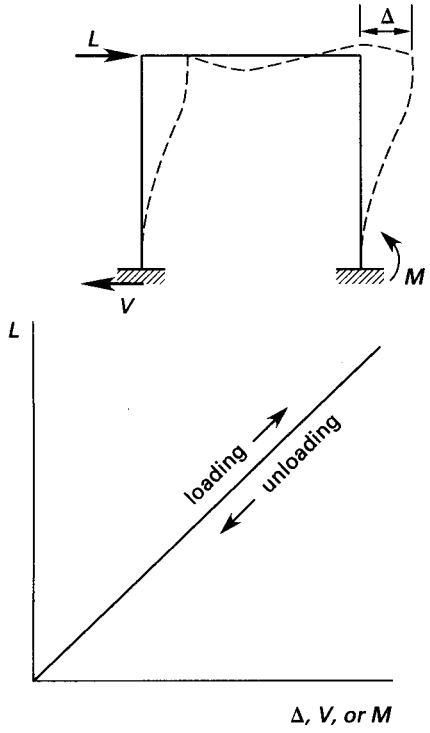

Figure 47.1 *Linear Elastic Behavior*

With a *linear elastic second-order analysis*, the assumption of elastic linear behavior is maintained, but the deflections are considered in the equilibrium equations. In a second-order analysis, equilibrium between internal and external forces is achieved in the final deformed configuration, not in the initial undeformed geometry.

Since the deformations of the structure cannot be computed precisely until the internal forces are obtained, a second-order solution is iterative. Due to computational difficulties in manual solutions, second-order effects have been traditionally included as corrections applied during the design process. The moment magnifier method used to design columns in the ACI code and LRFD Manual are typical examples. There is an increasing trend, however, to introduce second-order effects in computerized analyses. The P-Δ method described in Sec. 18 is a simplified second-order analysis technique.

With an *inelastic first-order analysis*, the potential for inelastic, disproportional behavior is considered, but equilibrium is assumed to occur in the undeformed configuration. *Plastic analysis* is a popular version of this method. The objective of plastic analysis is to obtain the *ultimate load* (maximum load) that the structure can carry. When supporting an ultimate load, the structure becomes a mechanism. A *mechanism* is a structure that can deform by rotation around a number of points. In highly stressed structures, these points are referred to as *plastic hinges* since the material at those points is loaded in the plastic region. Plastic analysis is often used in the design of continuous beams, where it is particularly easy to apply.

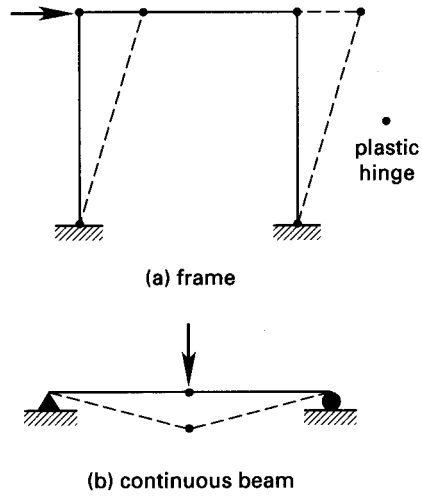

Figure 47.2 *Failure Mechanisms*

With an *inelastic second-order analysis*, inelastic response in the material is permitted, and the equilibrium equations are satisfied in the deformed configuration. Inelastic second-order analysis is a well-developed tool, but it is too complex to be used in most designs.

2. TRADITIONAL METHODS

Statically determinate structures can easily be solved by applying the equations of equilibrium, and advanced methods are seldom needed. Therefore, specialized methods of structural analysis generally address indeterminate structures. Indeterminate structural analysis procedures can be classified as either force methods or displacement (deformation, deflection, etc.) methods, depending on whether forces or displacements are used as basic unknowns. The classical *moment distribution*

and *slope deflection methods* are displacement-based solutions. The *stiffness method*, typically used as the basis of modern computerized structural analysis, also is a displacement method. The *flexibility method* is a force-based approach.

3. REVIEW OF WORK AND ENERGY

For a simple structure deflection a distance Δ in the direction of the applied force P, a simple mathematical definition of *work* is the product of force times displacement. Analogously, the work of a torque T (or moment) causing a rotation of ϕ radians is torque times rotation.

$$W = P\Delta \quad \text{[linear displacement]} \qquad 47.1$$

$$W = T\phi \quad \text{[rotation]} \qquad 47.2$$

The change in energy of an ideal conservative system to which work has been added is equal to the work.

$$W = U_2 - U_1 \qquad 47.3$$

4. REVIEW OF LINEAR DEFORMATION

The deformation of a tension or compression member due to axial force P is

$$\Delta = \frac{PL}{AE} \qquad 47.4$$

5. THERMAL LOADING

Structures subjected to temperature changes can be evaluated using the methods in this chapter by adding the appropriate thermally induced forces and moments to the externally applied loads. For example, the thermally induced axial load in a constrained member with a uniform temperature change is

$$P_{\text{th}} = \frac{\Delta_{\text{constrained}} AE}{L} = \alpha(T_2 - T_1)\left(\frac{LAE}{L}\right)$$
$$= \alpha(T_2 - T_1)AE \qquad 47.5$$

Bending moments will be induced in a structural member that experiences a temperature variation across its thickness (depth). If the temperature varies linearly with depth, and if the temperature difference is zero at the neutral axis (depth $h/2$), the thermally induced moment will be given by Eq. 47.6.

$$M = \alpha(T_{\text{extreme fiber}} - T_{\text{neutral axis}})\left(\frac{EI}{h}\right) \qquad 47.6$$

Any arbitrary linear variation can be treated as the sum of a uniform temperature change plus a linear variation with a value of zero at the section's neutral axis. In Eqs. 47.5 and 47.6, tension is considered to be positive, and compression is negative. For an axially constrained beam experiencing an increase in temperature at its upper surface, the beam will bow upwards (to lengthen the upper surface), and the moment will be negative.

6. DUMMY UNIT LOAD METHOD

The *energy method*, typically referred to as the *dummy load method*, is based on the *virtual work principle*.

> If a structure that is in equilibrium with a set of loads is given an arbitrary (virtual) deformation, the external work calculated from the applied loads and the virtual displacements is equal to the internal work of the internal stresses and the virtual strains.

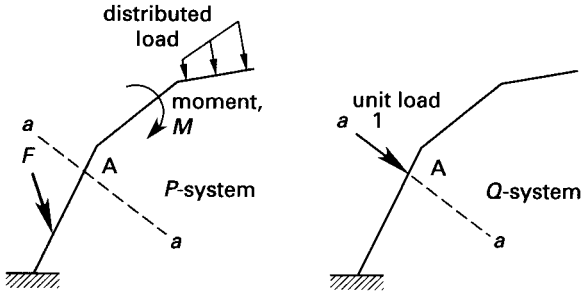

Figure 47.3 *Virtual Work Concepts*

Figure 47.3 illustrates a generalized structure subjected to a general load distribution and whose component of deformation at point A in the direction of line *aa* is desired. The analysis begins by considering the structure to be loaded by a unit load at point A along line *aa*. For convenience, the system of actual loads is designated as the "P-system," and the unit loading is designated as the "Q-system." The work of unit load can be calculated from the Q-system stresses and the P-system strains.

$$W_Q = 1 \times \Delta = \int \sigma_Q \epsilon_P dV \qquad 47.7$$

The integral in Eq. 47.7 is calculated as a discrete summation; the product is evaluated separately for stresses caused by moments, shears, and axial forces. Some of the terms in Eq. 47.8 may be zero or may be significantly negligible to be neglected.

$$W_Q = W_m + W_v + W_a + W_t \qquad 47.8$$

$$W_f = \int \left(\frac{m_Q m_P}{EI}\right) ds \qquad 47.9$$

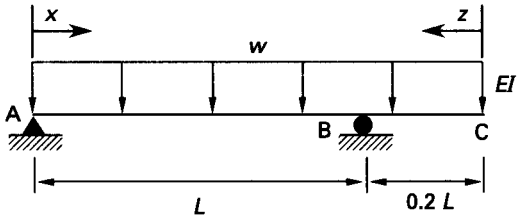
$$W_v = \int \left(\frac{V_Q V_P}{GA}\right) ds \qquad 47.10$$

$$W_a = \int \left(\frac{N_Q N_P}{EA}\right) ds \qquad 47.11$$

$$W_t = \int \left(\frac{T_Q T_P}{GJ}\right) ds \qquad 47.12$$

The sign convention used with Eqs. 47.8 through 47.12 is arbitrary, but it must be used consistently. If a certain direction is assumed positive in the P-system, the same direction must be taken as positive in the Q-system. A positive value of Δ indicates that the deflection is in the direction of the unit load.

To compute rotations rather than deflections, Eqs. 47.8 through 47.12 can still be used. The Q-system is loaded by a unit moment at the point where the rotation is wanted. m_Q, V_Q, N_Q, and T_Q are internal forces due to the unit moment rather than a unit load.



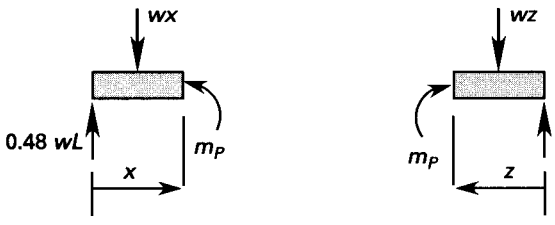
7. BEAM DEFLECTIONS BY THE DUMMY UNIT LOAD METHOD

A beam is a member that reacts to applied loads by bending. For most applications, axial stresses and torsion are both zero or negligible. And, except for deep beams (spans $\leq 3 \times$ depth), it is acceptable to assume that the work due to shear loading is zero. In this case, Eq. 47.8 reduces to

$$W_Q = W_f = \int \left(\frac{m_Q m_P}{EI}\right) ds \qquad 47.13$$

Example 47.1

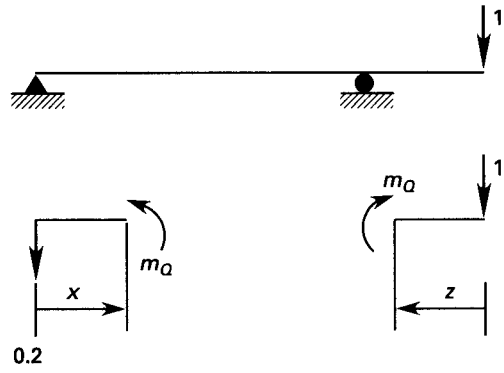
The simply supported cantilever beam shown is loaded uniformly. Shear deformation is negligible. What is the expression for the deflection at the cantilever end?



Solution

First, determine the moments, m_P, due to the applied loads. The moment diagram and the defining equations are determined from principles of statics. (The location x has its origin at A and increases from left to right, while z starts at point C and increases from right to left.)

$$m_P = 0.48wLx - 0.5wx^2 \quad \text{[segment AB]}$$



$$m_P = -0.5wz^2 \quad \text{[segment BC]}$$

Next, determine the moments due to the unit load.

$$m_Q = -0.2x \quad \text{[segment AB]}$$

$$m_Q = -z \quad \text{[segment BC]}$$

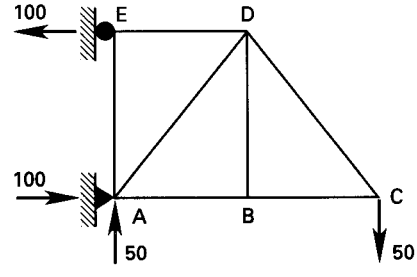
The deflection is the work done by a unit load. Substituting these expressions for m_P and m_Q into Eq. 47.13,

$$\Delta = \int_0^L \frac{(0.48wLx - 0.5wx^2)(-0.2x)}{EI} dx + \int_0^{0.2L} \frac{(-0.5wz^2)(-z)}{EI} dz$$

$$= \frac{0.0068wL^4}{EI}$$

8. TRUSS DEFLECTIONS BY THE DUMMY UNIT LOAD METHOD

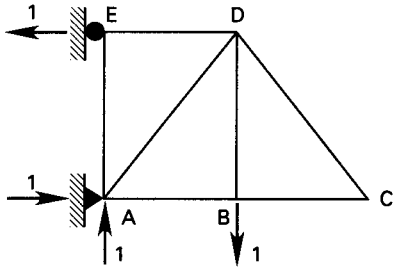
The applied loads on a truss are carried by axial forces solely, so Eq. 47.8 reduces to



$$W_Q = W_a = \int \left(\frac{N_Q N_P}{EA}\right) ds \qquad 47.14$$

Since the axial forces are constant in the truss members, the integral is evaluated as a summation over all of the members.

$$W_Q = W_a = \sum_i \left(\frac{N_{Q,i} N_{P,i}}{E_i A_i}\right) \qquad 47.15$$



Example 47.2

Use the dummy load method to determine the expression for the deflection at point B in the truss shown.

Solution

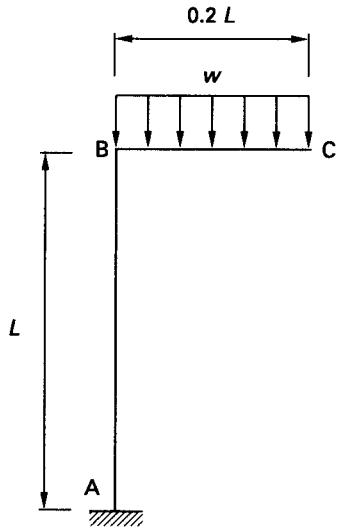
The unit-loaded truss is

The forces in the bars due to the applied load (on the P-system) as well as due to the unit load (on the Q-system) are determined by traditional methods of statics.

bar	N_P	N_Q	$N_P N_Q$
AB	−50.0	0.0	0.0
BC	−50.0	0.0	0.0
CD	70.71	0.0	0.0
DE	50.0	1.0	50.0
EA	0.0	0.0	0.0
AD	−70.71	−1.41	100.0
BD	0.0	1.0	0.0
			$\sum$ 150.0

The deflection is the work done by a unit load. Use Eq. 47.11.

$$\Delta = W_a \sum_i \left(\frac{N_{Q,i} N_{P,i}}{E_i A_i} \right)$$
$$= 150/AE$$

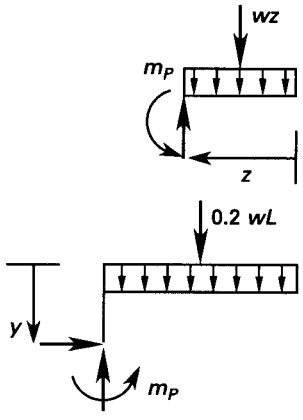


9. FRAME DEFLECTIONS BY THE DUMMY UNIT LOAD METHOD

For typically proportioned frames, a good approximation of the deflection can usually be obtained by considering only the flexural contribution. There are cases, however, where axial and shear deformations are significant enough to be included. In particular, shear deformations can be significant in structures with deep members, and axial deformations can have an important effect on the lateral displacements of tall frames subjected to wind or earthquake forces.

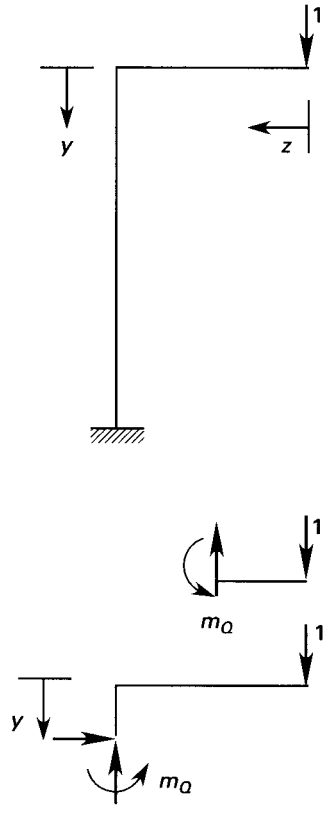
In rigid frames that resist loading primarily by flexure, using the unit dummy load method to calculate deflection is based on Eq. 47.9.

Example 47.3



Use the dummy load method to determine an expression for the vertical deflection at point C in the frame shown. Neglect shear and axial deformations.

Solution



The moments on the frame as loaded are

$$m_P = 0.02wL^2 \quad \text{[bar AB]}$$
$$m_P = 0.5wz^2 \quad \text{[bar BC]}$$

For the unit-loaded frame, the corresponding moments are

$$m_Q = 0.2L \quad \text{[bar AB]}$$
$$m_Q = z \quad \text{[bar BC]}$$

Substituting these expressions into Eq. 47.9,

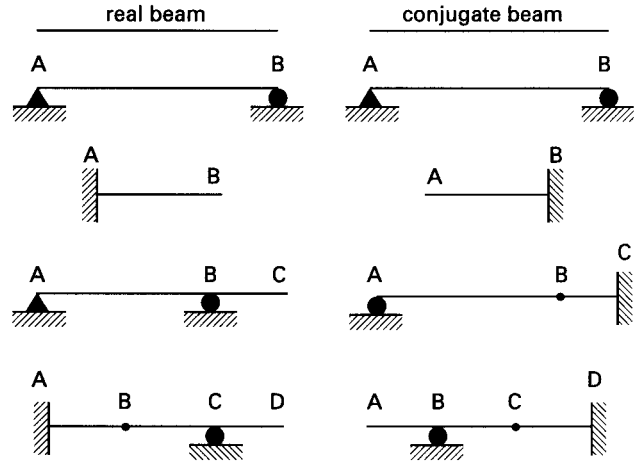
$$\Delta = \int_0^L \frac{(0.02wL^2)(0.2L)}{EI}dy + \int_0^{0.2L} \frac{(0.5wz^2)z}{EI}dz$$
$$= \frac{0.0042wL^4}{EI}$$

10. CONJUGATE BEAM METHOD

The conjugate beam method is a practical procedure for computing deflections in beams. In the conjugate beam method, a "conjugate beam" is loaded with the moment diagram for the real beam divided by the flexural stiffness product, EI. The conjugate beam has the same length as the real beam, but the support types are changed according to Table 47.1. When this is done, (a) the shear in the conjugate beam will be the same (numerically) as the slope on the real beam, and (b) the moment on the conjugate beam will be the same (numerically) as the deflection in the real beam.

Table 47.1 *Supports for Conjugate Beams*

real beam	conjugate beam
exterior simple support	exterior simple support
interior support	hinge
hinge	interior support
free end	fixed end
fixed end	free end



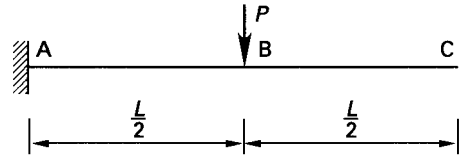


Figure 47.4 *Examples of Conjugate Beams*

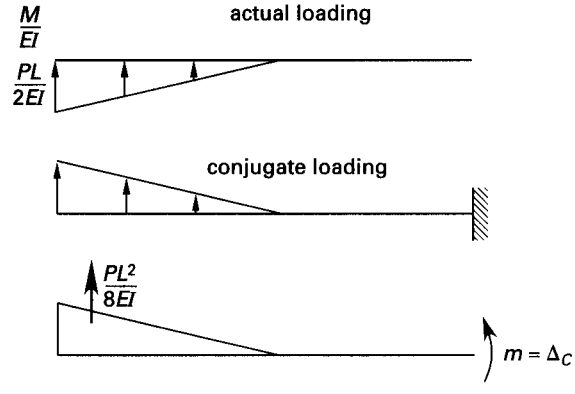
If the sign convention is such that downward loads on the real beam produce positive moments (the usual assumption), a positive moment on the conjugate beam corresponds to deflection downward. Likewise, slopes in the first and third quadrant are associated with shears that are up on the right side of a free-body diagram.



Example 47.4

Use the conjugate beam method to determine an expression for the deflection at point C on the cantilever beam shown. The cross section and modulus of elasticity are constant along the length of the beam.

Solution

The moment diagram for the real beam is shown. The conjugate beam has a free end at the left (because the real beam is fixed at that point) and a fixed end at the right (because the real beam is free at that point). The loading of the conjugate beam is M/EI, but since EI is constant, the loading distribution on the conjugate beam is the same as the moment diagram on the real beam.

The moment on the conjugate beam at point C is equal to the deflection on the real beam.

$$\Delta_C = \left(\frac{PL^2}{8EI}\right)\left(\frac{L}{2} + \frac{2}{3}\left(\frac{L}{2}\right)\right)$$
$$= \frac{5PL^3}{48EI}$$

11. INTRODUCTION TO THE FLEXIBILITY METHOD

The *flexibility method* (also known as the *method of consistent deformations*) is one of the most fundamental methods of indeterminate structural analysis. In practice, a manual application of this method is only convenient with structures having degrees of indeterminacy (I) of 1, 2, and (with effort) 3, since the number of deflection terms that must be calculated is $0.5I^2 + 1.5I$. The basis of the flexibility method is explained with the aid of Fig. 47.5(a), which shows a three-span continuous beam with an arbitrary loading.

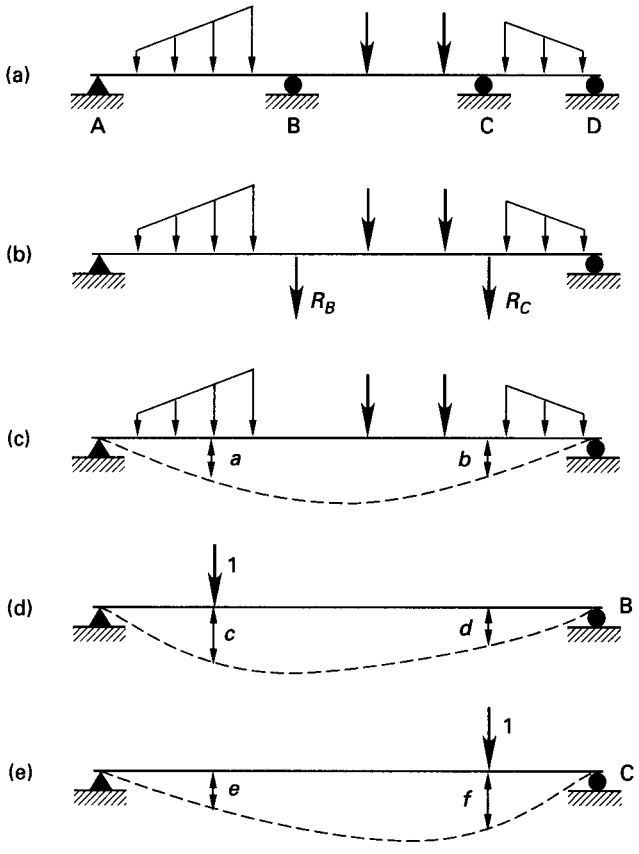


Figure 47.5 *Flexibility Method*

The beam in Fig. 47.5(a) is indeterminate to the second degree because there are five reactions and only three equations of statics to determine the reactions. However, we may consider any two of the four vertical reactions as being applied loads of unknown magnitudes. (The forces selected are known as *redundants*.) The number of redundants that must be removed to render the structure statically determinate is known as the *degree of static indeterminacy*, I. The structure with the redundants removed is known as the *primary structure*.

In Fig. 47.5(a), the vertical reactions at B and C may be considered applied loads on a simply supported statically determinate beam. Since the beam must remain in contact with the supports at reaction points, the values of the reactions at points B and C must be zero. Figures 47.5(a) and 47.5(b) are equivalent.

To illustrate how the equations of compatibility are set up, assume that the deflections at B and C are to be computed using superposition. Referring to Fig. 47.5(c), the first components are the deflections from the applied loading, which are designated as a and b. The deflections due to the reaction at B, R_B, are proportional to the magnitude of the reaction, so it is convenient to compute the deflections for a unit reaction and then to scale them by R_B. Designate the deflections from $R_B = 1$ as c and d and those from $R_C = 1$ as e and f. With this notation, the conditions of zero deflection at support points B and C can be mathematically expressed as Eqs. 47.16 and 47.17. These two equations can be solved simultaneously to obtain R_B and R_C. Once the reactions are known, any quantity of interest can be readily computed using statics.

$$a + cR_B + eR_C = 0 \qquad 47.16$$
$$b + dR_B + fR_C = 0 \qquad 47.17$$

This method can be modified to account for settling of the supports, as well. If there was a settlement of 0.5 in at B, then the equations would be

$$a + cR_B + eR_C = 0.5 \qquad 47.18$$
$$b + dR_B + fR_C = 0 \qquad 47.19$$

12. BASIC FLEXIBILITY METHOD PROCEDURE

The following steps constitute the procedure for using the flexibility method.

step 1: Transform the structure into a statically determinate structure by eliminating redundant reactions, moments, or internal forces. A set of redundants for a given indeterminate structure is not unique. Although some choices may lead to less numerical effort than others, all selections are equally valid. It is important to keep in mind, however, that the statically determinate primary system that remains must be stable.

For trusses, the degree of static indeterminacy is a combination of external indeterminacy (from redundant reactions) and

internal indeterminacy (from redundant members). The total degree of indeterminacy in trusses is

$$I = \text{no. of reactions} + \text{no. of members (bars)} - 2(\text{no. of joints}) \qquad 47.20$$

If Eq. 47.20 is zero, the truss is statically determinate; if it is negative, the truss is unstable. In cases where $I \geq 0$, the truss must also be checked for stability.

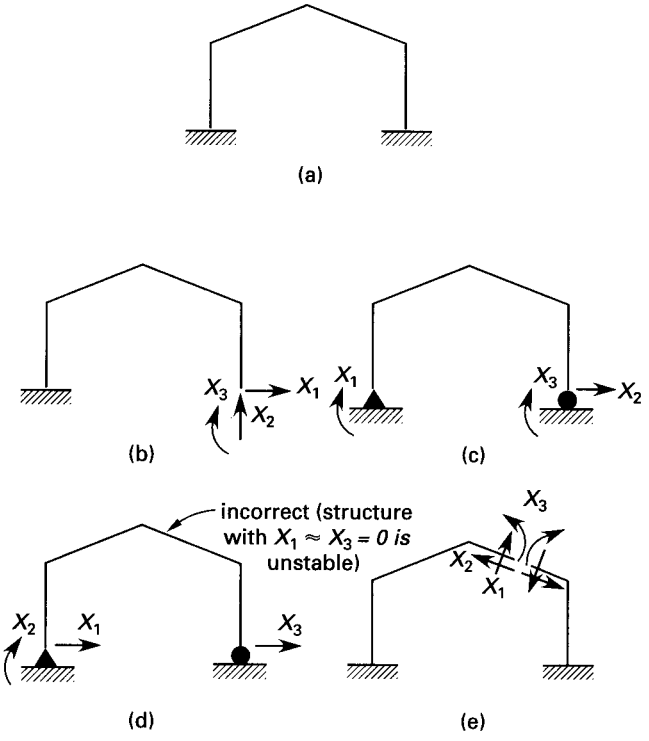

Figure 47.6 *Frame and Its Primary Structures*

Figure 47.6(a) illustrates a frame that is indeterminate to the third degree ($I = 3$). Three possible primary structures obtained by considering some of the reactions as redundants are shown as Fig. 47.6(b), (c), (d), and (e). However, Fig. 47.6(d) is inappropriate because the primary structure cannot resist horizontal forces and, therefore, is unstable. The redundants also need not be reactions at all, but can be taken as internal forces. For example, the axial, shear, and moment at an arbitrarily located cut can be selected as redundants as in Fig. 47.6(e). When internal forces are taken as redundants, the equilibrium forces act on both sides of the cut with opposite directions. For convenience, the redundants are designated as $X_1, X_2, \ldots X_n$, regardless of whether they are forces or moments. These X_i are collected in a vector $\mathbf{X}$.

$$\boldsymbol{X} = \begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_n \end{bmatrix} \qquad 47.21$$

step 2: Compute the deflections (or rotations) due to the applied loads at each of the locations (and in the directions) of the redundants. These deflections are designated as $\delta_1, \delta_2, \ldots, \delta_n$. These δ_i terms are collected in vector $\boldsymbol{\delta}$.

$$\boldsymbol{\delta} = \begin{bmatrix} \delta_1 \\ \delta_2 \\ \vdots \\ \delta_n \end{bmatrix} \qquad 47.22$$

For beams, it is generally appropriate to compute the deflections accounting only for flexural effects. For trusses, the deflections are due to axial elongations only. In most practical cases, frames can be solved accounting only for flexural deformations.

step 3: Compute the deflections for unit values of each of the redundants. These deflections are known as *flexibility coefficients* and are designated as $f_{i,j}$, where $f_{i,j}$ is the deflection at location i due to a unit value of the redundant at location j. The flexibility coefficients are collected in a flexibility matrix $\mathbf{F}$. Matrix $\mathbf{F}$ is symmetrical since $f_{i,j} = f_{j,i}$.

$$\mathbf{F} = \begin{bmatrix} f_{1,1} & f_{1,2} & \cdots & f_{1,n} \\ & f_{2,2} & \cdots & f_{2,n} \\ & & \cdots & f_{3,n} \\ & & & \vdots \\ & & & f_{n,n} \end{bmatrix} \qquad 47.23$$

step 4: Determine the settlements, if any, at the redundant supports. Collect these settlements in the matrix $\mathbf{S}$. Where there is no settling, all entries in $\mathbf{S}$ are zero (i.e., $\mathbf{S}$ is the null matrix).

step 5: Write the set of simultaneous equations that impose the geometrical requirements of compatibility. Using the format previously introduced, these equations are written in vector format.

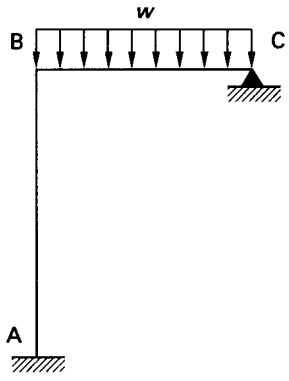
$$\mathbf{FX} = \mathbf{S} - \boldsymbol{\delta} \qquad 47.24$$

13. SYSTEMATIC FLEXIBILITY METHOD PROCEDURE

Most of the work in applying the flexibility method is associated with finding all of the deflections needed to set up the compatibility equations. While these deflections can be obtained using any applicable technique,

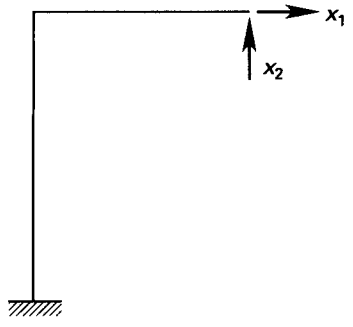
the dummy load method is most frequently used in practice. The following systematic approach can be used to integrate these two methods.

step 1: Select the redundants and their positive directions.



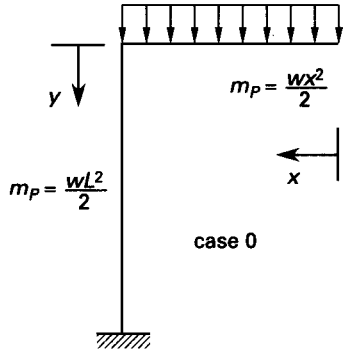
step 2: Determine equations that describe how internal forces vary throughout the structure. (For visualization purposes, it is often convenient to write these expressions on a sketch of the structure.) Designate the effects of the loads on the primary structure as "$X = 0$".

step 3: Derive equations for the relevant internal forces due to the unit values of each redundant. Designate the effects of the first redundant as "$X_1 = 1$", for the second as "$X_2 = 1$," and so on.

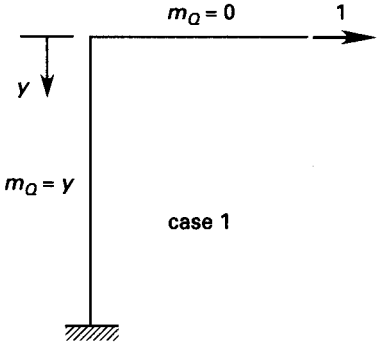


step 4: Compute the deflection terms. (Refer to Eqs. 47.7 through 47.11.) For the terms in F, obtain $f_{j,n}$ by integrating the product of the internal forces for $X_j = 1$ times $X_n = 1$. For the terms in δ, obtain δ_n by integrating the product of the internal forces for $X = 0$ times $X_n = 1$.

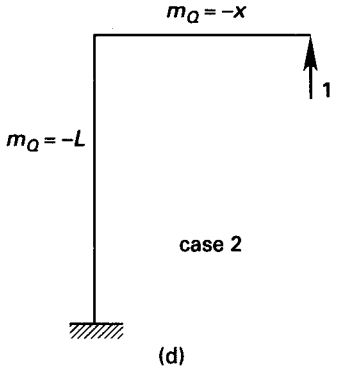
Example 47.5



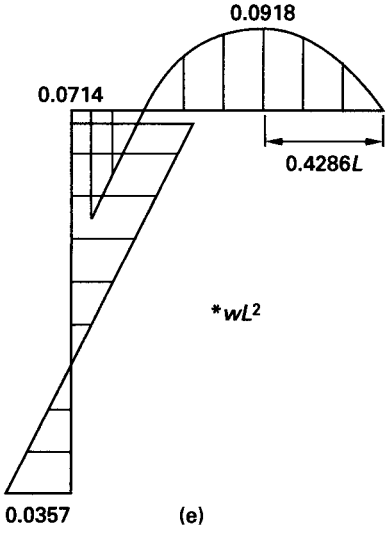
Use the flexibility method to draw the moment diagram for the frame shown. Neglect axial and shear deformations in the computations.



Solution



(a)



(b)

(c)

(d)

(e)

Refer to the illustration. From (a), the frame is indeterminate to the second degree. Select the two reactions at point C as the redundants. Expressions for the moments in the primary structure due to the loading as well as from the unit values of the redundants are shown in (b). From (c) and (d), the required deflection and flexibility coefficients are determined in the following expressions. Once the reactions are known, the moment diagram can be easily computed as shown in (e).

$$\delta_1 = \int_0^L \frac{wL^2 y}{2EI}dy = \frac{wL^4}{4EI}$$

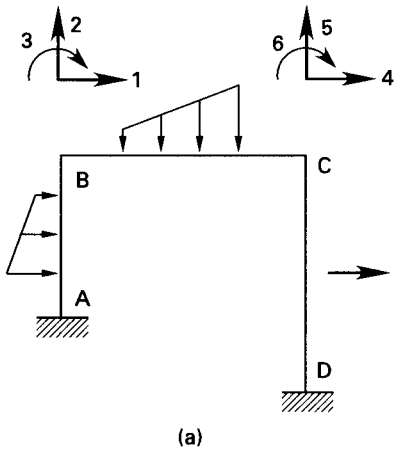
$$\delta_2 = \int_0^L \frac{-wx^3}{2EI}dx + \int_0^L \frac{-wL^3}{2EI}dy = \frac{-5wL^4}{8EI}$$

$$f_{1,1} = \int_0^L \frac{y^2}{EI}dx = \frac{L^3}{3EI}$$

$$f_{2,2} = \int_0^L \frac{x^2}{EI}dx + \int_0^L \frac{(-L)^2}{EI}dy = \frac{4L^3}{3EI}$$

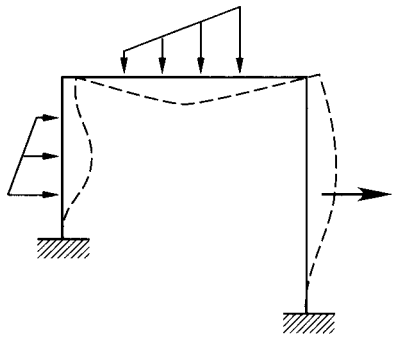
$$f_{1,2} = f_{2,1} = \int_0^L \frac{y(-L)}{EI}dy = \frac{-L^3}{2EI}$$

Substitute these values into Eq. 47.24 and solve.



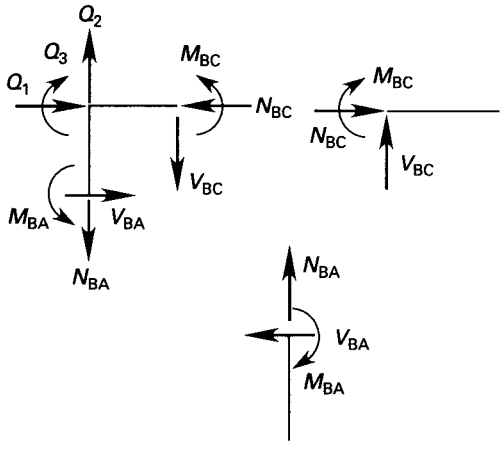
$$\frac{L^3}{EI}\begin{bmatrix} \frac{1}{3} & -\frac{1}{2} \\ -\frac{1}{2} & \frac{4}{3} \end{bmatrix}\begin{bmatrix} X_1 \\ X_2 \end{bmatrix} = \frac{wL^4}{EI}\begin{bmatrix} -\frac{1}{4} \\ \frac{5}{8} \end{bmatrix}$$

$$\begin{bmatrix} X_1 \\ X_2 \end{bmatrix} = wL\begin{bmatrix} -0.107 \\ 0.429 \end{bmatrix}$$

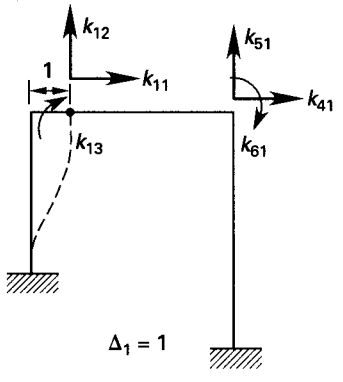


14. STIFFNESS METHOD

The *stiffness method* is based on the fact that the behavior of any structure can be viewed as the superposition of the effect of loads on a structure with joints that do not displace and the effect of the joint displacements. (The term "displacement" is used in a generic sense to mean both translation and rotation.)



With the stiffness method, the traditional degree of static indeterminacy is not considered when obtaining a solution. Instead, the number of independent joint displacements, known as the *degree of kinematic indeterminacy*, determines the number of simultaneous equations. While the equations in the flexibility method describe conditions of compatibility, equations in the stiffness method are statements of equilibrium at the joints.



(a)

(b)

(c)

(d)

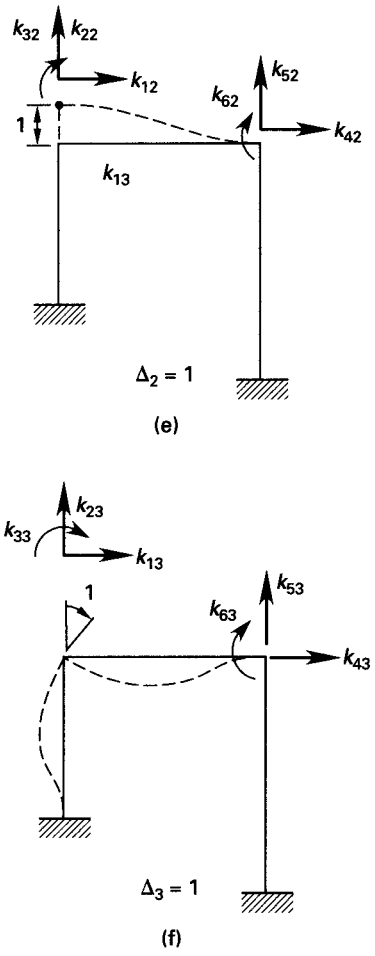


Figure 47.7 *Stiffness Method*

Consider the frame shown in Fig. 47.7(a). As shown in Fig. 47.7(b), the members are first assumed to behave as doubly fixed-ended beams, which is equivalent to stating that the joints do not translate or rotate. The magnitudes of the external joint forces needed to "lock" the joints are shown in Fig. 47.7(c) and can be readily obtained using simple statics. For example, restraining forces, Q, at joint B can be found from the equilibrium conditions at joint B.

$$V_{BA} - N_{BC} + Q_1 = 0 \quad [x\text{-direction}] \qquad 47.25$$

$$-N_{BA} - V_{BC} + Q_2 = 0 \quad [y\text{-direction}] \qquad 47.26$$

$$-M_{BA} - M_{BC} + Q_3 = 0 \quad [\text{moments}] \qquad 47.27$$

In many cases, the resulting locked joint will result in a fixed-end beam. The fixed-end moments (FEMs) can be read directly from App. 47.A for most common loading conditions.

Since there are actually no restraining forces acting, the effect that the negative of the restraining Q forces have on the structure must be determined. A convenient way to do this is to compute the joint forces needed to impose a unit value at each of the possible joint movements (also known as *degrees of freedom*, DOF) while keeping the others restrained. These forces are easy to compute: Any joint load distribution can be expressed as a linear combination of the forces. The deformed structure with unit displacements imposed on the first three DOFs is illustrated in Figs. 47.7(d) through 47.7(f).

With beams, the stiffness method is simplified by the fact that the DOFs are only joint rotations. Truss bars are pinned at the joints, so for trusses, only the two translational DOFs need to be considered at each joint. Since the loads in trusses are also applied at the joints, the analysis of locked joints leads to zero bar forces. For frames, there are typically three DOFs at each joint. However, solutions assuming the bar elongations to be negligible are often quite accurate. This simplification can be used to reduce the number of DOFs for manual solutions.

The external forces required to impose the unit displacements are designated using the letter k and two subscripts. The first subscript designates the DOF where the force is applied; the second subscript designates the DOF where the unit displacement was imposed. Thus, $k_{i,j}$ is the force at DOF i due to a unit displacement at DOF j. (The terms "displacement" and "force" are used in a generalized sense.) Some computational effort is saved by recognizing that the stiffness matrix, $\mathbf{k}$, is symmetrical, and $k_{i,j} = k_{j,i}$. The coefficients constituting $\mathbf{k}$ are the forces required to impose unit displacements at the end of an individual bar. The typical case of a prismatic member is depicted in Fig. 47.8.

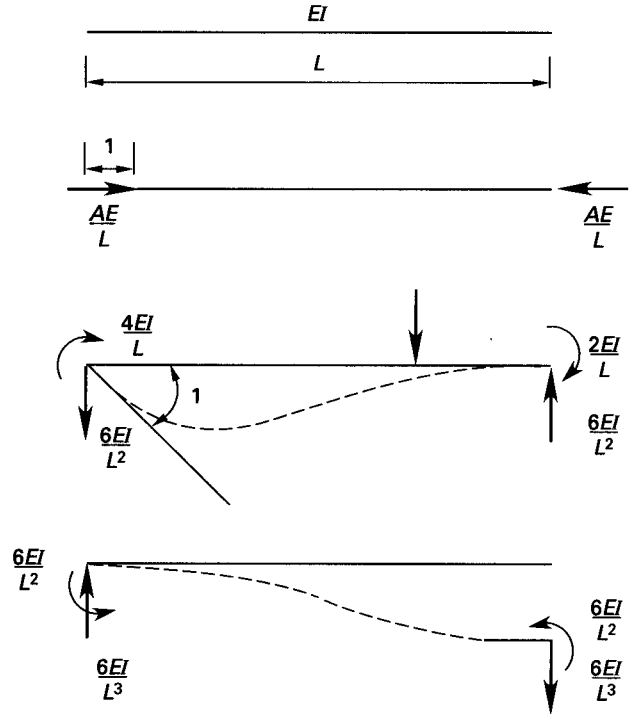

Figure 47.8 *Forces in the Prismatic Bar Due to Unit Displacements*

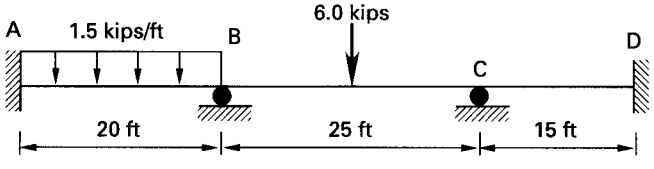
Equation 47.28 indicates that the Q forces must vanish (i.e., be zero). (The vector $\mathbf{\Delta}$ collects the displacements at all of the DOFs.)

$$\mathbf{k\Delta + Q = 0} \qquad 47.28$$

It is customary to write Eq. 47.28 in terms of a *load vector*, $\mathbf{L}$, that is the negative of the restraining force vector.



$$\mathbf{k\Delta + L} \qquad 47.29$$

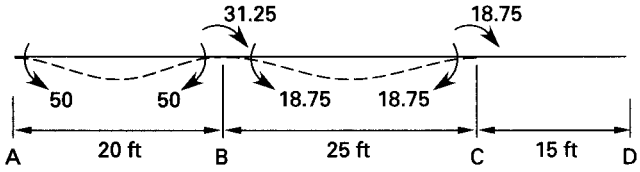
The actual conditions are obtained by summing the conditions that exist in the locked condition and the conditions from the unit displacements scaled by the appropriate $\mathbf{\Delta}$ values.

With the flexibility method, the number of simultaneous equations is equal to the degree of static indeterminacy. With the stiffness method, the number of simultaneous equations equals the number of degrees of freedom. When the number of equations is the same, the stiffness method is typically faster than the flexibility. This is because the terms in the equations are obtained from tabulated fixed-end moments and stiffness coefficients using basic principles of statics. In contrast, in the flexibility method, one must go through the time-consuming process of computing the deflections from basic principles. Closed form solutions are typically unavailable for the loading conditions encountered.

Example 47.6

Use the stiffness method to draw the moment diagram for the three-span beam shown. The product of the modulus of elasticity (E) and the centroidal moment of inertia (I) of the cross section is $EI = 28 \times 10^6$ in^2-kips.

Solution



Since the supports at A and D are fixed, the only DOFs are the rotations at B and C. If these DOFs are locked, the structure will be made up of three fixed-ended beams. From App. 47.A, the restraining moments are

$$\text{FEM}_{AB} = \text{FEM}_{BA} = \frac{wL^2}{12} = \frac{\left(1.5 \frac{\text{kips}}{\text{ft}}\right)(20 \text{ ft})^2}{12}$$
$$= 50 \text{ ft-kips}$$

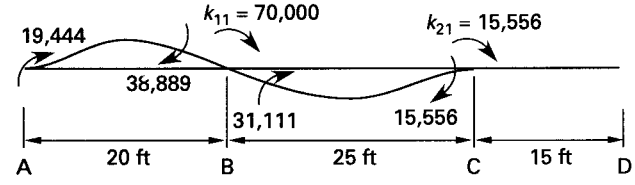
$$\text{FEM}_{BC} = \text{FEM}_{CD} = \frac{PL}{8} = \frac{\left(6 \frac{\text{kips}}{\text{ft}}\right)(25 \text{ ft})}{8}$$
$$= 18.75 \text{ ft-kips}$$

For equilibrium at joints B and C, the restraining moment vector, $\mathbf{Q}$, is

$$\mathbf{Q} = [31.25 \text{ ft-kips}, 18.75 \text{ ft-kips}]$$

The deformed configuration corresponding to a unit rotation at point B (DOF no. 1) is shown. Let clockwise be the positive direction. Calculate the nonzero moments at the ends of the bars for this configuration. (All other moments are zero.)

$$M_{AB} = \frac{2EI}{L} = \frac{(2)(28 \times 10^6 \text{ in}^2\text{-kips})}{(20 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)^2}$$
$$= 19{,}444 \text{ ft-kips}$$

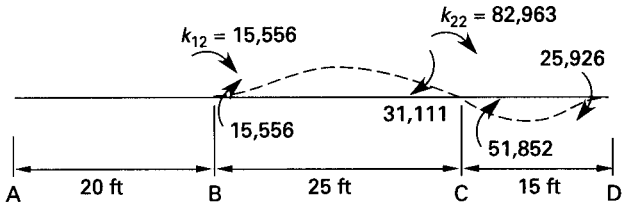


$$M_{BA} = \frac{4EI}{L} = \frac{(4)(28 \times 10^6 \text{ in}^2\text{-kips})}{(20 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)^2}$$
$$= 38{,}889 \text{ ft-kips}$$

$$M_{BC} = \frac{4EI}{L} = \frac{(4)(28 \times 10^6 \text{ in}^2\text{-kips})}{(25 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)^2}$$
$$= 31{,}111 \text{ ft-kips}$$

$$M_{CB} = \frac{2EI}{L} = \frac{(2)(28 \times 10^6 \text{ in}^2\text{-kips})}{(25 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)^2}$$
$$= 15{,}556 \text{ ft-kips}$$

Consider the rotational equilibrium requirement at joints B and C.



$$k_{1,1} = M_{BA} + M_{BC} = 38{,}889 \text{ ft-kips} + 31{,}111 \text{ ft-kips}$$
$$= 70{,}000 \text{ ft-kips}$$
$$k_{2,1} = M_{CB} + M_{CD} = 15{,}556 \text{ ft-kips} + 0$$
$$= 15{,}556 \text{ ft-kips}$$

Use the same procedure to determine the moments induced by the deformed structure corresponding to a unit rotation at DOF no. 2. (Note that the coefficients $k_{2,1}$ and $k_{1,2}$ are equal since the stiffness matrix is symmetrical.)

$$k_{2,2} = 82{,}963 \text{ ft-kips}$$

$$k_{1,2} = 15{,}556 \text{ ft-kips}$$

The stiffness matrix is

$$\mathbf{k} = \begin{bmatrix} 70{,}000 & 15{,}556 \\ 15{,}556 & 82{,}963 \end{bmatrix}$$

Use Eq. 47.29. The "deflections" are actually rotations, so use θ to represent the joint rotations.

$$\mathbf{k}\boldsymbol{\theta} = -\mathbf{Q}$$

$$\begin{bmatrix} 70{,}000 & 15{,}556 \\ 15{,}556 & 82{,}963 \end{bmatrix} \begin{bmatrix} \theta_B \\ \theta_C \end{bmatrix} = \begin{bmatrix} -31.25 \\ -18.75 \end{bmatrix}$$

The solution to this system of equations is $\theta_B = -0.000413$ rad and $\theta_C = -0.000149$ rad.

The actual moments at the ends of the members are obtained by superposition of the locked cases and the scaled contributions of the moments calculated from the unit values. For example, the moment at end M_{BA} is

$$\begin{aligned} M_{BA} &= 50 \text{ ft-kips} + (-0.000413 \text{ rad})(38{,}889 \text{ ft-kips}) \\ &= 33.92 \text{ ft-kips} \end{aligned}$$

Moments that are not at the ends of the bars can be obtained from statics once the end moments have been computed.

15. MOMENT DISTRIBUTION METHOD

The *moment distribution method* was developed by Prof. Hardy Cross in the early 1930s. The procedure is based on a locked-joint situation similar to stiffness. The name "moment distribution" derives from the fact that the external moments needed to obtain the locked condition are "distributed" using an iterative approach.

Although it is possible in principle to deal with axial deformations, practical moment distribution always assumes that the members do not change in length as a result of the applied loads. Moment distribution is particularly simple in cases where the fixed-length assumption is sufficient to ensure that the joints of the structure are fixed in space: This case is typically referred to as "structures without sidesway." Moment distribution can also be used when the joints in the structure displace (i.e., where there is sideway), although the procedure is not as efficient.

The moment required to induce a unit rotation at the end of a bar when the far end is assumed to be fixed is known as the *stiffness*, K. Referring to Fig. 47.8, the flexural stiffness is $K = 4EI/L$. The *carryover factor*, COF, is defined as the ratio of the moment that appears at the far end to the applied moment. Referring to Fig. 47.8, the carryover factor is COF = $\frac{1}{2}$.

Consider a situation where a number of bars meet at a common rigid joint while all of the far ends are fixed. Assume that the joint is subjected to an external applied moment, M. Each of the bars will support some portion of the applied moment. With m_i as the moment supported by bar i, the *distribution factor* for bar i (at the joint in question) is the fraction of the total applied moment supported.

$$\text{DF}_i = \frac{m_i}{M} \qquad 47.30$$

All of the bars that meet at the common joint rotate by an equal amount, θ. The moment that is induced by a rotation is the product of the flexural stiffness times the rotation.

$$m_i = K_i\theta \qquad 47.31$$

The sum of all the moments in the bars equal the applied moment.

$$\begin{aligned} M &= \sum_i m_i \\ &= \sum_i K_i\theta \end{aligned} \qquad 47.32$$

Combining Eqs. 47.30 and 47.32,

$$\text{DF}_i = \frac{K_i}{\sum_i K_i} \qquad 47.33$$

The sum of all of the distribution factors at a rigid joint is 1.

$$\sum_i \text{DF}_i = 1 \qquad 47.34$$

16. MOMENT DISTRIBUTION PROCEDURE: NO SIDESWAY

step 1: Draw a line diagram representation of the structure to be analyzed. This diagram will be used to record intermediate results.

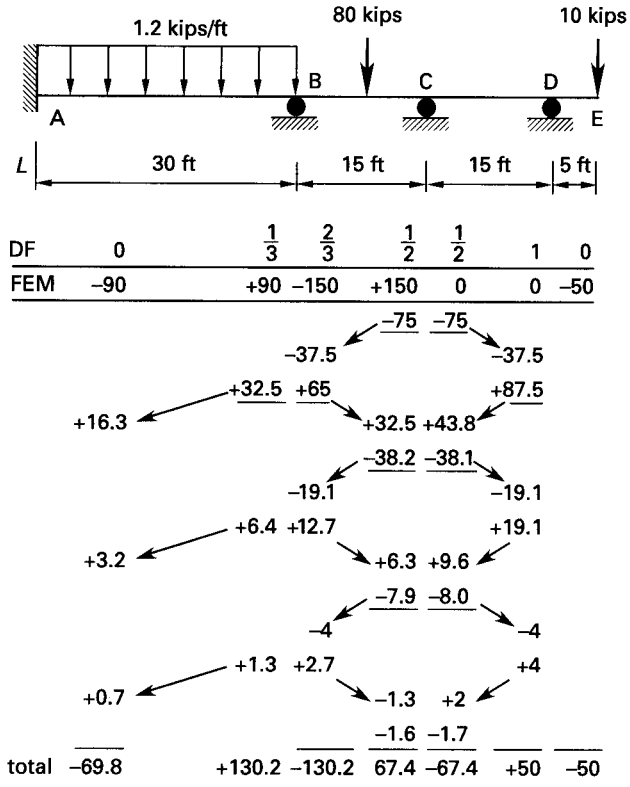
step 2: Except for cantilevered sections that have $K = 0$, compute the flexural stiffness for each bar using Eq. 47.35.

$$K = \frac{4EI}{L} \qquad 47.35$$

step 3: Use Eq. 47.33 to compute the distribution factor at each end of the bars. Record the values on the drawing of the structure. Since the distribution factor is a ratio of flexural stiffnesses, one can always take a common factor (e.g., the product EI) from the numerator and the denominator without affecting the results. It is convenient to remember that DF = 0 at fixed ends (representing infinite stiffness) and DF = 1 at simple supports.

step 4: Obtain the fixed-end moments from App. 47.A. (Adopt a consistent sign convention, such as "clockwise moments at the ends are positive.") Record the fixed-end moments on the drawing at the ends of each bar.

step 5: Go to any joint and compute the "unbalanced moment" (or "out of balance," OOB) by adding all the moments at the ends of the bars that meet there. Distribute the unbalanced moment to each bar. The distributed moments are equal to the product of the unbalanced moment times the distribution/break factor with the reversed sign. (Although the order used for releasing and locking the joints is arbitrary, convergence is fastest if the joint with the largest unbalance is handled first.



step 6: Carry one half of the distributed moment to the far end of the corresponding bar by multiplying the distributed moment by the *carryover factor*.

step 7: Repeat steps 6 and 7 until the unbalanced moment at the most unbalanced joint is insignificant (typically, less than 1% of the largest fixed-end moment).

step 8: Calculate the true moments at each bar end as the sum of moments that have been recorded at that end.

Example 47.7

Use the moment distribution method to determine the end moments for the continuous beam shown.

Solution

Use Eq. 47.35 to calculate the flexural stiffness of each bar. Since EI is constant and only the relative values of K affect the results, take $4EI$ as the longest span (30 ft in this case). Then,

$$K_{AB} = \frac{4EI}{L} = \frac{30 \text{ ft}}{30 \text{ ft}} = 1$$

$$K_{BC} = \frac{30 \text{ ft}}{15 \text{ ft}} = 2$$

$$K_{CD} = \frac{30 \text{ ft}}{15 \text{ ft}} = 2$$

$$K_{DE} = 0 \quad \text{[cantilever]}$$

Determine the distribution factors.

$$\text{DF}_{AB} = 0 \quad \text{[fixed end]}$$

$$\text{DF}_{BA} = \frac{K_{BA}}{\sum_i K_i} = \frac{1}{1+2} = 1/3$$

$$\text{DF}_{BC} = \frac{2}{1+2} = 2/3$$

$$\text{DF}_{CB} = \frac{2}{2+2} = 1/2$$

$$\text{DF}_{CD} = \frac{2}{2+2} = 1/2$$

$$\text{DF}_{DC} = \frac{2}{2+0} = 1 \quad \text{[free end]}$$

The fixed-end moments are determined from App. 47.A.

$$\text{FEM}_{AB} = \text{FEM}_{BA} = \frac{wL^2}{12}$$
$$= \frac{\left(1.2\ \frac{\text{kips}}{\text{ft}}\right)(30\ \text{ft})^2}{12} = 90\ \text{ft-kips}$$
$$\text{FEM}_{BC} = \text{FEM}_{CB} = PL/8$$
$$= \frac{(80\ \text{kips})(15\ \text{ft})}{8} = 150\ \text{ft-kips}$$
$$\text{FEM}_{DE} = (10\ \text{kips})(5\ \text{ft}) = 50\ \text{ft-kips}$$
$$\text{FEM}_{ED} = 0 \quad \text{[free end]}$$

Start the moment distribution at joint C. The unbalanced moment of 150 is reversed in sign and multiplied by the distribution factors, both of which are one half. This puts a balancing correction of -75 on either side of joint C, for a total balancing correction of -150. (The horizontal lines under the moments of -75 indicate that joint C has now been balanced.) Multiply the balancing moments by the carryover factors (0.5) and carry the products over to the far ends of BC and CD.

Continue by moving to joint B. The unbalanced moment is $90 - 150 - 37.5 = -97.5$, requiring a total balancing moment of 97.5. The balance is distributed according to the distribution factors of one third and two thirds, resulting in 32.5 and 65 on the left and right sides of the joint, respectively. When the balance is multiplied by the COF, half of the distributed moments are carried over to the far side. (The horizontal lines indicate that the joint is balanced.)

The procedure continues in this manner as the carryover values decrease in magnitude. Finish at joint C by distributing the unbalanced moment of $2 + 1.3$, but do not perform the carryover step. (The process should finish with a distribution so that the joint will be balanced.)

The end moments are obtained by summing all the entries at each location.

17. STRUCTURES WITH SIDESWAY

Analyzing structures with sidesway with the moment distribution procedure uses superposition of elementary joint-restrained cases. Consider the two-story frame shown in Fig. 47.9(a). This frame has two sway DOFs: the horizontal translations at each of the two floors. The first step in the analysis is to obtain the solution for the structure when the translations are restricted. This step is schematically depicted in Fig. 47.9(b). The forces, R_1 and R_2, against the fictitious restraints that are keeping the frame from swaying are obtained after the moment distribution is completed.

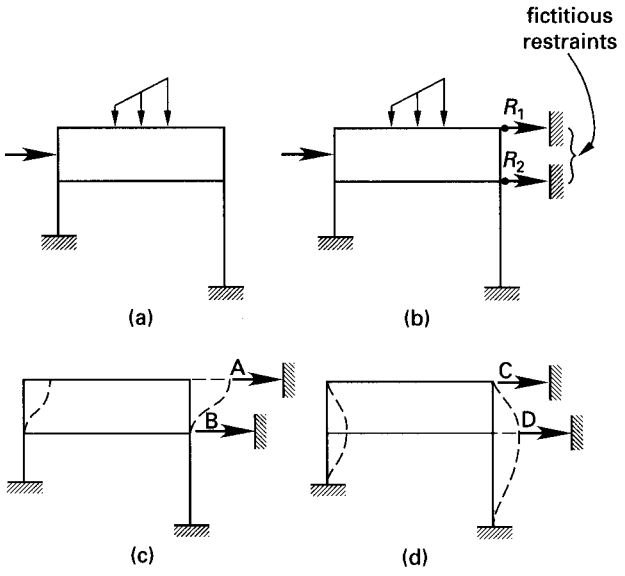


Figure 47.9 *Frames with Sidesway*

The next step consists of obtaining moment diagrams associated with arbitrary translations at each of the locations where the restraints were previously introduced. In these analyses, the translations are initially imposed with the joints held against rotation. The unbalanced moments generated are distributed using the standard moment distribution approach. The situation when the first restraint is "dragged" (while the second is held in place) is depicted prior to the moment distribution in Fig. 47.9(c). The deformed configuration when the second restraint is dragged an arbitrary amount is shown in Fig. 47.9(d). It is helpful to recall that the fixed-end moment generated by a relative displacement of magnitude Δ is

$$\text{FEM} = \frac{6EI\Delta}{L^2} \qquad 47.36$$

Once the moment distribution is complete, the forces at the fictitious restraints are computed using statics. For example, the force in the restraint at the second story is equal to the sum of the shear forces in the two columns.

The final solution is obtained as a linear combination of the no-sidesway case and scaled versions of the case with sidesway. The scaling is obtained by recognizing that the actual forces in the restraints are zero. For example, the requirements for the two-story frame of Fig. 47.9 are given by Eqs. 47.37 and 47.38, in which A, B, C, and D are the forces in the restraints for the unit displacement condition, and α and β are the scaling factors.

$$R_1 + \alpha\text{A} + \beta\text{C} = 0 \qquad 47.37$$
$$R_2 + \alpha\text{B} + \beta\text{D} = 0 \qquad 47.38$$

Designating the displaced moments from the sidesway evaluation at the first and second floors as MD_1 and MD_2, respectively, the complete solution for the moment at any particular joint is

$$M = M_{\text{sidesway restrained}} + \alpha\text{MD}_1 + \beta\text{MD}_2 \qquad 47.39$$

18. SECOND-ORDER (*P*-Δ) ANALYSIS

In a first-order analysis, the loads are supported and equilibrium is achieved on the structural geometry that exists prior to the application of the loads. However, this is an approximation since equilibrium is actually achieved in a deformed configuration. In a second-order analysis, the effects of deformations on the equilibrium requirements are considered.

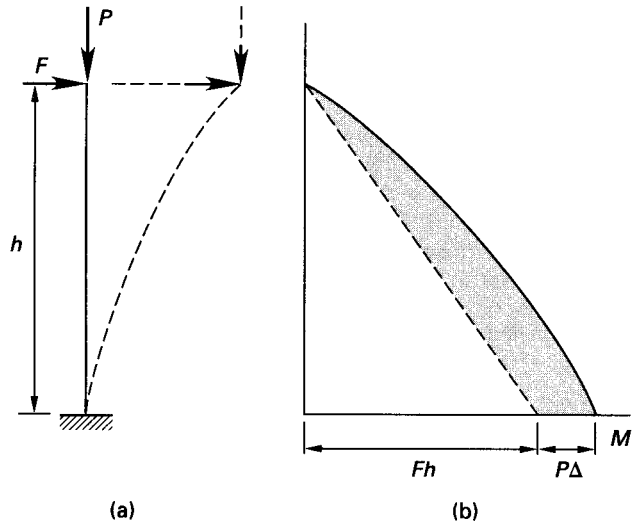

Figure 47.10 *Second-Order Effect on a Cantilever*

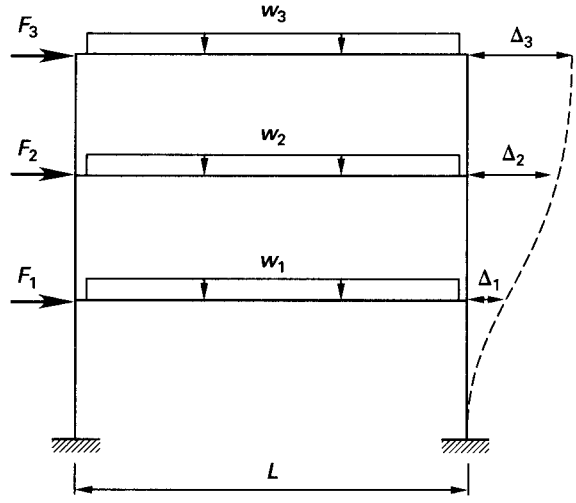
The approximation implicit in a first-order analysis is readily apparent in the cantilever column in Fig. 47.10(a). For the loading shown, the moment at the base in a first-order analysis is $M = Fh$. However, in the deformed configuration, the total moment at the base is actually $M = Fh + P\Delta$, as shown in Fig. 47.10(b). The total deflection Δ results from load F and the moments induced by both F and P when acting on the deformed geometry.

Second-order analyses of complex structures are best performed on computers, and these methods are increasingly being used. (ACI 318 and LRFD encourage second-order analysis as the preferred approach for incorporating P-Δ effects in the design of slender columns.)

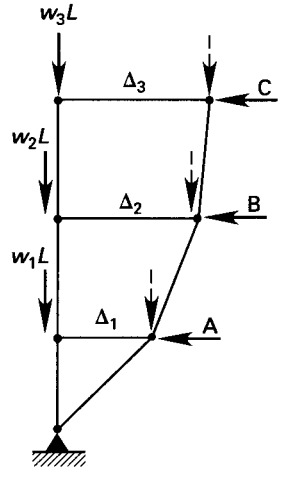
19. SIMPLIFIED SECOND-ORDER ANALYSIS

Second-order effects include bending members with respect to their chord, usually referred to as the P-δ effect, and the effects of joint translation, generally designated as the P-Δ effect. Structures where second-order effects are important are typically flexible and unbraced. In such structures, virtually all the difference between the correct solution and the results predicted by a first-order analysis derives from the P-Δ effect.



A simple iterative approach that incorporates the P-Δ effect in the analysis of building frames is schematically illustrated in Fig. 47.11. The steps are as follows.

step 1: Compute the deflections of the structure using a first-order analysis.



step 2: Consider that all the vertical loads are carried by an auxiliary structure consisting of a vertical stack of truss bars that is stabilized by horizontal links to the structure. This auxiliary structure experiences the displacements of the actual building.

step 3: Calculate the forces in the links (forces A, B, and C in Fig. 47.11(b)) from the free-body diagram of the auxiliary structure.

step 4: Repeat step 1, adding the forces in the link bars to the applied lateral loads. The solution converges when the forces in the links do not change significantly from one iteration to the next.

(a) loaded structure

(b) auxiliary structure

Figure 47.11 *P-Δ Analysis*

20. PLASTIC ANALYSIS

A *plastic analysis* determines the maximum load that a structure can sustain. Alternatively, plastic analysis determines the plastic moment capacity required to support a certain factored load. Although plastic analysis is applicable to all aspects of structural design, it is primarily used in the design of continuous steel beams.

In practical applications, plastic analysis assumes that a hinge is created when the moment at any section reaches the plastic moment. These hinges are known as *plastic hinges* because they are not points of zero moment, but locations where the moment is constant and equal to the plastic capacity M_p. The maximum load-carrying capacity of the structure is attained when there are sufficient hinges to turn the structure into a mechanism.

21. PLASTIC ANALYSIS OF BEAMS

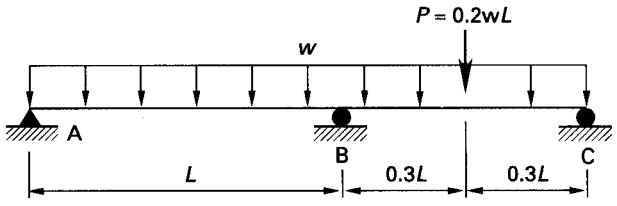
Either the *equilibrium method* or the *virtual work method* can be used in a plastic analysis of a beam. The virtual work method is used in the following analysis, which determines an unknown plastic moment capacity for a given factored load. (This is the usual case when designing steel beams.)

step 1: Postulate a number of plastic hinges that turn the beam into a mechanism. (If more than one mechanism is possible, all must be considered. The mechanism requiring the largest moment capacity governs.)

step 2: Impose a unit displacement on the point of the structure that deflects the most after the mechanism forms.

step 3: Calculate the total internal work at hinges 1, 2, ..., i. (The values of the rotations, $\theta_{p,i}$, at all of the hinges are known once the unit deflection is imposed.)

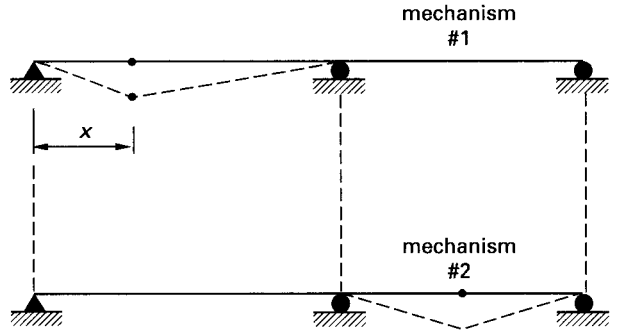
$$W_{\text{internal}} = \sum_i M_{p,i}\theta_{p,i} \qquad 47.40$$



step 4: Calculate the total external work performed by loads 1, 2, ..., j from the loads, P_j, and the corresponding displacements, Δ_j. The replacement of distributed loads by their resultants must be done on each of the segments of the mechanism independently. The loads P_i will typically include an appropriate load factor.

$$W_{\text{external}} = \sum_j P_j\Delta_j \qquad 47.41$$

step 5: Equate the internal work to the external work and solve for M_p.



Example 47.8

Use plastic analysis to calculate the maximum plastic moment from the loads acting on the two-span beam shown.

Solution

Two distinct mechanisms are possible.

Consider the first mechanism involving failure in span AB. Due to a lack of symmetry, the location of the positive plastic hinge is not known in advance. Designating the distance between the support at A and the positive-moment plastic hinge as x, the external work is given by Eq. 47.41.

$$W_{\text{external}} = 0.5wx + 0.5w(L - x) = 0.5wL$$

The internal work is given by Eq. 47.40.

$$W_{\text{internal}} = U_{\text{internal}} = M_P\left(\frac{1}{x} + \frac{1}{L-x}\right) + M_P\left(\frac{1}{L-x}\right)$$

Equate the external and internal work.

$$M_p = \frac{wLx(L-x)}{2(L+x)}$$

Determine the location of the maximum moment by taking the derivative with respect to x and equate the result to zero.

$$x_{\text{maximum } M_p} = L\left(\sqrt{2} - 1\right)$$

The maximum moment is found by substituting x into the expression for M_p.

$$M_{p,\max} = 0.08579wL^2$$

Now, consider the mechanism involving failure in span BC. The external work for a unit deflection is

$$W_{\text{external}} = (0.5wL + 0.2wL)(1) = 0.7wL$$

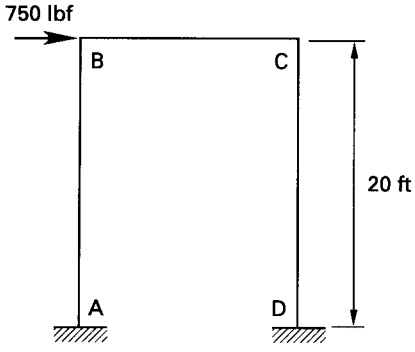
The internal work is

$$W_{\text{internal}} = U_{\text{internal}} = M_p\left(\frac{2}{0.3L}\right) + M_p\left(\frac{1}{0.3L}\right)$$

The plastic moment is found by setting the external and internal works equal to each other.

$$M_p = 0.07wL^2$$

This plastic moment is larger for the mechanism in span AB and thus controls.



22. APPROXIMATE METHOD: ASSUMED INFLECTION POINTS

Approximate methods are useful when an exact solution is not needed, when time is short, or when it is desired to quickly check an exact solution. If the location of a point of inflection on a statically indeterminate structure is known or assumed, that knowledge can be used to generate moments for the remainder of the structure.

The curvature on a structure changes between positive and negative at a point of inflection. Accordingly, the moment is zero at that point. If the point of inflection is assumed, then the moment at that point is also known. The applicability of this method depends on being able to predict the locations of the inflection points. Figure 47.12 provides reasonable predictions of these locations.

Example 47.9

Determine the fixed-end moment at joint A.

Solution

Assume that a point of inflection occurs on each vertical member at (0.55)(20 ft) = 11 ft above the supports. By symmetry and equilibrium, the shear at the inflection point is

$$V = \frac{750 \text{ lbf}}{2} = 375 \text{ lbf}$$

The moment at the base is

$$M = (11 \text{ ft})(375 \text{ lbf}) = 4125 \text{ ft-lbf}$$

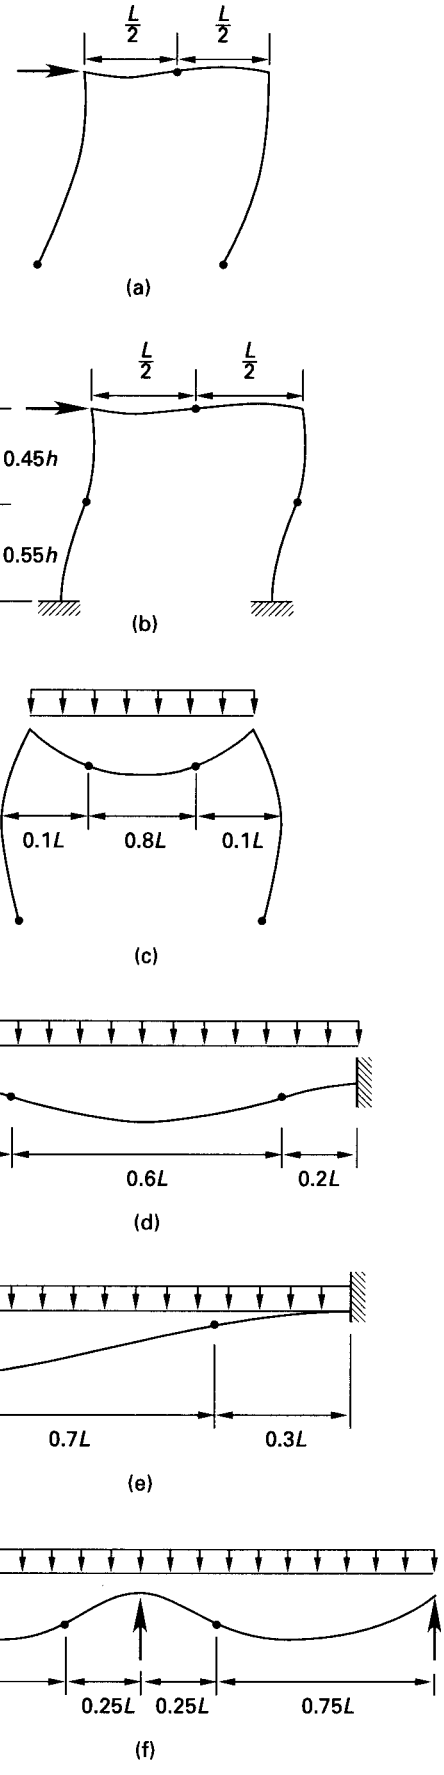


Figure 47.12 *Approximate Locations of Inflection Points*

The fixed-end moment is counterclockwise. Therefore, $M_{AB} = -4125$ ft-lbf.

23. APPROXIMATE METHOD: MOMENT COEFFICIENTS

With certain restrictions, ACI 318 permits continuous beams and slabs constructed of reinforced concrete to be designed using tabulated moment coefficients. This section deals specifically with beams and one-way slabs (slabs that support moments in one direction only) [ACI Sec. 8.3]. Approximate design of two-way slabs [ACI 13.6], known as the *direct design method*, follows different rules and is not covered here.

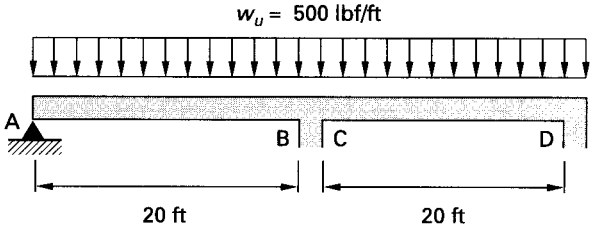
The maximum moments at the ends and midpoints of continuously loaded spans are taken as fractions of the distributed load function, wL^2, where L is the span length between supports and w is the ultimate factored load. The moment at some point along the beam is obtained from the *moment coefficient*, C_1. Table 47.2 contains the moment coefficients allowed by ACI 318.

$$M = C_1 w L^2 \qquad 47.42$$

The method of moment coefficients can be used when the following conditions are met: (a) The load is continuously distributed, (b) construction is not prestressed, (c) there are two or more spans, (d) the longest span length is less than 20% longer than the shortest, and (e) the beams are prismatic, having the same cross section along their lengths.

Table 47.2 *ACI Moment Coefficients*

condition	C_1
positive moments near midspan	
end spans	
simply supported	$\frac{1}{11}$
built-in support	$\frac{1}{14}$
interior spans	$\frac{1}{16}$
negative moments at exterior face of first interior support	
2 spans	$\frac{1}{9}$
3 or more spans	$\frac{1}{10}$
negative moments at other faces or interior supports	
all cases	$\frac{1}{11}$
negative moments at face of all supports	
slabs with spans not exceeding 10 ft, and beams with ratio of sum of column stiffnesses to beam stiffness exceed 8 at each end of the span	$\frac{1}{12}$
negative moments at exterior built-in support	
support is a cross beam or girder (spandrel beam)	$\frac{1}{24}$
support is a column	$\frac{1}{16}$



24. APPROXIMATE METHOD: SHEAR COEFFICIENTS

When the conditions in Sec. 16 are met, ACI 318 [Sec. 8.3] also permits approximating the critical shear using *shear coefficients*. For shear, the design coefficient is used with the average span loading, $\frac{1}{2}wL$. In Eq. 47.43, C_2 has a value of 1.15 for end members at the first interior support. For shear at the face of all other supports, $C_2 = 1$.

$$V = C_2\left(\frac{wL}{2}\right) \qquad 47.43$$

Example 47.10

Determine the critical moment and draw the moment diagram for the uniformly loaded, continuous beam shown. Support A is simple; supports BC and D are built-in column supports. The ultimate factored loading is 500 lbf/ft. All of the conditions necessary to use ACI moment coefficients are satisfied.

Solution

The moment at point A is zero since it is a simple support. Point B is an exterior face of the first interior support over a two-span beam. The moment there is

$$M_B = \left(\tfrac{-1}{9}\right)\left(500\ \frac{\text{lbf}}{\text{ft}}\right)(20\text{ ft})^2 = -22{,}222\text{ ft-lbf}$$

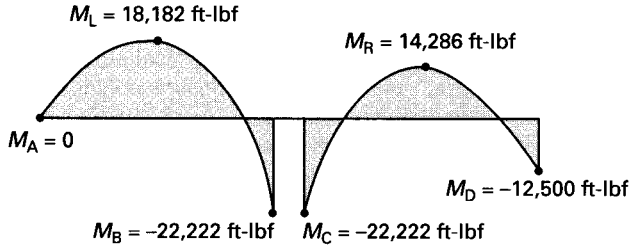
Point C is also an exterior face of a first interior support (counting from the opposite end).

$$M_C = M_B = -22{,}222\text{ ft-lbf}$$

Point D is an exterior column support.

$$M_D = \left(\tfrac{-1}{16}\right)\left(500\ \frac{\text{lbf}}{\text{ft}}\right)(20\text{ ft})^2 = -12{,}500\text{ ft-lbf}$$

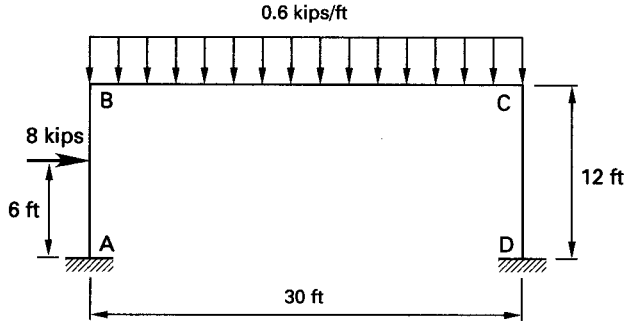
The left span is a simply supported end span. The maximum positive moment is



$$M_L = \left(\tfrac{1}{11}\right)\left(500\ \frac{\text{lbf}}{\text{ft}}\right)(20\text{ ft})^2 = 18{,}182\text{ ft-lbf}$$

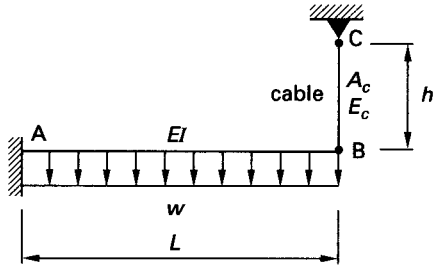
The right span is an end-span with a built-in support. The maximum positive moment is

$$M_R = \left(\tfrac{1}{14}\right)\left(500\ \frac{\text{lbf}}{\text{ft}}\right)(20\text{ ft})^2 = 14{,}286\text{ ft-lbf}$$



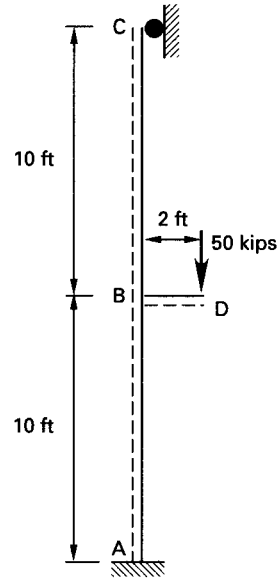
Structural

The critical moment diagram is



PRACTICE PROBLEMS

1. (*Time limit: one hour*) A single-story rigid timber frame is subjected to a uniform load acting over the beam plus a concentrated load at midheight of the left side column. The two columns are solid square, 14 in by 14 in. The beam is 12 in wide and 24 in deep. Determine the moment distribution.



2. A cantilever beam with a cable attached to its free end is loaded uniformly as shown. For the dimensions, properties, and loading indicated, determine (a) the force in the cable and (b) the maximum moment in the beam.

w = 1 kip/ft
L = 10 ft
h = 5 ft
E = 29,000 kips/in^2
E_c = 20,000 kips/in^2
A_c = 0.4 in^2
I = 200 in^2

Answers: (a) 3.49 kips; (b) 15.1 ft-kips

3. The column is loaded as shown. The product EI has a value of 10^4 kip-ft^2.

(a) What is the degree of static indeterminacy?

(A) 0 (determinate)
(B) 1
(C) 2
(D) 3

The answer is (B).

(b) Using the convention that compression on the side of the dashed line is positive, the moment at point A is most nearly

(A) −25 ft-kips
(B) 13 ft-kips
(C) 25 ft-kips
(D) 50 ft-kips

The answer is (B).

(c) The shear at point A is most nearly

(A) 0
(B) 5.6 kips
(C) 10 kips
(D) 50 kips

The answer is (B).

(d) The axial force in bar CB is most nearly

(A) 0
(B) 25 kips (tension)
(C) 50 kips (compression)
(D) 50 kips (tension)

The answer is (A).

(e) The shear in bar CB is most nearly
(A) 0
(B) 5.6 kips
(C) 10 kips
(D) 50 kips

The answer is (B).

(f) The point of inflection in bar AB is most nearly
(A) at A (there is no inflection point)
(B) 2.2 ft from A
(C) 5 ft from A
(D) 7.5 ft from A

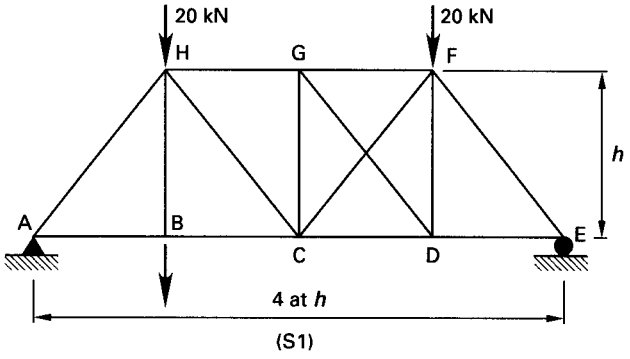
The answer is (B).

(g) The maximum moment in either AB or BC is most nearly
(A) −56 ft-kips
(B) 50 ft-kips
(C) 56 ft-kips
(D) 100 ft-kips

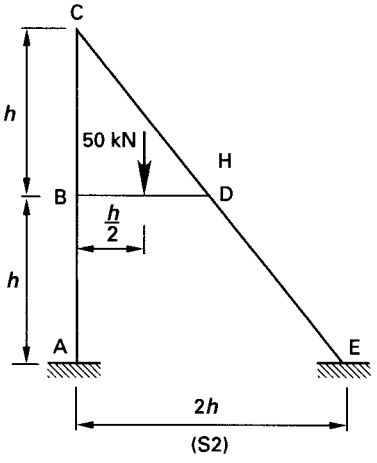
The answer is (C).

(h) Using the convention that deflection to the right is positive, the horizontal displacement of point B is most nearly
(A) −0.03 ft
(B) 0
(C) 0.03 ft
(D) 0.06 ft

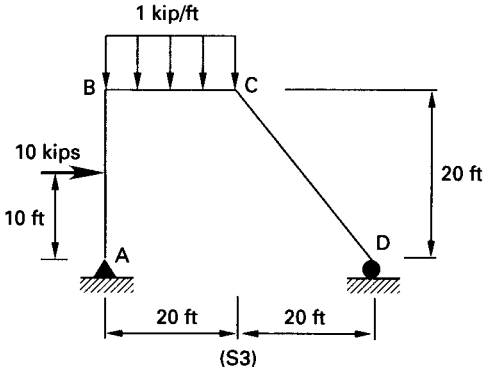
The answer is (C).



(i) If the support A is replaced by a pin, the moment at B in member BA will be most nearly
(A) −50 ft-kips
(B) −25 ft-kips
(C) 25 ft-kips
(D) 100 ft-kips



The answer is (A).



(j) If the support at A is replaced by a pin, the maximum shear in member CB will be most nearly
(A) 0
(B) 5 kips
(C) 7.5 kips
(D) 10 kips

The answer is (B).

4. The three structures shown are designated as S1, S2, and S3.

(a) The truss S1 is
(A) unstable
(B) statically indeterminate to the first degree
(C) statically indeterminate to the second degree
(D) determinate

The answer is (B).

(b) The frame S2 is
(A) statically indeterminate to the third degree
(B) statically indeterminate to the sixth degree
(C) statically indeterminate to the ninth degree
(D) determinate

The answer is (B).

(c) For truss S1, the force in bar HB is most nearly
(A) 0
(B) 20 kN (compression)
(C) 20 kN (tension)
(D) 40 kN (compression)

The answer is (C).

(d) For the truss S1, the force in bar HC is more nearly
(A) 0
(B) 7.1 kN (compression)
(C) 7.1 kN (tension)
(D) 40 kN (compression)

The answer is (B).

(e) The degree of kinematic indeterminacy in frame S2 is
(A) 0 (determinate)
(B) 3
(C) 6
(D) 9

The answer is (D).

(f) The sum of the horizontal reactions in frame S2 is most nearly
(A) 0
(B) 13 kN
(C) 25 kN
(D) 50 kN

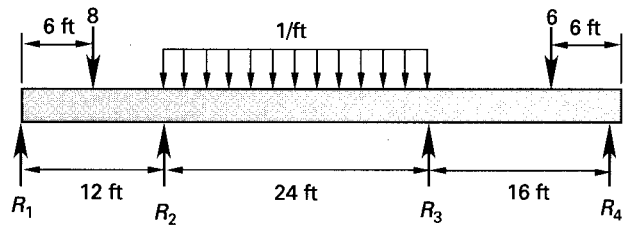
The answer is (A).

(g) For frame S3, the axial force in bar CD is most nearly
(A) 0
(B) 5.3 kips (compression)
(C) 5.3 kips (tension)
(D) 10 kips (compression)

The answer is (B).

(h) For frame S3, the maximum shear force on member BC is most nearly
(A) 10 kips
(B) 13 kips
(C) 15 kips
(D) 20 kips

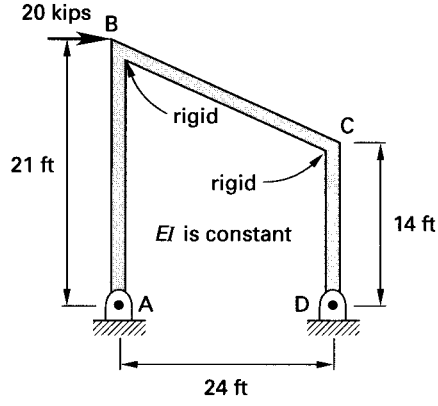
The answer is (B).



(i) For frame S3, the maximum positive moment on bar BC is most nearly
(A) 0
(B) 50 ft-kips
(C) 75 ft-kips
(D) 180 ft-kips

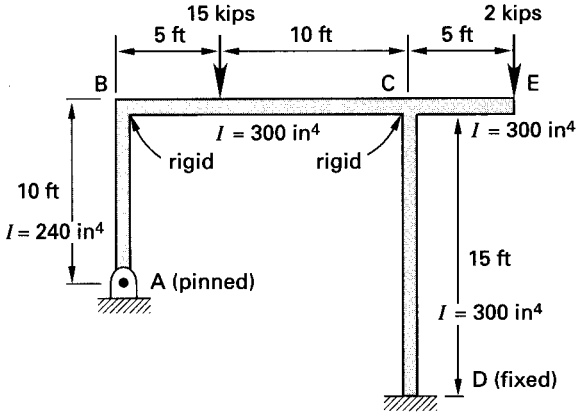
The answer is (D).

(j) For the frame S2, if the axial force on bar BC is assumed negligible and the axial force on AB is 5 kN, the maximum shear on beam BD is most nearly
(A) 0
(B) 10 kN
(C) 45 kN
(D) 50 kN



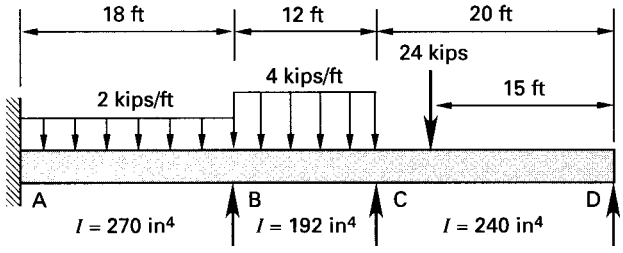
The answer is (C).

5. All supports on the continuous beam shown are simple. What are the reactions?



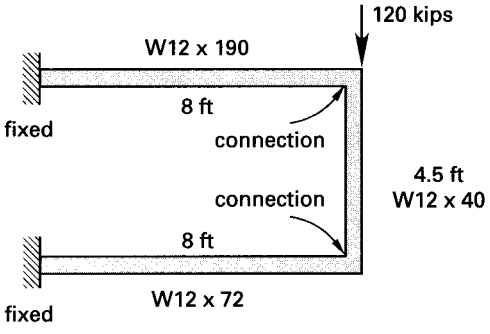
Answers: $R_1 = 0.53$; $R_2 = 19.67$; $R_3 = 16.35$; $R_4 = 1.45$.

6. In the structure shown, the two support points are pinned and the two joints are rigid. (a) What are the magnitudes of the moments at points B and C? (b) What are the reactions?



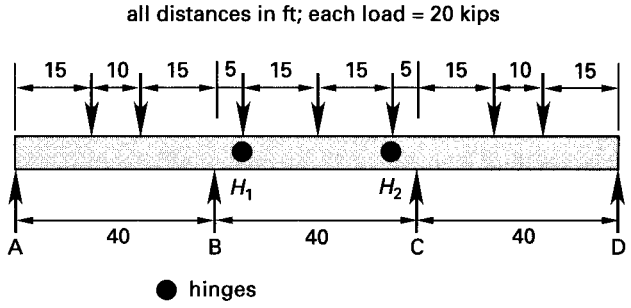
Answers: (a) $M_{AB} = 135$ ft-kips; $M_{CD} = 190$ ft-kips. (b) $A_x = 6.43$ kips [left]; $A_y = 17.5$ kips [down]; $D_x = 13.57$ kips [left]; $D_y = 17.5$ kips [up].

7. A frame with rigid joints is shown. (a) What are the horizontal reactions? (b) What are the joint moments at points B, C, and D?



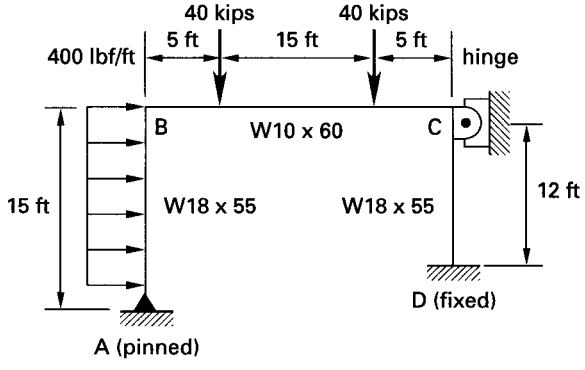
Answers: (a) $A_x = 1.41$ kips [left]; $D_x = 1.41$ kips [right]. (b) $M_B = 14.08$ ft-kips; $M_C = 21.95$ ft-kips; $M_D = -9.0$ ft-kips.

8. What are the magnitudes of the maximum moments on spans AB, BC, and CD?



Answers: $M_{max,AB} = 58.11$ ft-kips; $M_{max,BC} = 66.11$ ft-kips; $M_{max,CD} = 66.11$ ft-kips.

9. Determine the deflection of the frame shown assuming that the two connections are (a) pinned and (b) rigid.



Answers: (a) 0.49 in; (b) 0.235 in.

10. (*Time limit: one hour*) A continuous beam (W24 by 76, A36 steel) is loaded with a series of 20 kip point loads as shown. The beam contains two expansion joints that can be assumed to act as frictionless hinges. Determine the (a) maximum shear stress, (b) maximum bending stress, and (c) midpoint deflection.

Answers: (a) 2850 lbf/in^2; (b) 16,619 lbf/in; (c) 0.106 in [down].

11. (*Time limit: one hour*) All joints are rigid in the structure shown. The beam self-weights are to be disregarded. (a) Determine the horizontal reactions at A, C, and D. (b) Draw the moment diagram on the tension side of the frame.

Answers: $A_x = 6.11$ kips [right]; $C_x = -6.75$ kips [right]; $D_x = 18.86$ kips [left].

1. INTRODUCTION

Concrete (*portland cement concrete*) is a mixture of cement, aggregates, water, and air. The cement paste consists of a mixture of portland cement and water. The paste binds the coarse and fine aggregates into a rock-like mass as the paste hardens during the chemical reaction (*hydration*). Table 48.1 lists the approximate volumetric percentage of each ingredient.

Table 48.1 *Typical Volumetric Proportions of Concrete Ingredients*

component	air-entrained	non-air-entrained
coarse aggregate	31%	31%
fine aggregate	28%	30%
water	18%	21%
cement	15%	15%
air	8%	3%

2. CEMENT

Portland cement is produced by burning a mixture of lime and clay in a rotary kiln and grinding the resulting mass. Cement has a specific weight (density) of approximately 195 lbf/ft^3 (3120 kg/m^3) and is packaged in standard sacks ("bags") weighing 94 lbf (40 kg).

ASTM C-150 describes the five classifications of portland cement.

Type I—Normal portland cement: This is a general-purpose cement used whenever sulfate hazards are absent and when the heat of hydration will not produce a significant rise in the temperature of the cement. Typical uses are sidewalks, pavement, beams, columns, and culverts.

Type II—Modified portland cement: This cement has a moderate sulfate resistance, but is generally used in hot weather for the construction of large structures. Its heat rate and total heat generation are lower than those of normal portland cement.

Type III—High-early strength portland cement: This type develops its strength quickly. It is suitable for use when a structure must be put into early use or when long-term protection against cold temperatures is not feasible. Its shrinkage rate, however, is higher than those of types I and II, and extensive cracking may result.

Type IV—Low-heat portland cement: For massive concrete structures such as gravity dams, low-heat cement is required to maintain a low temperature during curing. The ultimate strength also develops more slowly than for the other types.

Type V—Sulfate-resistant portland cement: This type of cement is appropriate when exposure to sulfate concentration is expected. This typically occurs in regions having highly alkaline soils.

Types I, II, and III are available in two varieties: normal and air-entraining (designated by an "A" suffix). The compositions of the three types of air-entraining portland cement (types IA, IIA, and IIIA) are similar to types I, II and III, respectively, with the exception that an air-entraining material is added.

Many states use modified concrete mixes in order to reduce *concrete-disintegration cracking* ("D-cracking") in critical locations. Coarse aggregates are the primary cause of D-cracking, so the maximum coarse aggregate size is reduced. However, the higher cement paste content causes shrinkage cracking during setting, leading to increased water penetration and corrosion of reinforcing steel. The cracking can be reduced or eliminated by using *shrinkage-compensating cement*, known as "type-K cement" (named after ASTM C-846 type E-1(K)).

Type-K cement (often used in bridge decks) contains an aluminate that expands during setting, offsetting the shrinkage. The net volume change is near zero. The resulting concrete is referred to as *shrinkage-compensating concrete*.

3. AGGREGATE

Because aggregate makes up 60 to 75% of the total concrete volume, its properties influence the behavior of freshly mixed concrete and the properties of hardened concrete. Aggregates should consist of particles with sufficient strength and resistance to exposure conditions such as freezing and thawing cycles. Also, they should not contain materials that will cause the concrete to deteriorate.

Most sand and rock aggregate has a specific weight of approximately 165 lbf/ft^3 (2640 kg/m^3) corresponding to a specific gravity of 2.64.

Fine aggregate consists of natural sand or crushed stone up to $^3/_4$ in (19 mm), with most particles being smaller than 0.2 in (5 mm). Aggregates, whether fine or coarse, must conform to certain standards to achieve the best engineering properties. They must be strong, clean, hard, and free of absorbed chemicals. Fine aggregates must meet the particle-size distribution (grading).

The seven standard ASTM C-33 sieves for fine aggregates have openings ranging from 0.150 mm (no. 100 sieve) to $^3/_8$ in (9.5 mm). The fine aggregate should have not more than 45% passing any sieve and retained on the next consecutive sieve, and its fineness modulus should be not less than 2.3 or more than 3.11. The *fineness modulus* is an empirical factor obtained by adding the cumulative weight percentages retained on each of a specific series (usually no. 4, no. 8, no. 16, no. 30, no. 50, and no. 100) of sieves and dividing the sum by 100. (The dust or pan percentage is not included.)

Coarse aggregates consist of natural gravel or crushed rock, with pieces large enough to be retained on a no. 4 sieve (openings of 0.2 in or 4.75 mm). In practice, coarse aggregate is generally between $^3/_8$ in and $1^1/_2$ in (9.5 to 38 mm). Also, coarse aggregates should meet the gradation requirements of ASTM C-33.

Coarse aggregate has three main functions in a concrete mix: (a) to act as relatively inexpensive filler, (b) to provide a mass of particles that are capable of resisting the applied loads, and (c) to reduce the volume changes that occur during the setting of the cement-water mixture.

4. WATER

Water in concrete has three functions. (a) Water reacts chemically with the cement. This chemical reaction is known as *hydration*. (b) Water wets the aggregate. (c) The water and cement mixture, which is known as *cement paste*, lubricates the mixture and allows it to flow.

Water has a standard density of 62.4 lbf/ft^3 (1000 kg/m^3). 7.48 gal occupy 1 ft^3 (1000 L occupy 1 m^3). One ton (2000 lbf) of water has a volume of 240 gal.

Any potable water that has no pronounced odor or taste can be used for producing concrete. (With some quality restrictions, the ACI code also allows nonpotable water to be used in concrete mixing.) Impurities in water may affect the setting time, strength, and corrosion resistance. Water used in mixing concrete should be clean and free from injurious amounts of oils, acids, alkalis, salt, organic materials, and other substances that could damage the concrete or reinforcing steel.

5. ADMIXTURES

Admixtures are routinely used to modify the performance of concrete. Advantages include higher strength, durability, chemical resistance, and workability; controlled rate of hydration; and reduced shrinkage and cracking. Admixtures fall into several different categories, as classified by ASTM C-494.

Type A: water-reducing

Type B: set-retarding

Type C: set-accelerating

Type D: water-reducing and set-retarding

Type E: water-reducing and set-accelerating

Type F: high-range water-reducing

Type G: high-range water-reducing and set-regarding

ASTM C-260 covers air-entraining admixtures, which enhance freeze-thaw durability. ASTM C-1017 deals exclusively with plasticizers to produce flowing concrete. ACI 212 recognizes additional categories, including corrosion inhibitors and damproofing. Finally, microsilica, flyash, and synthetic fibers are routinely used in concrete.

Water-reducing mixtures disperse the cement particles throughout the plastic concrete, reducing water requirements by 5 to 10%. Water that would otherwise be trapped within the cement floc remains available to fluidize the concrete. Although water is necessary to produce concrete, using lesser amounts increases strength and durability and decreases permeability and shrinkage. The same slump can be obtained with less water.

High-range water reducers, also known as *superplasticizers*, function via the same mechanisms as regular water reducers. However, the possible water reduction is greater (e.g., 12 to 30%). Dramatic increases in slump, workability, and strength are achieved. *High-slump concrete* is suitable for use in sections that are heavily reinforced and in areas where consolidation cannot otherwise be attained. Also, concrete can be pumped at lower pump pressures, so the lift and pumping distance can be increased. Overall, superplasticizers reduce the cost of mixing, pumping, and finishing concrete.

Set accelerators increase the rate of cement hydration, shortening the setting time and increasing the rate of strength development. They are useful in cold weather (below 35 to 40°F or 2 to 4°C) or when urgent repairs are needed. While calcium chloride ($CaCl_2$) is a very effective accelerator, nonchloride, noncorrosive accelerators can provide comparable performance. (The ACI code does not allow chloride to be added to concrete used in prestressed construction or in concrete containing aluminum embedments.)

Set retarders are used in hot environments and where the concrete must remain workable for an extended period of time, allowing extended haul and finishing times. A higher ultimate strength will also result. Most retarders also have water-reducing properties.

Air entraining mixtures create microscopic air bubbles in the concrete. This improves the durability of hardened concrete subject to freezing and thawing cycles. The wet workability is improved, while bleeding and segregation are reduced.

A waste product of coal-burning power-generation stations, *flyash* is the most common *pozzolanic additive*. As cement sets, calcium silicate hydrate and calcium hydroxide are formed. While the former is a binder that holds concrete together, calcium hydroxide does not contribute to binding. However, flyash reacts with some of the calcium hydroxide to increase the binding. Also, by acting as a microfiller between cement particles, strength and durability are increased while permeability is reduced. When used as a replacement for less than 45% of the portland cement, flyash meeting ASTM C-618 contributes to resistance to scaling from road deicing chemicals.

Microsilica (*silica fume*) is an extremely fine particulate material, approximately 1/100th the size of cement particles. It is a waste product of electric arc furnaces. It acts as a "super pozzolan." Adding 5 to 15% microsilica will increase the pozzolanic reaction as well as act as a microfiller to reduce permeability.

It reacts with calcium hydroxide in the same manner as flyash. Microsilica is customarily used to achieve strengths in the 8000 to 9000 psi (55 to 62 MPa) range.

Corrosion-resisting compounds are intended to inhibit rusting of the reinforcing steel and prestressing strands. Calcium nitrate is commonly used to inhibit the corrosive action of chlorides. It acts by forming a passivating protective layer on the steel. Calcium nitrate has essentially no effect on the mechanical and plastic properties of concrete.

In the *Devlo admixture system*, the cement particles are coated with a stabilizer, halting the hydration process indefinitely. Setting can be reinitiated at will hours or days later. The manufacturer claims that the treatment has no effect on the concrete when it hardens.

6. SLUMP

The four basic concrete components (cement, sand, aggregate, and water) are mixed together to produce a homogeneous concrete mixture. The *consistency* and *workability* of the mixture affects the concrete's ability to be placed, consolidated, and finished without segregation or bleeding. The slump test is commonly used to determine consistency and workability.

The *slump test* consists of completely filling a slump cone mold in three layers of about one third of the mold volume. Each layer is rodded 25 times with a round, spherical-nosed steel rod of $^5/_8$ in (16 mm) diameter. When rodding the subsequent layers, the previous layers beneath are not penetrated by the rod. After rodding, the mold is removed by raising it carefully in the vertical direction. The slump is the difference in the mold height and the resulting concrete pile height. Typical values are 1 to 4 in (25 to 100 mm).

Concrete mixtures that do not slump appreciably are known as *stiff mixtures*. Stiff mixtures are inexpensive because of the large amounts of coarse aggregate. However, placing time and workability are impaired. Mixtures with large slumps are known as *wet mixtures* (*watery mixtures*) and are needed for thin castings and structures with extensive reinforcing. Slumps for concrete that is machine-vibrated during placement can be approximately one third less than for concrete that is consolidated manually.

7. DENSITY

The density, also known as *weight density, unit weight,* and *specific weight* of normal-weight concrete varies from about 140 lbf/ft^3 to about 160 lbf/ft^3 (2240 to 2560 kg/m^3), depending on the specific gravities of the constituents. For most calculations involving normal-weight concrete, the density may be taken as 145 to 150 lbf/ft^3 (2320 to 2400 kg/m^3). Lightweight concrete can have a density as low as 100 lbf/ft^3 (1600 kg/m^3).

8. COMPRESSIVE STRENGTH

The concrete's *compressive strength*, f'_c, is the maximum stress the concrete specimen can sustain in compressive axial loading. It is also the primary parameter used in ordering concrete. When one speaks of "6000 psi concrete," the compressive strength is being referred to. Compressive strength is expressed in psi or MPa. (MPa is equivalent to N/mm^2, which is also commonly quoted.)

Typical compressive strengths range from 4000 psi to 6000 psi (27 to 41 MPa) for traditional structural concrete, though concrete for residential slabs-on-grade and foundations will be lower (e.g., 2000 psi). 6000 psi (41 MPa) concrete is used in the manufacture of some concrete pipes, particularly those that are jacked in.

Cost is approximately proportional to concrete's compressive strength—a rule that applies to high-performance concrete as well as traditional concrete. For example, if 5000 psi concrete costs $50 per cubic yard, then 14,000 psi concrete will cost approximately $140 per cubic yard.

Compressive strength is controlled by selective proportioning of the cement, coarse and fine aggregates, water, and various admixtures. However, the compressive strength of traditional concrete is primarily dependent on the mixture's water/cement ratio. Provided that the mix is of a workable consistency, strength varies directly with the cement/water ratio. (This is *Abram's strength law*, named after Dr. Duff Abrams, who formulated the law in 1918.)

The standard ASTM compressive test specimen mold is a cylinder with a 6 in (150 mm) diameter and a 12 in (300 mm) height. Steel molds are more expensive than plastic molds, but they provide greater rigidity. (Some experts say specimens from steel molds test 3 to 15% higher.) The specimen is axially loaded to failure at a specific rate. The concrete is cured for a specific amount of time (three days, a week, 28 days, or more) at a specific temperature. Plain or lime-saturated heated water baths, as well as dry "hot boxes" heated by incandescent lights, are used for this purpose at some testing labs. To ensure uniform loading, the ends are smoothed by grinding or are capped in sulfur. For testing of very high-strength concrete, the ends may need to be ground glass-smooth in lapidary machines.

Since the ultimate load for 15,000 psi (103 MPa) and higher concrete exceeds the capacity (typically 300,000 lbf (1.34 MN)) of most testing machines, testing firms are switching to smaller cylinders with diameters of 4 in (100 mm) and heights of 8 in (200 mm) rather than purchasing 400,000 to 600,000 lbf (1.8 to 2.7 MN) machines.

The compressive strength is calculated as the maximum axial load, P, divided by the cross-sectional area, A, of the cylinder. Since as little as 0.1 in difference in the diameter can affect the test results by 5%, the diameter must be measured precisely.

$$f'_c = \frac{P}{A}$$

Compressive strength is normally measured on the 28th day after the specimens are cast. Since the strength of concrete increases with time, all values of f'_c must be stated with respect to a known age. If no age is given, a strength at a "standard" 28-day age is assumed.

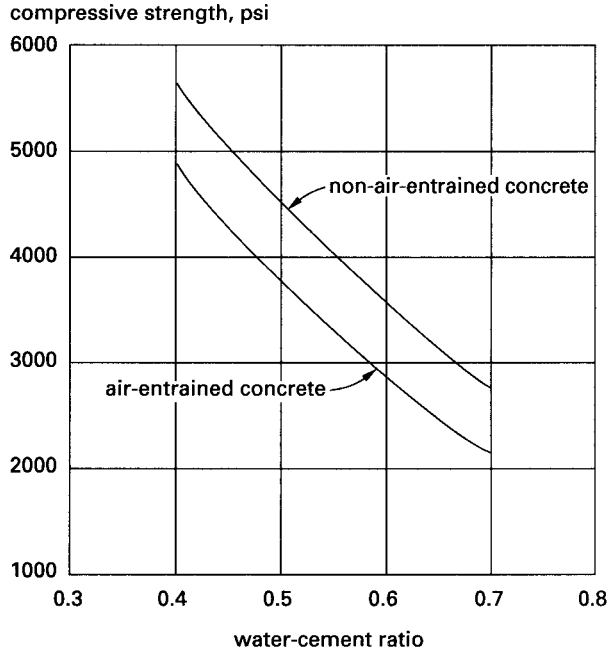

Figure 48.1 *Typical Concrete Compressive Strength Characteristics*

9. STRESS-STRAIN RELATIONSHIP

The stress-strain relationship for concrete is dependent on its strength, age at testing, rate of loading, nature of the aggregates, cement properties, and type and size of specimens. Typical stress-strain curves for concrete specimens loaded in compression at 28 days under a normal rate of loading are shown in Fig. 48.2.

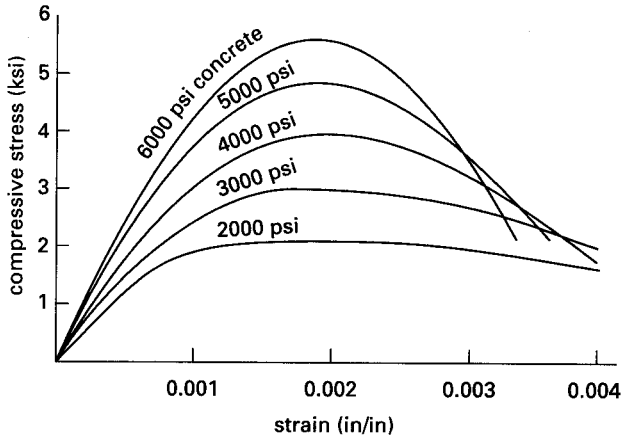

Figure 48.2 *Typical Concrete Stress-Strain Curves*

10. MODULUS OF ELASTICITY

The *modulus of elasticity* (also known as *Young's modulus*) is defined as the ratio of stress to strain in the elastic region. Unlike steel, the modulus of elasticity of concrete varies with compressive strength. Since the slope of the stress-strain curve varies with the applied stress, there are several ways of calculating the modulus of elasticity. Figure 48.3 shows a typical stress-strain curve for concrete with the *initial modulus*, the *tangent modulus*, and the *secant modulus* indicated.

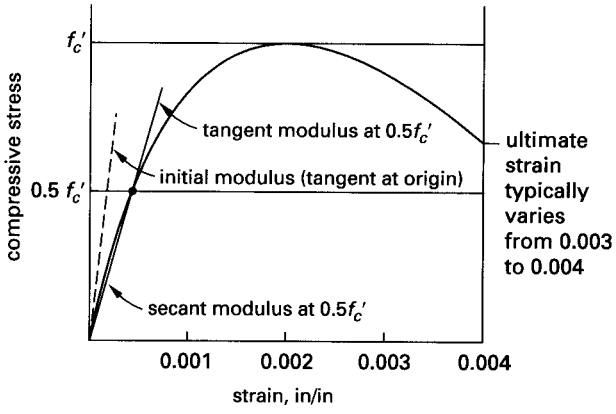

Figure 48.3 *Concrete Moduli of Elasticity*

The *secant modulus of elasticity* is specified by the American Concrete Institute Code for use with specific weights between 90 and 155 lbf/ft^3 (1440 to 2480 kg/m^3). Equation 48.1 is used for both instantaneous and long-term deflection calculations. In Eq. 48.1, w_c is in lbf/ft^3 (kg/m^3), and E_c and f_c' are in lbf/in^2 (MPa) (ACI 318 8.5.1).

$$E_c = w_c^{1.5} 0.043 \sqrt{f_c'} \quad \text{[SI]} \qquad 48.1(a)$$

$$E_c = w_c^{1.5} 33 \sqrt{f_c'} \quad \text{[U.S.]} \qquad 48.1(b)$$

For normal-weight concrete, the ACI code suggests Eq. 48.2, corresponding to a specific weight of approximately 145 lbf/ft^3 (2320 kg/m^3) (ACI 318 8.5.1).

$$E_c = 5000 \sqrt{f_c'} \quad \text{[SI]} \qquad 48.2(a)$$

$$E_c = 57{,}000 \sqrt{f_c'} \quad \text{[U.S.]} \qquad 48.2(b)$$

11. SPLITTING TENSILE STRENGTH

The extent and size of cracking in concrete structures are affected to a great extent by the tensile strength of the concrete. The ASTM C-496 *split cylinder testing procedure* is the standard test to determine the tensile strength of concrete. A 6 in × 12 in cylinder is placed on its side as in Fig. 48.4, and the maximum load, P, that causes the cylinder to split in half is used to calculate the split tensile strength.

$$f_{ct} = \frac{2P}{\pi DL} \qquad 48.3$$

ACI 318 5.1.4 suggests that the splitting tensile strength f_{ct} can be calculated from correlations with compressive strength, and ACI 318 11.2 indirectly gives such correlations.

$$f_{ct} = 6.7 \sqrt{f_c'} \quad \text{[normal weight]} \qquad 48.4$$

$$f_{ct} = 5.7 \sqrt{f_c'} \quad \text{[sand lightweight]} \qquad 48.5$$

$$f_{ct} = 5 \sqrt{f_c'} \quad \text{[other lightweight]} \qquad 48.6$$

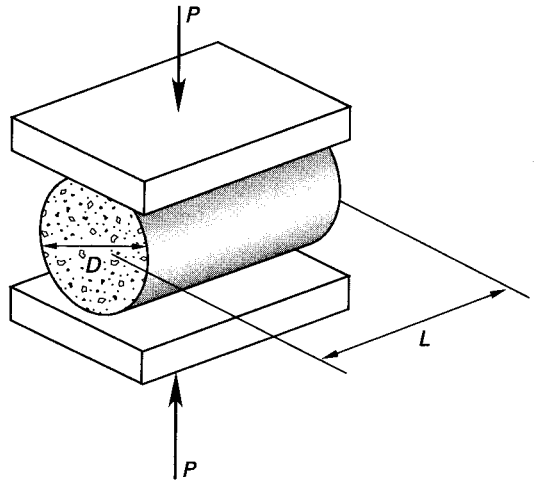

Figure 48.4 *Splitting Tensile Test*

12. MODULUS OF RUPTURE

The tensile strength of concrete in flexure is known as the *modulus of rupture*, f_r, and is an important parameter for evaluating cracking and deflection in beams. The tensile strength of concrete is relatively low, about

Structural

10 to 15% (and occasionally up to 20%) of the compressive strength. ASTM procedure C-78 gives the details of beam testing using *third point loading*. The modulus of rupture is calculated from Eq. 48.7.

$$f_r = \frac{Mc}{I} \quad \text{[tension]} \qquad 48.7$$

Eq. 48.7 gives higher values for tensile strength than the *splitting tensile strength test* because the stress distribution for concrete is not linear as is assumed in Eq. 48.7. For normal-weight concrete, the ACI code provides Eq. 48.8. For all-lightweight concrete, the modulus of rupture is taken as 75% of the calculated values. Other special rules for lightweight concrete may apply (ACI 318 9.5.2.3).

$$f_r = 0.62\sqrt{f'_c} \quad \text{[SI]} \qquad 48.8(a)$$

$$f_r = 7.5\sqrt{f'_c} \quad \text{[U.S.]} \qquad 48.8(b)$$

13. SHEAR STRENGTH

Concrete's true *shear strength* is difficult to determine in the laboratory because pure shear failure is affected by other stresses in addition to the shear load. Reported values of shear strength vary greatly with the method used, but they are a small percentage (e.g., 25% or less) of the ultimate compressive strength.

14. POISSON'S RATIO

Poisson's ratio is the ratio of the lateral strain to axial strain. It varies in concrete from 0.11 to 0.23, with an average value being 0.17.

15. REINFORCING STEEL

Steel is an alloy consisting almost entirely of iron. It also contains small quantities of carbon, silicon, manganese, sulfur, phosphorus, and other elements. Carbon has the greatest effect on the steel's properties. The carbon content is normally less than 0.5% by weight, with 0.2 to 0.3% being common percentages.

The density of steel is essentially unaffected by its composition, and a value of 0.283 lbf/in^3 (7820 kg/m^3) can be used.

Reinforcing steel may be formed from billet steel, axle steel, or rail steel. Most modern reinforcing bars are made from new billet steel. (Special bars of titanium, stainless steel, corrosion-resistant alloys, and glass fiber composites may see extremely limited use in corrosion-sensitive applications.) The following ASTM designations are used for steel reinforcing bars.

ASTM A-615: billet steel, grades 40 and 60 (symbol "S")

ASTM A-615: billet steel, grade 75 for no. 11, no. 14, and no. 18 bars (symbol "N")

ASTM A-616: rail steel, grades 50 and 60 (symbols "R" and "⊥")

ASTM A-617: axle steel, grades 40 and 60 (symbol "A")

ASTM A-706: low-alloy steel, grade 60 (symbol "W")

Reinforcing steel used for concrete structures comes in the form of bars (known as "rebar"), welded wire fabrics, or wires. Reinforcing bars can be plain or deformed; however, most bars are manufactured deformed to increase the bond between concrete and steel. Figure 48.5 shows how the surface is deformed by rolling a pattern on the bar surface. The patterns used vary with the manufacturer.

Plain round reinforcing bars are designated by their nominal diameters in fractions of an inch or in millimeters (e.g., 1/2 in, 5/8 in, etc.) Deformed bars are also round, with sizes designed in numbers of eighths of an inch or in millimeters. Standard deformed bars are manufactured in sizes no. 3 to no. 11, with two special large sizes, no. 14 and no. 18, also available on special order. Metric (SI) bar designations are based on a "soft" conversion of the bar diameter to millimeters. For example, the traditional no. 3 bar has a nominal diameter of 3/8 in, and this bar has a metric designation of no. 10 because it has a 9.5 mm diameter (approximately 10 mm). Hard metric conversions, where bars with slightly different diameters would be used in metric projects, were once considered but ultimately rejected. Hard conversions are used in Canadian bar sizes.

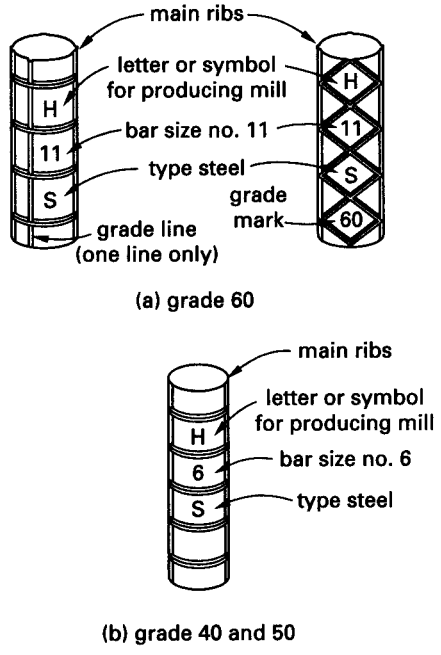

Figure 48.5 *Deformed Bars*

16. MECHANICAL PROPERTIES OF STEEL

A typical stress-strain curve for ductile structural steel is shown in Fig. 48.6. The curve consists of elastic, plastic, and strain-hardening regions.

The *elastic region* is the portion of the stress-strain curve where the steel will recover its size and shape upon release of load. Within the *plastic region*, the material shows substantial deformation without noticeable change of the stress. Plastic deformation, or *permanent set*, is any deformation that remains in the material after the load has been removed. In the *strain-hardening region*, additional stress is necessary to produce additional strain. This portion of the stress-strain diagram is not important from the design point of view because the large amount of strain occurs within this range.

The slope of the linear portion within the elastic range is the *modulus of elasticity*. The modulus of elasticity for all types of ductile reinforcing steels is taken to be 29×10^6 psi (200 GPa) (ACI 318 8.5.2). (The modulus of elasticity is sometimes quoted as 30×10^6 psi (207 GPa). This value may apply to hard steels used for other purposes, but not to steel used for reinforcing concrete.)

The steel *grade* corresponds to its nominal yield tensile strength in ksi (thousands of pounds per square inch). Grade-60 steel with a yield strength of 60 ksi (413 MPa) is the most common, though grades 40 and 50 are also available upon request. SI values of steel strength are obtained using "soft" conversions. That is, steel properties are the same in customary U.S. and SI values. Only the designations are different.

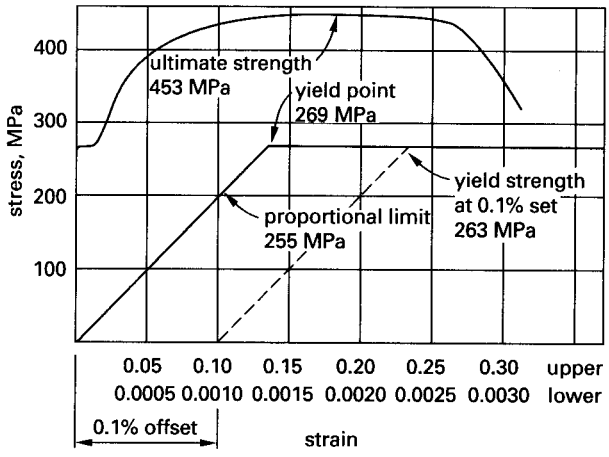

Figure 48.6 *Typical Stress-Strain Curve for Ductile Steel*

17. CHLORIDE CORROSION

Chloride has been used as a concrete additive for a long time. In some fresh concrete, calcium chloride is deliberately added to the mix as a low-cost means of increasing early strength. In cold weather, chloride speeds up the initial set before the cement paste freezes.

However, corrosion from chlorides is a major problem for steel-reinforced concrete. On roads and bridges, deicing chemicals and environmental salt corrode from the outside in. In buildings, chloride from concrete accelerators works from the inside out. In both, chloride ions migrate through cracks to attack steel reinforcing bars.

Once corrosion has begun, the steel is transformed into expanding rust, putting pressure on surrounding concrete and causing the protective concrete layer to spall.

The ACI code limits chloride concentrations in four categories: prestressed concrete, reinforced concrete exposed to chloride, reinforced concrete protected from moisture in service, and other reinforced concrete construction. At the lowest end of these limits, the code permits 0.06% chloride in prestressed concrete. At the high end, the code permits 1.00% chloride in reinforced concrete that is kept dry. (These percentages are on a weight basis, as ion. A 1% chloride concentration is approximately equivalent to 2% calcium chloride, since $CaCl_2$ is approximately 63% chloride by weight.)

18. ELECTRICAL PROTECTION OF REBAR

There are two major methods of using electricity to prevent chloride corrosion. *Cathodic protection* lowers the active corrosion potential of the reinforcing steel to immune or passive levels. Current is supplied from an external direct-current source. The current flows from an anode embedded in the concrete or from a surface-mounted anode mesh covered with 1.5 to 2 in of concrete. From there, the current passes through the electrolyte (the water and salt in the pores of the concrete) to the steel. The steel acts as the cathode, which is protected.

Installation is simple. Power consumption is very low. Maintenance is essentially zero. Large areas should be divided into "zones," each with its own power supply and monitoring equipment. This protection scheme has initial and ongoing expenses, as the system and power supply must remain in place throughout the life of the structure.

An alternative method, developed in Europe, also attaches steel mesh electrodes to the surface and uses a current. However, the treatment is maintained only for a limited amount of time (1 to 2 months). An electrolytic cellulose paste is sprayed on and the current is applied. Chloride ions migrate from the rebar and are replaced by alkali ions from the paste. This raises the pH and forms a passivating oxide layer around the rebar. The mesh and cellulose are removed and discarded when the treatment is complete. Protection lasts for years. This electrolytic treatment may not be effective with epoxy-coated bars, prestressed structures (where chemical reactions can cause embrittlement), and bridge decks (due to the duration of shutdown required for treatment).

19. COATED REBAR

Corrosion-resistant *epoxy-coated rebar* ("green bar") has been in use in the United States since the 1970s, most of it in bridge decks and other traffic structures. After proper cleaning, standard rebar is given a 0.005 to 0.012 in (0.13 to 0.30 mm) electrostatic spray coating of epoxy. The epoxy is intended to be flexible enough to permit subsequent bending and cold working.

Epoxy's effectiveness, once described as "maintenance-free in corrosive environments," is now questioned by some. Corrosion protection is apparently less than expected when poor manufacturing quality and installation practices remove or damage portions of the coating. Corrosion of coated bars can be reduced by coating after bending and by using alternative "pipeline coatings," which are thicker but less flexible than epoxy.

Epoxy-coated rebar is now seen as one of several fabrication methods needed to prevent or slow chloride corrosion in *bridge decks*, including cathodic protection, lateral and longitudinal prestressing, less-porous and low-slump concrete, thicker (3 in or more) topping layers, cathodic protection, interlayer membranes and asphalt concrete, latex-modified or silica fume concrete overlays, corrosion-resistant additives, surface sealers (with or without overlays), galvanizing steel rebar, polymer impregnation, and polymer concrete.

20. HIGH-PERFORMANCE CONCRETE

High-performance concrete (HPC) (or *high-strength concrete*) is a general term used to describe concrete with a compressive strength above 6000 psi (41 MPa), although this limit continues to increase. Specifying HPC with strengths of 6000 to 10,000 psi (41 to 69 MPa) for high-rise construction is now routine. Ready-mix plants can deliver 9000 to 15,000 psi (62 to 103 MPa) concrete, and 20,000 psi (138 MPa) concrete has seen limited use.

High strength is achieved in a variety of ways. Superplasticizers and other mineral admixtures (e.g., pozzolans such as flyash, silica fume, and precipitated silica) are the main components affecting strength.

HPC allows engineers to design structures with smaller structural members (i.e., columns and beams), reducing dead load and increasing usable space. Though HPC is more costly than standard concrete, the long-term benefits to the building owner can be substantial. The benefits of HPC use, however, may not be realizable in areas where concrete thickness is mandated by strict building codes.

21. FIBER-REINFORCED CONCRETE

Fiber-reinforced concrete (FRC) contains small steel, polymer (polyolefin or polypropylene), carbon, glass, or brass fibers approximately 0.5 to 2 in (12 to 50 mm) long dispersed randomly throughout the mix. (The term *carbon-fiber-reinforced concrete*, CFRC, is used with carbon reinforcement.) Synthetic fibers are specified by ASTM C-1116.

As setting concrete loses water, it shrinks. Fibers are added to control surface cracking during the setting process. These fibers intersect cracks that form during shrinkage. For control of surface cracking, fibers are added in a proportion of approximately 0.1% by volume corresponding to 1.5 lbm/ft^3 (24 kg/m^3) of concrete.

Fibers can also be used to carry a portion of the service load, though the volumetric fraction must be much higher: 4 to 10%. Steel fibers are commonly used in airport pavements, industrial floors, bridge decks, and tunnel lining. Glass fibers are used in precast products. The fibers carry the load once microcracking from flexural loading has occurred, at approximately 3500 psi (24 MPa). Microreinforced concretes with compressive strengths of 30,000 psi (207 MPa) and higher have been reported.

22. POLYMER CONCRETE

Polymer concrete is a material primarily used for rapid repair (sealing or overlaying) of concrete, usually bridge decks. Sometimes dubbed "MMA concrete" after one of its components, it is delivered as two components that are mixed together prior to use: (a) a premixed powder of fine aggregates coated with polymers, initiators, and pigments; and (b) a liquid methyl-methacrylate (MMA) monomer. Setting is rapid, though complete curing may take several weeks. Final performance is similar or superior to traditional concrete.

Polymer concrete can be precast into products with compressive strengths up to 15,000 psi (103 MPa) and flexural strengths up to 300 psi (2.1 MPa). It is water- and corrosion-resistant, thin, lightweight, and colorfast, making it ideal for some bridge components.

23. LIGHTWEIGHT CONCRETE

Aggregate having a specific weight of 70 lbf/ft^3 (1120 kg/m^3) or less is known as *lightweight aggregate* and is used in the production of *lightweight concrete*. Lightweight concrete in which only the coarse aggregate is lightweight is known as *sand-lightweight concrete*. If both the coarse and fine aggregates are lightweight, the concrete is known as *all-lightweight concrete*. Unless noted otherwise, concrete in this chapter is assumed to be *normal weight concrete*.

24. SELF-PLACING CONCRETE

Self-placing concrete (also known as *self-compactible concrete, self-consolidating concrete, flowable concrete,* and *nonvibration concrete*) is used to reduce labor needs and construction time, particularly where congestion of steel reinforcing bars make the consolidation of concrete

difficult. Such concrete does not require vibration and thus reduces site noise and placement defects. Self-placing concrete relies on viscosity agents to produce liquid-like flow characteristics.

25. ROLLER-COMPACTED CONCRETE

Roller-compacted concrete (RCC), also known as *roll-crete*, is a very lean, no-slump, almost-dry concrete, similar to damp gravel in consistency. It is primarily used in dams, though use has been extended to heavy-duty pavements (e.g., logging roads, freight yards, and truck stopping areas) where a perfectly smooth surface is not required. RCC is attractive because of its low cost. Requiring less time and labor to complete, an RCC dam costs about half the price of a conventional concrete gravity dam and about one third less than an earth or a rockfill dam.

Scrapers and bulldozers spread and compact RCC in broad 1 to 2 ft (30 to 71 cm) thick lifts, and vibratory rollers or dozers consolidate it to the specified density with multiple (4 to 10) passes. A compressive strength of approximately 2000 psi (14 MPa) is achieved, identical to the strength of a conventional mixture with the same water-cement ratio.

Seepage in RCC dams occurs primarily through the interfaces between the lifts, but this seepage can be controlled or eliminated with a variety of practices. The abutments and one or both faces should be constructed from normal concrete. Each new lift of RCC should be bedded in a $\frac{1}{4}$ to $\frac{1}{2}$ in (6 to 12 mm) thin layer of high-slump cement-paste mortar. The time between lifts can be reduced, and slightly wetter mixes can be used. Other methods of reducing seepage include using more cement, flyash, and water in the core of the dam; incorporating a PVC membrane between the cast-in-place face and the RCC; and building up the lifts in small 6 in (150 mm) layers. Since RCC tends to clump in temperatures greater than 90°F (32°C), in extreme cases placement can be limited to winter months or cooler nights.

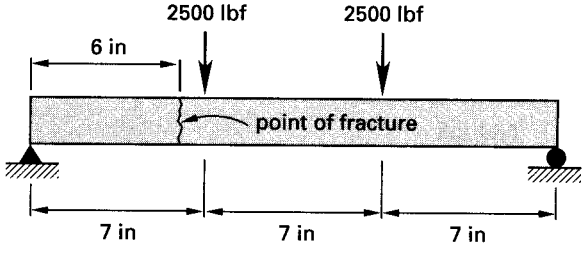
26. SOIL CEMENT

Soil cement is a combination of soil, water, and a small amount of cement (about 10%). Soil cement is low in price, strong, and easy to work with, can take repeated wetting and heavy wave action, and can stand up to freeze-thaw cycles. Placed soil cement looks like concrete or rock. It has proven to be an ideal material for river bank protection, reservoir and channel lining, facing for earthfill damps, seepage control, pipe bedding, and foundation stabilization.

27. CONTROLLED LOW-STRENGTH MATERIAL

Controlled low-strength material (CLSM) is a mixture of flyash, fine aggregates, cement (about 5%), and water. Delivered in a semi-fluid state, it flows readily into place, needs no tamping or vibration, and achieves a compressive strength of 100 psi (700 kPa) within 24 hr. It has proven to be an efficient and economical backfilling material for culverts, bridge abutments, and trenches.

PRACTICE PROBLEMS



1. A batch of fine aggregate was sieve graded. The percentages retained on each sieve are shown. What is the sand's fineness modulus?

sieve	percentage retained
4	4
8	11
16	21
30	22
50	24
100	17
dust (pan)	1

(A) 0.99
(B) 1.8
(C) 2.9
(D) 99

The answer is (C).

2. (*Time limit: one hour*) The 6 in × 6 in concrete beam section shown was tested in a third-point loading apparatus. The failure occurred outside the middle third as shown under a maximum total load of 5000 lbf. The beam was normal-weight concrete with a compressive strength of 5000 psi.

(a) The maximum shear force is most nearly
(A) 625 lbf
(B) 1250 lbf
(C) 2500 lbf
(D) 5000 lbf

The answer is (C).

Structural

(b) The maximum bending moment is most nearly
(A) 5000 in-lbf
(B) 10,000 in-lbf
(C) 15,000 in-lbf
(D) 17,500 in-lbf

The answer is (D).

(c) The shear force within the middle third of the beam is most nearly
(A) zero
(B) 625 lbf
(C) 1250 lbf
(D) 2500 lbf

The answer is (A).

(d) The bending moment within the middle third of the beam
(A) is zero.
(B) increases linearly from right to left.
(C) is parabolic in shape.
(D) is a straight line with zero slope.

The answer is (D).

(e) The modulus of rupture is most nearly
(A) 320 psi
(B) 420 psi
(C) 520 psi
(D) 620 psi

The answer is (B).

(f) If the fracture occurred within the middle third, the modulus of rupture is most nearly
(A) 420 psi
(B) 450 psi
(C) 470 psi
(D) 490 psi

The answer is (D).

(g) The modulus of rupture using the ACI empirical equation is most nearly
(A) 530 psi
(B) 550 psi
(C) 570 psi
(D) 590 psi

The answer is (A).

(h) If the beam is made of lightweight concrete, the modulus of rupture is most nearly
(A) 380 psi
(B) 400 psi
(C) 420 psi
(D) 440 psi

The answer is (B).

(i) The center-point loading test is no longer standard in determining the modulus of rupture for concrete because
(A) it yields higher values of modulus of rupture than the true values.
(B) it is difficult to perform accurately in the laboratory.
(C) it costs more than the third-point loading test.
(D) of all of the above.

The answer is (B).

(j) The modulus of rupture test yields a higher value of strength than a direct tensile test and splitting tensile test made on the same specimen because
(A) the assumed stress block shape does not match the real shape.
(B) direct tensile tests are sensitive to any accidental eccentricity.
(C) the concrete is assumed to be perfectly elastic.
(D) of all of the above.

The answer is (D).

3. If a concrete has a density of 2300 kg/m^3 and a compressive strength of 15 MPa, what modulus of elasticity is predicted by ACI 318?
(A) 14 MPa
(B) 18 MPa
(C) 28 MPa
(D) 18 GPa

The answer is (D).

4. (*Time limit: one hour*) A normal-weight concrete specimen tested at 28 days yielded the following results.

(a) A 6 in × 12 in concrete cylinder failed at an axial compressive force of 105,000 lbf. The ultimate compressive strength is most nearly
(A) 1200 psi
(B) 1900 psi
(C) 3700 psi
(D) 17,500 psi

The answer is (C).

(b) A 6 in × 12 in concrete cylinder resisted a transverse force of 45,000 lbf in a split tensile cylinder test. The concrete tensile strength is most nearly
(A) 400 psi
(B) 450 psi
(C) 625 psi
(D) 666 psi

The answer is (A).

(c) A 6 in square unreinforced beam section resisted a force of 5400 lbf on a 21 in span length. A third-point loading test was used, and the fracture occurred within the middle third. The modulus of rupture is most nearly

(A) 150 psi
(B) 400 psi
(C) 525 psi
(D) 900 psi

The answer is (C).

(d) The ratio of the modulus of rupture to the compressive strength is most nearly

(A) 4%
(B) 5%
(C) 12%
(D) 14%

The answer is (D).

(e) The ratio of the split tensile strength to the compressive strength is most nearly

(A) 8%
(B) 11%
(C) 17%
(D) 20%

The answer is (B).

(f) The conclusion that could be stated based on the answers of parts (d) and (e) is

(A) concrete is weak in tension and strong in compression.
(B) concrete is weak in tension and strong in shear.
(C) concrete is strong in tension and weak in compression.
(D) none of the above.

The answer is (A).

(g) Given a compressive strength of 3700 lbf/in^2, the approximate value of the modulus of rupture is most nearly

(A) 460 psi
(B) 500 psi
(C) 550 psi
(D) 600 psi

The answer is (A).

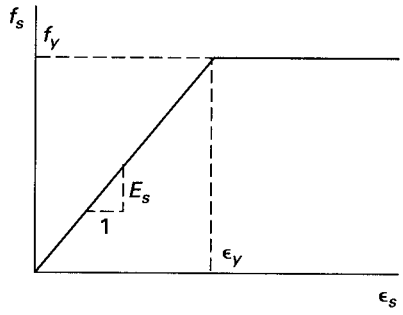
(h) Given a compressive strength of 3700 psi, the approximate value of the split tensile strength is most nearly

(A) 300 psi
(B) 410 psi
(C) 500 psi
(D) 600 psi

The answer is (B).

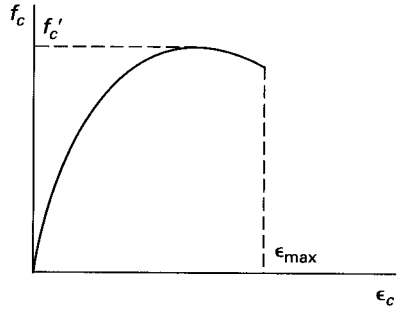
(i) From the compression test, the axial strain was 0.0015 in/in and the lateral strain was 0.00027 in/in. The Poission's ratio is most nearly

(A) 0.00027
(B) 0.0015
(C) 0.10
(D) 0.18



The answer is (D).

(j) For the beam in part (c), if the fracture occurred 1 in away from the left support, the value of the modulus of rupture obtained from this test



(A) is less than the correct value.
(B) equals the correct value.
(C) is higher than the correct value.
(D) becomes indeterminate.

The answer is (D).

5. Stress-strain curves are shown for grade-60 steel rebar and 4000 psi normal-weight concrete.

steel

concrete

(a) What is the yield strength of the steel?

(A) 30 ksi
(B) 36 ksi
(C) 50 ksi
(D) 60 ksi

The answer is (D).

Structural

(b) What is the modulus of elasticity of the steel?

(A) 10×10^6 psi
(B) 29×10^6 psi
(C) 30×10^6 psi
(D) 36×10^6 psi

The answer is (B).

(c) What is the steel strain at the yield point?

(A) 0.002 in/in
(B) 0.003 in/in
(C) 0.06 in/in
(D) 0.09 in/in

The answer is (A).

(d) What is the concrete's compressive strength?

(A) 2000 psi
(B) 4000 psi
(C) 6000 psi
(D) 8000 psi

The answer is (B).

(e) What is the concrete's modulus of elasticity?

(A) 1.1×10^6 psi
(B) 1.7×10^6 psi
(C) 2.9×10^6 psi
(D) 3.6×10^6 psi

The answer is (D).

(f) What is the concrete's ultimate compressive strain?

(A) 0.001 in/in
(B) 0.003 in/in
(C) 0.005 in/in
(D) 0.009 in/in

The answer is (B).

1. DESIGN CONSIDERATIONS

Concrete can be designed for compressive strength or durability in its hardened state. In its wet state, concrete should have good workability. *Workability* relates to the effort required to transport, place, and finish wet concrete without segregation or bleeding. Workability is often closely correlated with slump. All other design requirements being met, the most economical mix should be selected.

Durability is defined as the ability of concrete to resist environmental exposure or service loadings. One of the most destructive environmental factors is the freeze/thaw cycle. ASTM C-666, "Standard Test Method for Resistance of Concrete to Rapid Freezing and Thawing," is the standard laboratory procedure for determining the freeze-thaw durability of hardened concrete. This test determines a *durability factor*, the number of freeze-thaw cycles required to produce a certain amount of deterioration.

ACI 318 Sec. 4.2.2 places minimum limits on the water-cement ratio and strength for concrete with special exposures, including concrete exposed to freeze-thaw cycles, deicing chemicals, and chloride, and installations requiring low permeability.

Specifying an air-entrained concrete will improve the durability of concrete subject to freeze-thaw cycles or deicing chemicals. The amount of entrained air needed will depend on the exposure conditions and the size of coarse aggregate, as prescribed in ACI 318 Sec. 4.2.1.

Table 49.1 *Typical Slumps by Application*

	slump, in (mm)	
application	maximum	minimum
reinforced footings and foundations	3 (76)	1 (25)
plain footings and substructure walls	3 (76)	1 (25)
slabs, beams, and reinforced walls	4 (102)	1 (25)
reinforced columns	4 (102)	1 (25)
pavements and slabs	3 (76)	1 (25)
heavy mass construction	2 (51)	1 (25)
roller-compacted	0	0

(Multiply in by 25.4 to obtain mm.)

2. STRENGTH ACCEPTANCE TESTING

When extensive statistical data are not available, acceptance testing of laboratory-cured specimens can be evaluated per ACI 318 5.6.2.3. This section states that the compressive strength of concrete is considered satisfactory if both of the following criteria are met: (a) No single test (average of two cylinders) is more than 500 psi (3.45 MPa) below the specified compressive strength. (b) The average of any three consecutive test strengths equals or exceeds the specified compressive strength.

3. BATCHING

All concrete ingredients are weighed or volumetrically measured before being mixed, a process known as *batching*. Weighing is more common because it is simple and

Structural

accurate. However, water and liquid admixtures can be added by either volume or weight. The following accuracies are commonly specified or assumed in concrete batching: cement, 1%; water, 1%; aggregates, 2%; and admixtures, 3%. ACI 318 Sec. 4.2.1 specifies the accuracy of air entrainment as $1\frac{1}{2}\%$.

4. WATER-CEMENT RATIO AND CEMENT CONTENT

Concrete strength is inversely proportional to the *water-cement ratio* (referred to in ACI 318 as the *water-cementious ratio*), the ratio of the amount of water to the amount of cement in a mixture, usually stated as a decimal by weight. Typical values are approximately 0.45 to 0.60 by weight. (Alternatively, the water-cement ratio may be stated as the number of gallons of water per 94 lbm sack of cement, in which case typical values are 5 to 7.)

A mix is often described by the number of sacks of cement needed to produce 1 yd^3 of concrete. For example, a mix using 6 sacks of cement per cubic yard would be described as a "6-sack mix." Another method of describing the cement content is the *cement factor*, which is the number of cubic feet of cement per cubic yard of concrete.

Example 49.1

A concrete mixture using 340 lbf of water per cubic yard has a water-cement ratio of 0.60 by weight. (a) Determine the ideal weight and volume of cement needed to produce 1.0 yd^3 of concrete. (b) How many sacks of cement are needed to produce a 4 in thick concrete slab 9 ft × 4 ft with this mix?

Solution

(a) The cement requirement is found from the water-cement ratio.

$$W_{\text{cement}} = \frac{W_{\text{water}}}{0.6} = \frac{340\ \frac{\text{lbf}}{\text{yd}^3}}{0.6} = 567\ \text{lbf/yd}^3$$

From Table 49.2, the specific weight of cement is 195 lbf/ft^3. The volume of the cement is

$$V_{\text{cement}} = \frac{W_{\text{cement}}}{\gamma_{\text{cement}}} = \frac{567\ \frac{\text{lbf}}{\text{yd}^3}}{195\ \frac{\text{lbf}}{\text{ft}^3}} = 2.91\ \text{ft}^3/\text{yd}^3$$

(b) The slab volume is

$$V_{\text{slab}} = \frac{(4\ \text{in})(9\ \text{ft})(4\ \text{ft})}{\left(12\ \frac{\text{in}}{\text{ft}}\right)\left(27\ \frac{\text{ft}^3}{\text{yd}^3}\right)} = 0.444\ \text{yd}^3$$

The cement weight needed is

$$W_{\text{cement}} = (0.444\ \text{yd}^3)\left(567\ \frac{\text{lbf}}{\text{yd}^3}\right) = 252\ \text{lbf}$$

From Table 49.2, each sack weighs 94 lbf. The number of sacks is

$$\frac{252\ \text{lbf}}{94\ \frac{\text{lbf}}{\text{sack}}} = 2.7\ \text{sacks} \quad [3\ \text{sacks}]$$

5. PROPORTIONING MIXES

The oldest method of proportioning concrete is the *arbitrary proportions method* (*arbitrary volume method* or *arbitrary weight method*). Ingredients of average properties are assumed, and various proportions are logically selected. Tabular or historical knowledge of mixes and compressive strengths may be referred to. Proportions of cement, fine aggregate, and coarse aggregate are designated (in that sequence). For example, 1:2:3 means that one part of cement, two parts of fine aggregate, and three parts of coarse aggregate are combined. The proportions are generally in terms of weight; volumetric ratios are rarely used. (In the rare instances where the mix proportions are volumetric, the ratio values must be multiplied by the bulk densities to get the weights of the constituents. Then weight ratios may be calculated and the absolute volume method applied directly.)

For more critical applications, the actual ingredients can be tested in various logical proportions. This is known as the *trial batch method* or the *trial mix method*. This method is more time-consuming initially, since the cured specimens must be obtained for testing.

Although some "extra" concrete ends up being brought to the job site, once determined, mix quantities should be rounded up, not down. Otherwise, the concrete volume may be delivered short.

6. ABSOLUTE VOLUME METHOD

The *yield* is the volume of wet concrete produced in a batch. Typical units are cubic yards (referred to merely as "yards") but may also be cubic feet or cubic meters. The yield that results from mixing known quantities of ingredients can be found from the *absolute volume method*, also known as the *solid volume method* and *consolidated volume method*. This method uses the

specific gravities or densities for all the ingredients to calculate the absolute volume each will occupy in a unit volume of concrete. The absolute volume (solid volume, consolidated volume, etc.) is

$$V_{\text{absolute}} = \frac{m}{(\text{SG})\rho_{\text{water}}} \quad \text{[SI]} \quad \textit{49.1(a)}$$

$$V_{\text{absolute}} = \frac{W}{(\text{SG})\gamma_{\text{water}}} \quad \text{[U.S.]} \quad \textit{49.1(b)}$$

The absolute volume method assumes that, for granular materials such as cement and aggregates, there will be no voids between particles. Therefore, the amount of concrete is the sum of the solid volumes of cement, sand, coarse aggregate, and water.

To use the absolute volume method, it is necessary to know the solid densities of the constituents. In the absence of other information, Table 49.2 can be used.

Table 49.2 *Summary of Approximate Properties of Concrete Components*

cement	
specific weight	195 lbf/ft^3 (3120 kg/m^3)
specific gravity	3.13
weight of one sack	94 lbf (42 kg)
fine aggregate	
specific weight	165 lbf/ft^3 (2640 kg/m^3)
specific gravity	2.64
coarse aggregate	
specific weight	165 lbf/ft^3 (2640 kg/m^3)
specific gravity	2.64
water	
specific weight	62.4 lbf/ft^3 (1000 kg/m^3) 7.48 gal/ft^3 (1000 L/m^3) 239.7 gal/ton (1 L/kg)
specific gravity	1.00

(Multiply lbf/ft^3 by 16 to obtain kg/m^3.)
(Multiply lbf by 0.45 to obtain kg.)

7. ADJUSTMENTS FOR WATER AND AIR

In most problems, the weights and volumes of the components must be adjusted for air entrainment and aggregate water content. This determines the *adjusted weights* of the components.

The *saturated, surface-dry* (SSD) condition occurs when the aggregate holds as much water as it can without trapping any free water between the aggregate particles. Calculations of yield should be based on the SSD densities, and the water content should be adjusted (increased or decreased) to account for any deviation from the SSD condition. Any water in the aggregate above the SSD water content must be subtracted from the water requirements. Any porosity (water affinity) below the SSD water content must be added to the water requirements.

The phrase "5% excess water" (or similar) is ambiguous and can result in confusion when used to specify batch quantities. There are two methods in field use, differing in whether the percentage is calculated on a wet or dry basis. Table 49.3 summarizes the batching relationships for both bases. (Though Table 49.3 is written for sand, it can also be used for coarse aggregate.)

There is also a similar confusion about air entrainment. The volumetric basis can be calculated either with or without entrained air. If "5% air" means that the concrete volume is 5% air, then the solid volume is only 95% of the final volume. The solid volume should be divided by 0.95 to obtain the final volume. However, if "5% air" means that the concrete volume is increased by 5% when the air is added, the solid volume should be multiplied by 1.05 to obtain the final volume.

The bases of these percentages must be known. If they are not, then either definition could apply. Regardless, the final volume is not affected significantly by either interpretation.

Table 49.3 *Dry and Wet Basis Calculations*

	dry basis	wet basis
fraction moisture, f	$\dfrac{W_{\text{excess water}}}{W_{\text{SSD sand}}}$	$\dfrac{W_{\text{excess water}}}{W_{\text{SSD sand}} + W_{\text{excess water}}}$
weight of sand, $W_{\text{wet sand}}$	$W_{\text{SSD sand}} + W_{\text{excess water}}$	$W_{\text{SSD sand}} + W_{\text{excess water}}$
	$(1+f)W_{\text{SSD sand}}$	$\left(\dfrac{1}{1-f}\right) W_{\text{SSD sand}}$
weight of SSD sand, $W_{\text{SSD sand}}$	$\dfrac{W_{\text{wet sand}}}{1+f}$	$(1-f)W_{\text{wet sand}}$
weight of excess water, $W_{\text{excess water}}$	$fW_{\text{SSD sand}}$	$fW_{\text{wet sand}}$
	$\dfrac{fW_{\text{wet sand}}}{1+f}$	$\dfrac{fW_{\text{SSD sand}}}{1-f}$

Structural

Example 49.2

A mix is designed as 1:1.9:2.8 by weight. The water-cement ratio is 7 gal per sack. (a) What is the concrete yield in cubic feet? (b) How much sand, coarse aggregate, and water is needed to make 45 yd^3 of concrete?

Solution

(a) The solution can be tabulated. Refer to Table 49.2.

material	ratio	weight per sack cement (lbf)	solid density (lbf/ft^3)	absolute volume (ft^3/sack)
cement	1.0	$1 \times 94 = 94$	195	$\frac{94}{195} = 0.48$
sand	1.9	$1.9 \times 94 = 179$	165	$\frac{179}{165} = 1.08$
coarse	2.8	$2.8 \times 94 = 263$	165	$\frac{263}{165} = 1.60$
water				$\frac{7}{7.48} = 0.94$
				4.10

The solid yield is 4.10 ft^3 of concrete per sack of cement.

(b) The number of one-sack batches is

$$\frac{(45 \text{ yd}^3)\left(27 \frac{\text{ft}^3}{\text{yd}^3}\right)}{4.10 \frac{\text{ft}^3}{\text{sack}}} = 296.3 \text{ sacks}$$

Order a minimum of 297 sacks of cement. Calculate the remaining order quantities from the cement weight and the mix ratios.

$$\begin{aligned} W_{\text{sand}} &= 1.9 W_{\text{cement}} \\ &= (1.9)\left(94 \frac{\text{lbf}}{\text{sack}}\right)(297 \text{ sacks}) \\ &= 53{,}044 \text{ lbf} \end{aligned}$$

$$\begin{aligned} W_{\text{coarse aggregate}} &= (2.8)\left(94 \frac{\text{lbf}}{\text{sack}}\right)(297 \text{ sacks}) \\ &= 78{,}170 \text{ lbf} \end{aligned}$$

$$V_{\text{water}} = \left(7 \frac{\text{gal}}{\text{sack}}\right)(297 \text{ sacks}) = 2079 \text{ gal}$$

Example 49.3

50 ft^3 of 1:2.5:4 (by weight) concrete are to be produced. The ingredients have the following properties.

ingredient	SSD density (lbf/ft^3)	moisture (dry basis from SSD)
cement	197	–
fine aggregate	164	5% excess (free moisture)
coarse aggregate	168	2% deficit (absorption)

5.5 gal of water are to be used per sack, and the mixture is to have 6% entrained air. What are the ideal order quantities expressed in tons?

Solution

Proceed as in Ex. 49.2.

material	ratio	weight per sack cement (lbf)	solid density (lbf/ft^3)	absolute volume (ft^3/sack)
cement	1.0	$1 \times 94 = 94$	197	$\frac{94}{197} = 0.477$
sand	2.5	$2.5 \times 94 = 235$	164	$\frac{235}{164} = 1.433$
coarse	4.0	$4.0 \times 94 = 376$	168	$\frac{376}{168} = 2.238$
water				$\frac{5.5}{7.48} = 0.735$
				4.883

The solid yield is 4.883 ft^3 of concrete per sack of cement. The yield with 6% air is

$$\frac{4.883 \frac{\text{ft}^3}{\text{sack}}}{1 - 0.06} = 5.19 \text{ ft}^3/\text{sack}$$

The ideal number of one-sack batches required is

$$\frac{50 \text{ ft}^3}{5.19 \frac{\text{ft}^3}{\text{sack}}} = 9.63 \text{ sacks}$$

The required sand weight as ordered (not SSD) is

$$\frac{(9.63 \text{ sacks})(1 + 0.05)\left(94 \frac{\text{lbf}}{\text{sack}}\right)(2.5)}{2000 \frac{\text{lbf}}{\text{ton}}} = 1.19 \text{ tons}$$

The required coarse aggregate weight as ordered (not SSD) is

$$\frac{(9.63 \text{ sacks})(1 - 0.02)\left(94 \frac{\text{lbf}}{\text{sack}}\right)(4.0)}{2000 \frac{\text{lbf}}{\text{ton}}} = 1.77 \text{ tons}$$

The excess water contained in the sand is

$$(1.19 \text{ tons})\left(\frac{0.05}{1 + 0.05}\right)\left(239.7 \frac{\text{gal}}{\text{ton}}\right) = 13.58 \text{ gal}$$

The water needed to bring the coarse aggregate to SSD conditions is

$$(1.77 \text{ tons})\left(\frac{0.02}{1 - 0.02}\right)\left(239.7 \frac{\text{gal}}{\text{ton}}\right) = 8.66 \text{ gal}$$

The total water needed is

$$\left(5.5\ \frac{\text{gal}}{\text{sack}}\right)(9.63\ \text{sacks}) + 8.66\ \text{gal} - 13.58\ \text{gal} = 48.0\ \text{gal}$$

8. MIXING

Mixing coats the surface of all aggregate particles with cement paste and blends all the ingredients into a uniform, homogeneous mass. The mixing method depends on many factors, including the quantity of concrete required for the job, the location of the job, the availability of the ingredients, and transportation costs.

Stationary mixers are mixing units that are to be moved from one job site to another. Large stationary mixers can also be found in ready-mix plants, usually located off the job site. They are available in sizes from 2 ft^3 to 12 yd^3 (0.6 to 9.1 m^3).

Mobile batcher mixers are special trucks that proportion each batch by volume, feeding and continuously mixing aggregates, water, and cement in the mixer.

9. TRANSPORTING AND HANDLING

The homogeneity of the concrete mix must not change during transport and handling at the job site. To achieve the predetermined desired wet and hardened properties, concrete should be transported to the job site without delay. With delays, the concrete may begin to set, making consolidation difficult and increasing the possibility of voids (also known as *honeycombs*) in the finished product. Delays also increase the possibility of *segregation*, which occurs when the coarse aggregate separates from the sand-cement mortar.

10. PLACING

Before placing concrete, forms must be clean and free from any foreign substances such as oil, ice, and snow. All surfaces must be moistened, especially in hot weather and when concrete is to be placed on subgrades. All reinforcing steel bars and other embedded items should be secured in their place and be free from rust, scale, and oil.

Concrete should be placed in a manner that eliminates or minimizes segregation. It should not be dumped in piles and then leveled. Concrete should be placed continuously in horizontal layers.

11. CONSOLIDATION

Freshly placed concrete must be compacted to eliminate entrapped air, rock pockets, and voids. Consolidation can be done manually or mechanically, depending on the workability of concrete, the shape and size of formwork, and the spacing between reinforcing bars. Workable concrete can be consolidated easily by hand-rodding, while stiff mixtures with low water-cement ratios must be consolidated using mechanical methods such as vibration.

Vibration is the most common technique for consolidating concrete. Vibration can be applied internally or externally. Both types of vibration are characterized by the amplitude and frequency of vibration (expressed in vibrations per minute (vpm)). Internal vibration is normally used to consolidate concrete in columns, beams, and slabs. External vibration is accomplished by using vibrating tables, surface vibrators such as vibratory screeds, plate vibrators, or vibratory hand floats or trowels. External vibration is used in cases of thin and heavily reinforced concrete members. Also it is used for stiff mixes where internal vibrators cannot be used.

12. CURING

The strength that concrete achieves depends on the *curing process*. During curing, the temperature and humidity must be controlled. Concrete strength increases with age as long as moisture and favorable temperatures are present for hydration of the cement. Therefore, concrete should be kept saturated or nearly saturated until the chemical reaction between water and cement is completed. Loss of water will reduce the hydration process and cause the concrete to shrink and crack.

There are three primary ways of keeping concrete moist and at a favorable temperature. (a) Water can be copiously applied to make it available to meet the hydration demands. Flat surfaces can be ponded or immersed. Vertical and horizontal surfaces can be sprayed or fogged. Saturated fabric coverings such as cotton mats, burlap, and rugs can be placed over the concrete. (b) The mixing water can be prevented from evaporating by sealing the surface. Impervious paper, plastic sheets, and membrane-forming curing compounds are commonly used. (c) The rate of strength development can be accelerated by providing heat. Live steam, heating coils, and electrically heated forms or pads are used.

13. HOT-WEATHER CONCRETING

Concrete should be mixed, transported, placed, and finished at a temperature that will not affect its properties in the fresh or hardened state. Hot weather will increase evaporation and water demand, decrease the slump, and increase the rate of setting. Counteracting these effects by adding more water to concrete will decrease strength and durability of concrete in the hardened state.

Previous studies have shown that increasing the concrete temperature from 50°F to 100°F (10°C to 38°C) would require an additional 33 lbf of water per cubic yard (20 kg per cubic meter) just to maintain a 3 in (75 mm) slump. This additional water would decrease the compressive strength by 12 to 15%. Such a loss of strength could disqualify the concrete mix.

Rather than increase the water, an effort is made to limit the temperatures at which the concrete is placed. Concrete having a temperature between 50°F and 60°F (10°C and 16°C) is generally considered ideal, but placement in this temperature range is not always possible. However, many specifications require that concrete be placed when its temperature is less than 85 to 90°F (29 to 32°C).

14. COLD-WEATHER CONCRETING

Concrete temperature has a direct effect on the strength and workability of concrete. Therefore, in cold weather, steps should be taken to ensure a safe and desirable temperature for concrete during mixing, placing, finishing, and curing.

ACI 306C defines cold weather as a period when the mean daily temperature is less than 40°F (4°C) for more than three consecutive days. At such temperatures, the rate of cement hydration decreases, delaying the strength development. Not only must concrete be delivered at the proper temperature, but the temperature of the forms, reinforcing steel, and ground must be considered. Concrete should not be placed on frozen concrete or on frozen ground.

The mix temperature at the time of pouring can be raised by heating the ingredients. Water is easily heated, but it is not advisable to exceed a temperature of 140 to 180°F (60 to 82°C), as the concrete may *flash set* (i.e., harden suddenly). Aggregate can also be steam-heated prior to use.

15. FORMING METHODS

Most concrete is shaped by stationary forms (also known as *formwork*, *in-place forms*, and *in-situ forms*). Forms for flat surfaces are usually constructed from plywood. Forms for curved and intricate surfaces may be constructed by any convenient means, including using plywood and polymer forms. After hardening, forms are stripped off by hand.

Where a long or wide exposed surface is being cast, concrete can be poured behind a slowly moving form that remains in contact with the concrete just long enough to set the shape. This method, known as *slip forming*, is often used in the placement of curbs and gutters, highways, open channels, and some pipes. Manual finishing may be employed to obtain the desired surface.

16. LATERAL PRESSURE ON FORMWORK

Formwork must be strong enough to withstand hydraulic loading from the concrete during curing. The hydraulic load is greatest immediately after pouring. As the concrete sets up, it begins to support itself, and the lateral force against the formwork is reduced. Publication ACI 347 predicts the maximum lateral pressure for regular (type I) concrete with a 4 in (100 mm) slump (or less), ordinary work, and internal vibration. The maximum pressure depends on the temperature, T, and the vertical rate of pour, R. (Equations 49.2 and 49.3 are valid only with customary US units.)

$$p_{\text{max,psf}} = 150 + 9000\left(\frac{R_{\text{ft/hr}}}{T_{\text{°F}}}\right) \quad [R \leq 7 \text{ ft/hr}] \quad 49.2$$

$$p_{\text{max,psf}} = 150 + \frac{43{,}400}{T_{\text{°F}}} + 2800\left(\frac{R_{\text{ft/hr}}}{T_{\text{°F}}}\right) \quad [R > 7 \text{ ft/hr}] \quad 49.3$$

PRACTICE PROBLEMS

1. (*Time limit: one hour*) The following information is submitted for a proposed concrete mix.

cement	
specific gravity	3.15
fine aggregate	
fineness modulus	2.65
specific gravity	2.48
absorption	3.0%
coarse aggregate	
specific gravity	2.68
dry bulk density	105 lbf/ft^3
absorption	0.7%
concrete	
slump	5 in
water	5.0 gal/sack
air content	4%
cement content	6.5 sack mix
coarse aggregate	0.57 ft^3/ft^3 bulk

(a) What is the dry weight of the coarse aggregate in 1 yd^3 of concrete?

(A) 1120 lbf/yd^3
(B) 1300 lbf/yd^3
(C) 1500 lbf/yd^3
(D) 1600 lbf/yd^3

The answer is (D).

(b) What is the absolute volume of the coarse aggregate in 1 yd^3 of concrete?

(A) 8.2 ft^3/yd^3
(B) 8.3 ft^3/yd^3
(C) 8.7 ft^3/yd^3
(D) 9.7 ft^3/yd^3

The answer is (D).

(c) What is the water-cement ratio?
(A) 0.42
(B) 0.44
(C) 0.46
(D) 0.48

The answer is (B).

(d) What is the weight of cement in 1 yd^3 of fresh concrete?
(A) 610 lbf/yd^3
(B) 720 lbf/yd^3
(C) 820 lbf/yd^3
(D) 910 lbf/yd^3

The answer is (A).

(e) What is the absolute volume of fine aggregate in 1 yd^3 of fresh concrete?
(A) 7.8 ft^3
(B) 8.8 ft^3
(C) 9.8 ft^3
(D) 11 ft^3

The answer is (B).

(f) What is the SSD weight of the sand in 1 yd^3 of fresh concrete?
(A) 1250 lbf
(B) 1270 lbf
(C) 1300 lbf
(D) 1370 lbf

The answer is (D).

(g) What is the absolute volume of the cement in 1 yd^3 of this fresh concrete?
(A) 3.1 ft^3
(B) 3.2 ft^3
(C) 3.3 ft^3
(D) 3.4 ft^3

The answer is (A).

(h) What is the volume of water designed for use in 1 yd^3 of fresh concrete?
(A) 3.3 ft^3
(B) 3.8 ft^3
(C) 4.3 ft^3
(D) 4.8 ft^3

The answer is (C).

(i) If the oven-dry weight of the coarse aggregate were 1600 lbf, how much water would it need to absorb to reach SSD conditions?
(A) 5.3 lbf
(B) 11 lbf
(C) 32 lbf
(D) 1100 lbf

The answer is (B).

(j) The unit weight of this concrete mix is most nearly
(A) 140 lbf/ft^3
(B) 143 lbf/ft^3
(C) 145 lbf/ft^3
(D) 150 lbf/ft^3

The answer is (B).

2. (*Time limit: one hour*) A trial batch of concrete is needed according to the following requirements and characteristics.

no. of sacks of cement per yd^3 of concrete	7
entrained air	6%
total water-cement ratio	0.54

For economical reasons, two different sizes of coarse aggregate were used. The aggregates have the following characteristics.

	specific gravity	moisture	percentage of aggregate
fine aggregate	2.60	5% excess	36%
$\frac{3}{4}$ in coarse aggregate	2.65	2% excess	18%
1.0 in coarse aggregate	2.62	3% deficit	46%

(a) The weight of cement needed for 2 yd^3 of concrete is most nearly
(A) 660 lbf
(B) 1300 lbf
(C) 1500 lbf
(D) none of the above

The answer is (B).

(b) The volume of cement required for 2 yd^3 is
(A) 3.4 ft^3
(B) 5.4 ft^3
(C) 6.7 ft^3
(D) 7.0 ft^3

The answer is (C).

Structural

(c) The weight of water needed for 2 yd^3 is
(A) 670 lbf
(B) 710 lbf
(C) 870 lbf
(D) 940 lbf

The answer is (A).

(d) The volume of water needed for 2 yd^3 is
(A) 8.4 ft^3
(B) 9.7 ft^3
(C) 11 ft^3
(D) 12 ft^3

The answer is (C).

(e) The absolute volume of fine aggregate in 2 yd^3 is
(A) 11.7 ft^3
(B) 12.5 ft^3
(C) 13.4 ft^3
(D) 14.2 ft^3

The answer is (A).

(f) The SSD weight of fine aggregate in 2 yd^3 is
(A) 1800 lbf
(B) 1850 lbf
(C) 1910 lbf
(D) 1990 lbf

The answer is (C).

(g) The absolute volume of the 3/4 in coarse aggregate in 2 yd^3 is
(A) 5.9 ft^3
(B) 6.2 ft^3
(C) 6.8 ft^3
(D) 7.1 ft^3

The answer is (A).

(h) The absolute volume of the 1 in coarse aggregate in 2 yd^3 is
(A) 15.0 ft^3
(B) 16.8 ft^3
(C) 17.3 ft^3
(D) 18.1 ft^3

The answer is (A).

(i) The SSD weight of the 3/4 in coarse aggregate in 2 yd^3 is
(A) 860 lbf
(B) 970 lbf
(C) 1050 lbf
(D) 1120 lbf

The answer is (B).

(j) The SSD weight of the 1 in coarse aggregate in 2 yd^3 is
(A) 2460 lbf
(B) 2480 lbf
(C) 2510 lbf
(D) 2630 lbf

The answer is (A).

3. 1.5 yd^3 of portland cement concrete with the following specifications are needed.

cement content	6.5 sacks/yd^3
water-cement ratio	5.75 gal/sack
cement specific gravity	3.10
fine-aggregate specific gravity	2.65
coarse-aggregate specific gravity	2.00
aggregate grading	30% fine; 70% coarse (by volume)
free moisture (SSD basis)	1.5% excess in fine aggregate 3.0% deficient in coarse aggregate
entrained air	5%

(a) What is the as-delivered weight of the cement?
(A) 710 lbf
(B) 850 lbf
(C) 920 lbf
(D) 1100 lbf

The answer is (C).

(b) What is the as-delivered weight of the fine aggregate?
(A) 1300 lbf
(B) 1500 lbf
(C) 1600 lbf
(D) 1900 lbf

The answer is (A).

(c) What is the as-delivered weight of the coarse aggregate?
(A) 1850 lbf
(B) 1970 lbf
(C) 2140 lbf
(D) 2220 lbf

The answer is (D).

(d) What is the as-delivered weight of the water?
(A) 440 lbf
(B) 520 lbf
(C) 690 lbf
(D) 820 lbf

The answer is (B).

1. INTRODUCTION

The design of reinforced concrete beams is governed by the provisions of the American Concrete Institute code ACI 318. Many of the code equations are not homogeneous—the units of the result cannot be derived from those of the input. Whenever nonhomogeneous equations appear in this chapter, the units listed in the nomenclature should be used.

2. STEEL REINFORCING

Figure 50.1 illustrates typical reinforcing used in a simply supported reinforced concrete beam. The straight longitudinal bars resist the tension induced by bending, and the *stirrups* resist the diagonal tension resulting from shear stresses. As shown in Fig. 50.1(b), it is also possible to bend up the longitudinal bars to resist diagonal tension near the supports. This alternative, however, is rarely used because the saving in stirrups tends to be offset by the added cost associated with bending the longitudinal bars. In either case, the stirrups are usually passed underneath the bottom steel for anchoring. Much less frequently, they are welded to the bottom steel. Prior to pouring the concrete, the horizontal steel is supported on *bolsters* (*chairs*), of which there are a variety of designs.

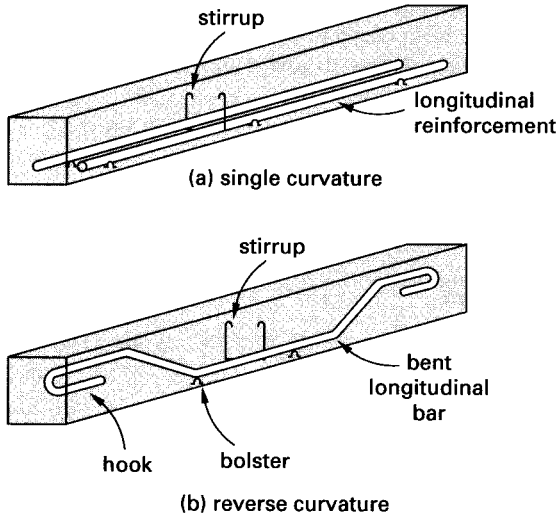

Figure 50.1 *Typical Reinforcement in Beams*

3. TYPES OF BEAM CROSS SECTIONS

The design of reinforced concrete beams is based on the assumption that concrete does not support any tensile loads. A consequence of this assumption is that the effective shape of a cross section is determined by the part of the cross section that is in compression. Consider the design of monolithic slab-and-girder systems. As Fig. 50.2 shows, moments are negative (i.e., there is tension on the top fibers) near the columns. The effective section in the region of negative moments is rectangular (Fig. 50.2(b)). Elsewhere, moments are positive, and the effective section may be either rectangular or T-shaped, depending on the depth of the compressed region (Fig. 50.2(c)).

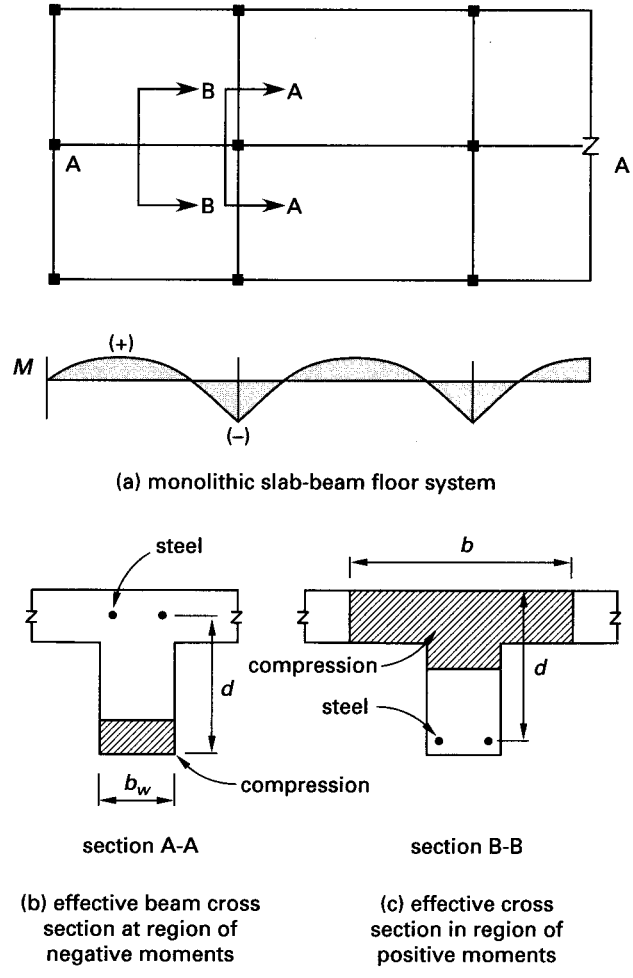

Figure 50.2 *Slab-Beam Floor System*

Reinforced concrete sections can be singly or doubly reinforced. Doubly reinforced sections are used when concrete in the compression zone cannot develop the required moment capacity. Doubly reinforced sections are also used to reduce long-term deformations resulting from creep and shrinkage.

Depending on the ratio of beam clear span to the depth of the cross section, beams may be considered "regular" or deep. For detailing of flexural steel, the *deep beam*

classification applies when the ratio of the clear span to the overall depth is greater than 0.4 for continuous spans or 0.8 for simple spans [ACI 318 10.7.1]. For the purpose of shear design, a beam is considered deep if the clear span over the effective depth is less than 5 (i.e., $l_n/d < 5$) [ACI 318 11.8].

4. ALLOWABLE STRESS VS. STRENGTH DESIGN

Reinforced concrete members can be sized using two alternative design procedures. With the *allowable stress method*, stresses induced in the concrete and the steel are estimated assuming that the behavior is linearly elastic. The member is sized so that the computed stresses do not exceed certain predetermined values. With the *strength design method*, the actual stresses are not the major concern. Rather, a capacity is designed that will support factored (i.e., amplified) loads. Although both methods produce adequate designs, strength design is considered to be more rational. This chapter only covers strength design provisions.

It is important to recognize that even though beam cross sections are sized on the basis of ultimate strength, the effects (i.e., deflection, strain, etc.) from the factored moments are computed using elastic analysis. The benefits of moment redistribution (which are considered in plastic steel design) are not realized.

5. SERVICE LOADS, FACTORED LOADS, AND LOAD COMBINATIONS

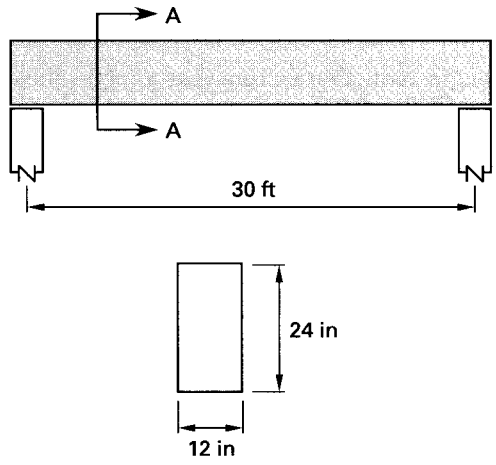
The objective in all designs is to ensure that the safety margin against collapse is adequate. In ACI 318, this margin is achieved by designing beam strength to be equal to or greater than the effect of the service loads amplified by appropriate load factors.

The term *service loads* designates the actual loads (forces or moments). The term *factored loads* designates the service loads increased by various amplifying *load factors*. The load factors depend both on the uncertainty of the various loads as well as on the load combination being considered. Load factors and load combinations are specified in ACI 318 9.2. The factored loads are designated using the subscript u (ultimate). The moment and shear due to factored loads are M_u and V_u, respectively.

When only dead and live loads act, the load combination that is used for design is

$$U = 1.4D + 1.7L \qquad 50.1$$

With wind loading, the load combinations are



$$U = 0.75(1.4D + 1.7L + 1.7W) \qquad 50.2$$

$$U = 0.9D + 1.3W \qquad 50.3$$

If the lateral loads are seismic (earthquake) in origin, Eqs. 50.2 and 50.3 still apply with W replaced by $1.1E$. However, seismic design is highly specialized and requires additional knowledge.

Example 50.1

The simply supported beam shown is subjected to a dead load of 1.2 kips/ft and a live load of 0.8 kips/ft in addition to its own dead weight. What moment should be used to determine the steel reinforcement at the center of the beam?

section A-A

Solution

The weight of the beam is

$$\frac{(12\text{ in})(24\text{ in})\left(150\ \frac{\text{lbf}}{\text{ft}^3}\right)}{\left(12\ \frac{\text{in}}{\text{ft}}\right)^2\left(1000\ \frac{\text{lbf}}{\text{kip}}\right)} = 0.3\text{ kips/ft}$$

The total dead load is

$$\begin{aligned} D &= 1.2\ \frac{\text{kips}}{\text{ft}} + 0.3\ \frac{\text{kips}}{\text{ft}} \\ &= 1.5\text{ kips/ft} \end{aligned}$$

The factored load is

$$\begin{aligned} w_u &= 1.4D + 1.7L \\ &= (1.4)\left(1.5\ \frac{\text{kips}}{\text{ft}}\right) + (1.7)\left(0.8\ \frac{\text{kips}}{\text{ft}}\right) \\ &= 3.46\text{ kips/ft} \end{aligned}$$

The factored moment at the center of the beam is

$$\begin{aligned} M_u &= \frac{w_u L^2}{8} = \frac{\left(3.46\ \frac{\text{kips}}{\text{ft}}\right)(30\text{ ft})^2}{8} \\ &= 389\text{ ft-kips} \end{aligned}$$

Structural

6. DESIGN STRENGTH AND DESIGN CRITERIA

ACI 318 uses the subscript n to indicate a "nominal" quantity. A *nominal value* can be interpreted as being in accordance with theory for the specified dimensions and material properties. The nominal moment and shear capacities are designated M_n and V_n, respectively.

The *design strength* is the product of the *nominal strength* times a *strength reduction factor* (also known as a *capacity reduction factor*), ϕ.

$$\text{design strength} = (\text{nominal strength})\phi \qquad 50.4$$

The strength reduction factors that apply to beams are given in ACI 318 9.3.2.

$$\phi = 0.9 \quad \text{[flexure]} \qquad 50.5(a)$$

$$\phi = 0.85 \quad \text{[for shear]} \qquad 50.5(b)$$

The design criteria for all sections in a beam are

$$\phi M_n \geq M_u \qquad 50.6(a)$$

$$\phi V_n \geq V_u \qquad 50.6(b)$$

7. MINIMUM STEEL AREA

ACI 318 sets limits on the minimum and maximum areas of tension steel. The minimum area of tension steel is

$$A_{s,\min} = \frac{\sqrt{f'_c}\,b_w d}{4f_y} \geq \frac{1.4 b_w d}{f_y} \quad \text{[SI]} \qquad 50.7(a)$$

$$A_{s,\min} = \frac{3\sqrt{f'_c}\,b_w d}{f_y} \geq \frac{200 b_w d}{f_y} \quad \text{[U.S.]} \qquad 50.7(b)$$

When the bending moment produces tension in the flange of a statically determinate T-beam, the value of $A_{s,\min}$ calculated from Eq. 50.7 must be increased. For this condition, ACI 318 10.5.2 requires that the minimum steel be taken as the smaller of what is calculated from either Eq. 50.7 (with b_w set equal to the width of the flange) or Eq. 50.8.

$$A_{s,\min} = \frac{\sqrt{f'_c}\,b_w d}{2f_y} \quad \text{[SI]} \qquad 50.8(a)$$

$$A_{s,\min} = \frac{6\sqrt{f'_c}\,b_w d}{f_y} \quad \text{[U.S.]} \qquad 50.8(b)$$

Minimum steel provisions of Eq. 50.8 do not have to be followed if the area of steel provided exceeds the calculated amount required by at least 33% [ACI 318 10.5.3].

8. MAXIMUM STEEL AREA

In a *ductile failure mode*, the steel yields in tension before the concrete crushes in compression (which would be a *brittle failure mode*). Ductile failure occurs when the steel tensile strength is lower than the concrete compressive strength. The area of tension steel where steel yielding occurs simultaneously with concrete crushing in compression is known as the *balanced steel area*, A_{sb}. An *underreinforced beam* is defined as one having a steel area less than A_{sb}. An *overreinforced beam* has more steel than A_{sb}.

ACI 318 10.3.3 ensures ductile failure by limiting the maximum amount of tension steel to 75% of the balanced reinforcement. For a singly reinforced beam, the maximum steel area is

$$A_{s,\max} = 0.75 A_{sb} \qquad 50.9$$

The balanced steel area is

$$A_{sb} = \frac{0.85 f'_c A_{cb}}{f_y} \qquad 50.10$$

Figure 50.3 illustrates that the compression area for balanced conditions, A_{cb}, extends from the most compressed fiber to a depth equal to a_b.

$$a_b = \beta_1 \left(\frac{600}{600 + f_y}\right) d \quad \text{[SI]} \qquad 50.11(a)$$

$$a_b = \beta_1 \left(\frac{87{,}000}{87{,}000 + f_y}\right) d \quad \text{[U.S.]} \qquad 50.11(b)$$

The factor β_1 is defined as

$$\beta_1 = 0.85 \quad [f'_c \leq 27.6 \text{ MPa}] \quad \text{[SI]} \qquad 50.12(a)$$

$$\beta_1 = 0.85 \quad [f'_c \leq 4000 \text{ lbf/in}^2] \quad \text{[U.S.]} \qquad 50.12(b)$$

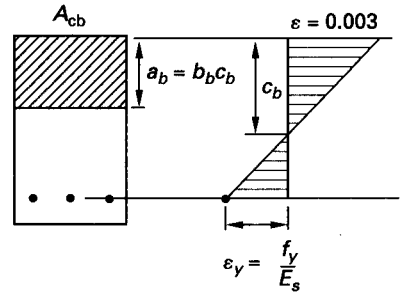
$$\beta_1 = 0.85 - (0.05)\left(\frac{f'_c - 27.6}{6.9}\right) \geq 0.65 \quad \text{[SI]} \qquad 50.12(c)$$

$$\beta_1 = 0.85 - (0.05)\left(\frac{f'_c - 4000}{1000}\right) \geq 0.65 \quad \text{[U.S.]} \qquad 50.12(d)$$

Combining Eqs. 50.10 and 50.11, for rectangular sections, the balanced steel area is

$$A_{sb} = \left(\left(\frac{0.85\beta_1 f'_c}{f_y}\right)\left(\frac{600}{600 + f_y}\right)\right) bd \quad \text{[SI]} \qquad 50.13(a)$$

$$A_{sb} = \left(\left(\frac{0.85\beta_1 f'_c}{f_y}\right)\left(\frac{87{,}000}{87{,}000 + f_y}\right)\right) bd \quad \text{[U.S.]} \qquad 50.13(b)$$



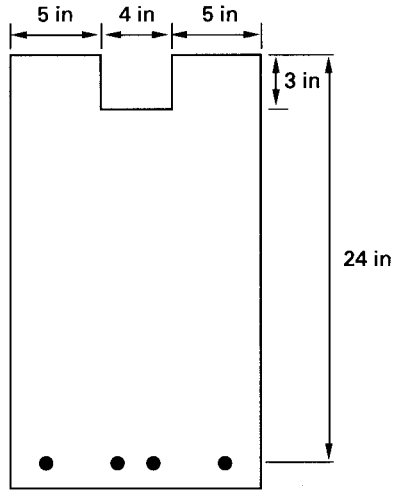


Figure 50.3 *Beam at Balanced Condition*

Example 50.2

For the beam cross section shown, assume the centroid of the tension steel is at a depth of 24 in. $f'_c = 4000$ lbf/in^2, and $f_y = 60,000$ lbf/in^2. Calculate the maximum area of reinforcing steel that can be used.

Solution

The depth of the equivalent rectangular stress block at balance is obtained from Eq. 50.11 with $\beta_1 = 0.85$.

$$\begin{aligned} a_b &= \beta_1 \left(\frac{87{,}000}{87{,}000 + f_y} \right) d \\ &= (0.85) \left(\frac{87{,}000}{87{,}000 + 60{,}000} \right) (24 \text{ in}) \\ &= 12.07 \text{ in} \end{aligned}$$

The area A_{cb} included in the depth a_b is

$$\begin{aligned} A_{cb} &= (10 \text{ in})(3 \text{ in}) + (14 \text{ in})(12.07 \text{ in} - 3 \text{ in}) \\ &= 156.98 \text{ in}^2 \end{aligned}$$

Substitute into Eq. 50.10.

$$\begin{aligned} A_{sb} &= \frac{0.85 f'_c A_{cb}}{f_y} \\ &= \frac{(0.85) \left(4000 \frac{\text{lbf}}{\text{in}^2} \right) (156.98 \text{ in}^2)}{60{,}000 \frac{\text{lbf}}{\text{in}^2}} \\ &= 8.89 \text{ in}^2 \end{aligned}$$

The maximum steel permitted without the use of compression steel is given by Eq. 50.9.

$$\begin{aligned} A_{s,\max} &= 0.75 A_{sb} = (0.75)(8.89 \text{ in}^2) \\ &= 6.67 \text{ in}^2 \end{aligned}$$

9. STEEL COVER AND BEAM WIDTH

The following details must be considered in the design of steel-reinforced concrete beams. The beam widths in Table 50.2 are derived from them.

- All steel, including shear reinforcement, must be adequately covered by concrete. A minimum of 1.5 in of cover is generally required. Table 50.1 provides more specific details.
- The minimum horizontal *clear distance* between bars is the larger of one bar diameter or 1 in [ACI 318 7.6].
- The minimum vertical clear distance between steel layers is 1 in.
- Although it is not an ACI requirement, it is common practice to use a ratio of beam depth to width that satisfies Eq. 50.14.

$$1.5 \leq d/b \leq 2.5 \qquad 50.14$$

Table 50.1 *Minimum Cover on Nonprestressed Steel*

cast against and permanently exposed to earth	3 in

(Multiply in by 25.4 to obtain mm.)
[a]Using no. 3 stirrups. If stirrups are not used, deduct 0.75 in.
[b]The bar diameter for no. 4 bars and larger is less than the minimum bend diameter for $1\frac{1}{2}$ in for no. 3 stirrups. A small allowance has been included in the beam widths to achieve a full bend radius.
[c]For additional horizontal bars, the beam width is increased by adding the value in the last column.

Structural

10. NOMINAL MOMENT CAPACITY OF SINGLY REINFORCED SECTIONS

The moment capacity of a reinforced concrete cross section derives from the couple composed of the tensile force in the steel and the compressive force in the concrete. These forces are equal. The steel force is limited to the product of the steel area times the steel yield stress. Therefore, the nominal moment capacity is

$$M_n = f_y A_s \times \text{lever arm} \qquad 50.15$$

The maximum nominal moment capacity will occur when the steel yields and the lever arm reaches a maximum value. However, since the true distribution of compressive forces at ultimate capacity is nonlinear, it is difficult to determine the lever arm length. To simplify the analysis, ACI 318 permits replacing the true nonlinear distribution of stresses with a simple uniform distribution where the stress equals $0.85f'_c$ [ACI 318 10.2.7]. This is known as the *Whitney assumption*. As shown in Fig. 50.4(c), β_1 is the ratio of the depth of the equivalent rectangular stress block to the true depth of the neutral axis.

The nominal moment capacity can be computed for any singly reinforced section with the following procedure.

step 1: Compute the tension force.

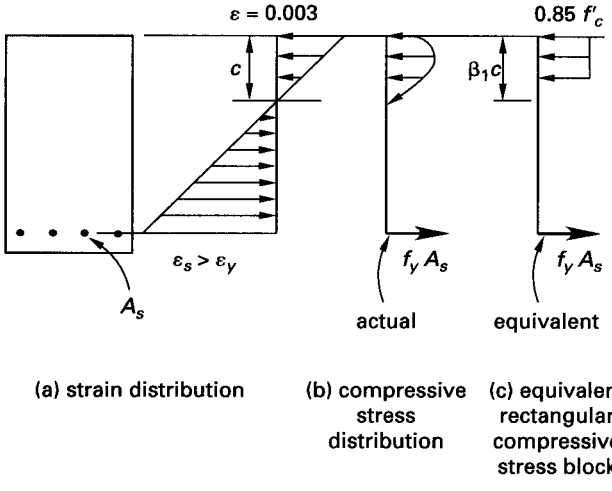
$$T = f_y A_s \qquad 50.16$$

step 2: Calculate the area of concrete that, at a stress of $0.85f'_c$, gives a force equal to T.

$$A_c = \frac{T}{0.85f'_c} = \frac{f_y A_s}{0.85f'_c} \qquad 50.17$$

step 3: Locate the centroid of the area A_c. Designating the distance from the centroid of the compression region to the most compressed fiber designated as λ,

$$M_n = A_s f_y (d - \lambda) \qquad 50.18$$



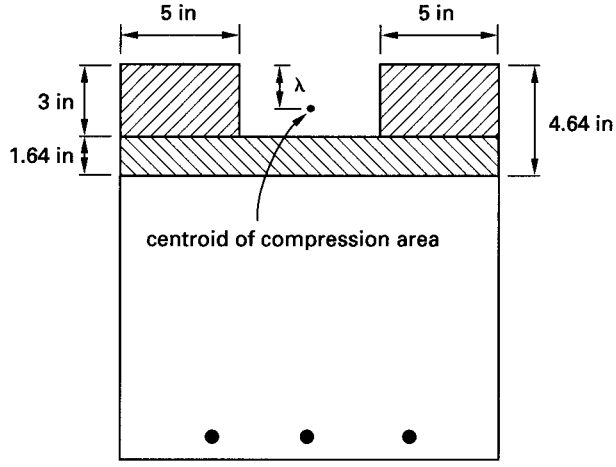


Figure 50.4 *Conditions at Maximum Moment*

Example 50.3

The cross section of the beam shown is reinforced with 3.0 in^2 of steel. (The cross section and material properties of this example are the same as those used in Ex. 50.2.) $f'_c = 4000$ lbf/in^2, and $f_y = 60{,}000$ lbf/in^2. Calculate the design moment capacity ϕM_n.

Solution

In Ex. 50.2, the balanced steel area was found to be 8.89 in^2. 3.0 in^2 is less than the balanced area (and less than maximum area), so the steel yields at ultimate loading. The area of concrete required to balance the steel force at yield is given by Eq. 50.17.

$$\begin{aligned} A_c &= \frac{f_y A_s}{0.85f'_c} \\ &= \frac{\left(60{,}000\ \frac{\text{lbf}}{\text{in}^2}\right)(3\ \text{in}^2)}{(0.85)\left(4000\ \frac{\text{lbf}}{\text{in}^2}\right)} \\ &= 52.94\ \text{in}^2 \end{aligned}$$

Sum moments of the areas about the top of the section.

$$\begin{aligned} &(10\ \text{in})(3\ \text{in})(1.5\ \text{in}) \\ &\quad + (1.64\ \text{in})(14\ \text{in})\left(3\ \text{in} + \frac{1.64\ \text{in}}{2}\right) \\ &\quad = (52.94\ \text{in}^2)\lambda \\ &\lambda = 2.51\ \text{in} \end{aligned}$$

The nominal moment capacity is obtained from Eq. 50.18.

$$\begin{aligned} M_n &= A_s f_y (d - \lambda) \\ &= \frac{(3\ \text{in}^2)\left(60{,}000\ \frac{\text{lbf}}{\text{in}^2}\right)(24\ \text{in} - 2.51\ \text{in})}{\left(12\ \frac{\text{in}}{\text{ft}}\right)\left(1000\ \frac{\text{lbf}}{\text{kip}}\right)} \\ &= 322.4\ \text{ft-kips} \end{aligned}$$

The design moment capacity is

$$\begin{aligned}\phi M_n &= (0.9)(322.4 \text{ ft-kips}) \\ &= 290 \text{ ft-kips}\end{aligned}$$

11. BEAM DESIGN: SIZE KNOWN, REINFORCEMENT UNKNOWN

If the ultimate moment, M_u, due to the factored loads is known or can be computed, beam design reduces to determining the amount of reinforcing steel required. Although formulas for determining rectangular cross sections can be derived, an iterative approach is sufficiently simple.

Equation 50.19 is derived by changing the $\geq$ sign in Eq. 50.6(a) to an equality and substituting Eq. 50.18 for M_n.

$$A_s = \frac{M_u}{\phi f_y (d - \lambda)} \qquad 50.19$$

Equation 50.19 is easily solved if a value for λ is first assumed. (A value of $0.1d$ is typically a good estimate.) The design procedure consists of estimating λ, solving for A_s from Eq. 50.19, and checking the moment capacity for the selected steel using the actual associated λ. If the values of the capacity, ϕM_n, and the demand, M_u, are not sufficiently close, the area of steel is adjusted (i.e., extrapolated) by multiplying it by (M_u/M_n). Even though the relationship between steel area and moment is linear only over small variations, this procedure seldom requires additional iterations because the adjusted steel area will be very close to the exact solution.

It should be noted that, in actual practice, it is customary to provide the required steel area using at most two different bar sizes. For this reason, and because only a limited number of bar sizes is available, some excess steel is typically unavoidable.

Example 50.4

The beam cross section in Ex. 50.2 is used in a simply supported beam having a span of 25 ft. The beam is subjected to a service dead load (which includes its own weight) of 1.2 kips/ft and a live load of 2 kips/ft. $f'_c = 5000$ lbf/in^2, and $f_y = 60{,}000$ lbf/in^2. Determine the required steel area for the maximum moment.

Solution

The factored load is

$$\begin{aligned}w_u &= 1.4D + 1.7L \\ &= (1.4)\left(1.2 \frac{\text{kips}}{\text{ft}}\right) + (1.7)\left(2 \frac{\text{kips}}{\text{ft}}\right) \\ &= 5.08 \text{ kips/ft}\end{aligned}$$

The maximum moment is

$$\begin{aligned}M_u &= \frac{wL^2}{8} = \frac{\left(5.08 \frac{\text{kips}}{\text{ft}}\right)(25 \text{ ft})^2}{8} \\ &= 396.88 \text{ ft-kips}\end{aligned}$$

Estimate λ.

$$\begin{aligned}\lambda &= 0.1d = (0.1)(24 \text{ in}) \\ &= 2.4 \text{ in}\end{aligned}$$

From Eq. 50.19,

$$\begin{aligned}A_s &= \frac{M_u}{\phi f_y (d - \lambda)} \\ &= \frac{(396.88 \text{ ft-kips})\left(12 \frac{\text{in}}{\text{ft}}\right)}{(0.9)\left(60 \frac{\text{kips}}{\text{in}^2}\right)(24 \text{ in} - 2.4 \text{ in})} \\ &= 4.08 \text{ in}^2\end{aligned}$$

Compute M_n for this steel area. From Eq. 50.17,

$$\begin{aligned}A_c &= \frac{f_y A_s}{0.85 f'_c} \\ &= \frac{(4.08 \text{ in}^2)\left(60 \frac{\text{kips}}{\text{in}^2}\right)}{(0.85)\left(5 \frac{\text{kips}}{\text{in}^2}\right)} \\ &= 57.60 \text{ in}^2\end{aligned}$$

Locate the centroid of the compressed zone.

$$\begin{aligned}&(10 \text{ in})(3 \text{ in})(1.5 \text{ in}) \\ &\quad + (1.97 \text{ in})(14 \text{ in})\left(3 \text{ in} + \frac{1.97 \text{ in}}{2}\right) \\ &\quad = (57.60 \text{ in}^2)\lambda \\ &\lambda = 2.69 \text{ in}\end{aligned}$$

The nominal moment capacity obtained from Eq. 50.18 is

$$\begin{aligned}M_n &= A_s f_y (d - \lambda) \\ &= \frac{(4.08 \text{ in}^2)\left(60 \frac{\text{kips}}{\text{in}^2}\right)(24 \text{ in} - 2.69 \text{ in})}{12 \frac{\text{in}}{\text{ft}}} \\ &= 434.71 \text{ ft-kips}\end{aligned}$$

The design moment capacity is

$$\begin{aligned}\phi M_n &= (0.9)(434.71 \text{ ft-kips}) \\ &= 391.24 \text{ ft-kips}\end{aligned}$$

Since the design moment capacity (391.24 ft-kips) is slightly less than the factored moment (396.88 ft-kips), the "exact" steel area required is nominally larger than the estimated value of 4.08 in^2. The steel area is extrapolated as

$$A_{s,\text{new}} = A_s\left(\frac{M_u}{M_n}\right)$$
$$= \left(\frac{396.88 \text{ ft-kips}}{391.24 \text{ ft-kips}}\right)(4.08 \text{ in}^2)$$
$$= 4.14 \text{ in}^2$$

The value of ϕM_n for this adjusted steel area is 396.4 ft-kips, essentially the same as M_u.

12. BEAM DESIGN: SIZE AND REINFORCEMENT UNKNOWN

If beam size (i.e., cross section) and area of reinforcement are both unknown, there will not be a unique solution. In principle, the procedure involves first choosing a beam cross section and then sizing the steel in the usual manner. The beam is sized by (a) selecting a depth to ensure that deflections are not a problem (see Sec. 17) and (b) selecting a width so that the ratio of depth to width is reasonable. Then, the steel is checked to see that it does not exceed the limit of $0.75A_{sb}$ prescribed in ACI 318 and that it is larger than or equal to the minimum value.

Portions of the design procedure can be streamlined for rectangular cross sections by deriving an explicit formula relating the nominal moment capacity to the relevant design parameters. For a rectangular cross section,

$$\lambda = \frac{A_c}{2b} \qquad 50.20$$

Combining Eqs. 50.17, 50.19, and 50.20,

$$M_n = A_s f_y d\left(1 - \frac{A_s f_y}{1.7 f'_c bd}\right) \qquad 50.21$$

Since the steel ratios corresponding to minimum and maximum steel are easily calculated for rectangular sections (in particular, from Eq. 50.15), a convenient form of Eq. 50.21 is obtained by expressing the steel area in terms of the *steel ratio* (*reinforcement ratio*), ρ, which is defined as

$$\rho = \frac{A_s}{bd} \qquad 50.22$$

Combining Eqs. 50.21 and 50.22,

$$M_n = \rho bd^2 f_y\left(1 - \frac{\rho f_y}{1.7 f'_c}\right) \qquad 50.23$$

The balanced steel ratio is

$$\rho_{sb} = \left(\frac{0.85\beta_1 f'_c}{f_y}\right)\left(\frac{600}{600 + f_y}\right) \quad \text{[SI]} \qquad 50.24(a)$$

$$\rho_{sb} = \left(\frac{0.85\beta_1 f'_c}{f_y}\right)\left(\frac{87{,}000}{87{,}000 + f_y}\right) \quad \text{[U.S.]} \qquad 50.24(b)$$

The minimum steel is derived from Eq. 50.19.

$$\rho_{\min} = \frac{\sqrt{f'_c}}{f_y} \geq \frac{1.4}{f_y} \quad \text{[SI]} \qquad 50.25(a)$$

$$\rho_{\min} = \frac{3\sqrt{f'_c}}{f_y} \geq \frac{200}{f_y} \quad \text{[U.S.]} \qquad 50.25(b)$$

The following steps constitute a procedure for designing a beam with a rectangular cross section.

step 1: Select a value of ρ between the minimum and maximum values. (Larger values will lead to smaller concrete cross sections.) It is widely held that values $\rho f_y / f'_c$ near 0.18 lead to economical beams.

Table 50.3 *Total Areas for Various Numbers of Bars*

bar size	nominal diameter (in)	weight (lbf/ft)	number of bars 1	2	3	4	5	6	7	8	9	10
no. 3	0.375	0.376	0.11	0.22	0.33	0.44	0.55	0.66	0.77	0.88	0.99	1.10

no. 18[a]	2.257	13.60	4.00	8.00	12.0	16.0	20.00	24.0	28.00	32.00	36.00	40.00

(Multiply in^2 by 645 to obtain mm^2.)
[a]No. 14 and no. 18 are typically used in columns only.

step 2: Calculate the required value of bd^2 from Eq. 50.23.

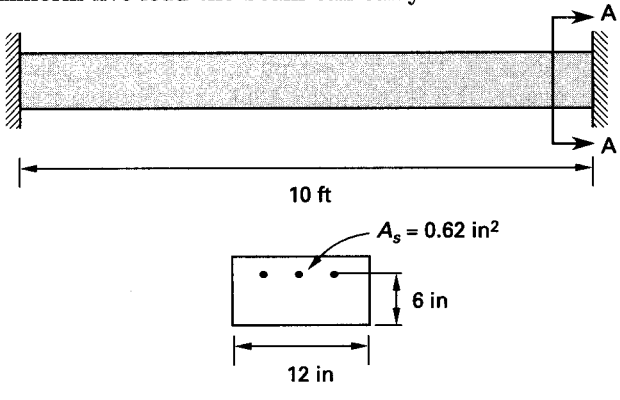
step 3: Choose appropriate values of b and d. A good choice is to keep d/b between 1.50 and 2.5. For beams with a single layer of tension steel, the value of d is approximately equal to $h - 2.5$ in. Furthermore, explicit computation of deflections can be obviated if a depth is chosen that is larger than a certain fraction of the span. (See Table 50.4.) The dimensions b and h are usually rounded to the nearest whole inch.

step 4: If the actual bd^2 quantity is notably different from the bd^2 calculated in step 2, use Eq. 50.23 to recalculate the associated ρ value.

step 5: Calculate the required steel area as

$$A_s = \rho bd \qquad 50.26$$

step 6: Select reinforcing steel bars to satisfy the distribution and placement requirements of ACI 318. (Refer to Tables 50.2 and 50.3.)



step 7: Design the shear reinforcement. (See Sec. 20.)

step 8: Check cracking requirements. (See Sec. 13.)

step 9: Check deflection. (See Sec. 15.)

Example 50.5

The span of a beam with the cross section shown is 10 ft, and the ends are built in. $f'_c = 3500$ lbf/in^2, and $f_y = 40{,}000$ lbf/in^2. The maximum load is controlled by the capacity in the negative moment region. Based solely on flexural requirements, what is the maximum uniform live load the beam can carry?

Solution

The beam is rectangular, so Eq. 50.22 can be used to calculate M_n.

$$\rho = \frac{A_s}{bd} = \frac{0.62 \text{ in}^2}{(12 \text{ in})(6 \text{ in})} = 0.00861$$

From Eq. 50.23,

$$\begin{aligned} M_n &= \rho bd^2 f_y \left(1 - \frac{\rho f_y}{1.7 f'_c}\right) \\ &= (0.00861)(12 \text{ in})(6 \text{ in})^2 \left(40 \frac{\text{kips}}{\text{in}^2}\right) \\ &\quad \times \left(1 - \frac{(0.00861)\left(40 \frac{\text{kips}}{\text{in}^2}\right)}{(1.7)\left(3.5 \frac{\text{kips}}{\text{in}^2}\right)}\right) \\ &= 140.2 \text{ in-kips} \end{aligned}$$

For a beam fixed at both ends, the maximum negative moment occurs at the ends and is

$$M_u = \phi M_n = \frac{w_u L^2}{12}$$

Solve for the factored uniform load.

$$\begin{aligned} w_u &= \frac{12 \phi M_n}{L^2} \\ &= \frac{(12)(0.9)(140.2 \text{ in-kips})}{(10 \text{ ft})^2 \left(12 \frac{\text{in}}{\text{ft}}\right)} \\ &= 1.26 \text{ kips/ft} \end{aligned}$$

Using a unit weight of 150 lbf/ft^3 for the concrete, the weight of the beam is

$$\begin{aligned} w_d &= \frac{\left(150 \frac{\text{lbf}}{\text{ft}^3}\right)(12 \text{ in})(6 \text{ in})}{\left(1000 \frac{\text{lbf}}{\text{kip}}\right)\left(12 \frac{\text{in}}{\text{ft}}\right)^2} \\ &= 0.075 \text{ kips/ft} \qquad \left[\begin{array}{c}\text{use 0.10 kips/ft} \\ \text{to account for steel}\end{array}\right] \end{aligned}$$

Assuming no additional dead load acts on the beam,

$$\begin{aligned} w_u &= 1.26 \frac{\text{kips}}{\text{ft}} = 1.4D + 1.7L \\ &= (1.4)\left(0.10 \frac{\text{kip}}{\text{ft}}\right) + 1.7 w_l \\ &= 1.26 \text{ kips/ft} \end{aligned}$$

Solve for the maximum live load.

$$w_l = 0.66 \text{ kips/ft}$$

Example 50.6

Design a rectangular beam with only tension reinforcement to carry service moments of 34.3 ft-kips (dead) and 30 ft-kips (live). $f'_c = 3500$ lbf/in^2, and $f_y = 40{,}000$ lbf/in^2. No. 3 bars are used for shear reinforcing. (Do not design stirrup placement.)

Structural

Solution

The factored moment is

$$\begin{aligned} M_u &= 1.4M_d + 1.7M_l \\ &= (1.4)(34.3 \text{ ft-kips}) + (1.7)(30 \text{ ft-kips}) \\ &= 99.02 \text{ ft-kips} \end{aligned}$$

$$\begin{aligned} M_n &= \frac{M_u}{\phi} \\ &= \frac{99.02 \text{ ft-kips}}{0.9} = 110.02 \text{ ft-kips} \end{aligned}$$

Select a reinforcement ratio $\rho = 0.18f'_c/f_y$ to achieve a reasonably economical design.

$$\begin{aligned} \rho &= \frac{(0.18)\left(3500 \frac{\text{lbf}}{\text{in}^2}\right)}{40{,}000 \frac{\text{lbf}}{\text{in}^2}} \\ &= 0.0158 \end{aligned}$$

Substitute ρ and M_n into Eq. 50.23 and solve for bd^2.

$$\begin{aligned} bd^2 &= \frac{M_n}{\rho f_y\left(1 - \frac{\rho f_y}{1.7f'_c}\right)} \\ &= \frac{(110.02 \text{ ft-kips})\left(12 \frac{\text{in}}{\text{ft}}\right)\left(1000 \frac{\text{lbf}}{\text{kip}}\right)}{(0.0158)\left(40{,}000 \frac{\text{lbf}}{\text{in}^2}\right)} \\ &\quad \times \left(1 - \frac{(0.0158)\left(40{,}000 \frac{\text{lbf}}{\text{in}^2}\right)}{(1.7)\left(3500 \frac{\text{lbf}}{\text{in}^2}\right)}\right) \\ &= 2337 \text{ in}^3 \end{aligned}$$

Choose $d/b = 1.8$.

$$\begin{aligned} d^3 &= (1.8)(2337 \text{ in}^3) = 4207 \text{ in}^3 \\ d &= 16.14 \text{ in} \\ b &= \frac{16.14 \text{ in}}{1.8} = 8.97 \text{ in} \end{aligned}$$

The total depth includes the effective depth (16.14 in), the diameter of the stirrup ($^3/_8$ in), the cover (1.5 in), and half the diameter of the longitudinal bars. Assuming no. 8 bars, the theoretical depth is

$$\begin{aligned} h &= 16.14 \text{ in} + 0.375 \text{ in} + 1.5 \text{ in} + 0.5 \text{ in} \\ &= 18.515 \text{ in} \end{aligned}$$

The overall dimensions are typically rounded to the nearest inch. Select $b = 9$ in and $h = 19$ in. The actual d is $h - 2.375$ in $= 16.625$ in.

It is appropriate to solve for the reinforcement ratio, ρ, corresponding to the final dimensions. This can be easily done with Eq. 50.23 and the actual value of bd^2.

$$bd^2 = (9 \text{ in})(16.625 \text{ in})^2 = 2487.5 \text{ in}^3$$

The resulting value, $\rho = 0.0147$, is smaller than the initial value of 0.0158 because the dimensions were rounded up. The required steel area is

$$\begin{aligned} A_s &= \rho bd = (0.0147)(9 \text{ in})(16.625 \text{ in}) \\ &= 2.13 \text{ in}^2 \end{aligned}$$

Select three no. 8 bars, which gives a total area of 2.37 in^2.

13. SERVICEABILITY: CRACKING

Flexural design procedures for singly reinforced concrete beams are based on strength. *Serviceability* considerations involve checking that deflections and crack widths are not excessive at service loads.

The low tensile strength of concrete makes cracking of concrete beams inevitable. It is possible, however, to keep the width of the cracks sufficiently small so that the tension steel remains protected by the cover concrete. The size of "acceptable" cracks depends on the exposure conditions. In any case, acceptable crack widths range from 0.006 to 0.016 in (0.15 to 0.41 mm), clearly having no effect on the appearance of the member. While cracking reduces the stiffness of the beam, it has no effect on the ultimate strength.

The basic goal in the control of cracking is to ensure that the elongation of the tension side of the beam is distributed between a large number of closely spaced small cracks instead of being taken up in a few widely spaced large cracks. If it is concluded that unacceptable cracking will occur, then smaller reinforcement bars must be used to redistribute the steel around a greater area.

Since the elongation of the tension steel is proportional to the stress acting on it, the potential importance of cracking is larger in high-strength steels. Experience has shown that cracking is not a problem for beams reinforced with steel bars having a yield stress equal to or less than 40,000 lbf/in^2 (276 MPa).

ACI 318 provides a simplified approach for evaluating cracking in beams with reinforcement having $f_y >$ 40,000 lbf/in^2 (276 MPa). The method does not deal directly with crack widths, but instead, controls a parameter, z, that is proportional to crack width. ACI 318 specifies that z is not to exceed 145 kips/in (25 MN/m) for exterior exposures or 175 kips/in (30 MN/m) for interior exposures. The parameter z is defined in ACI 318 10.6.4 as

$$z = f_s\sqrt[3]{d_c A} \qquad 50.27$$

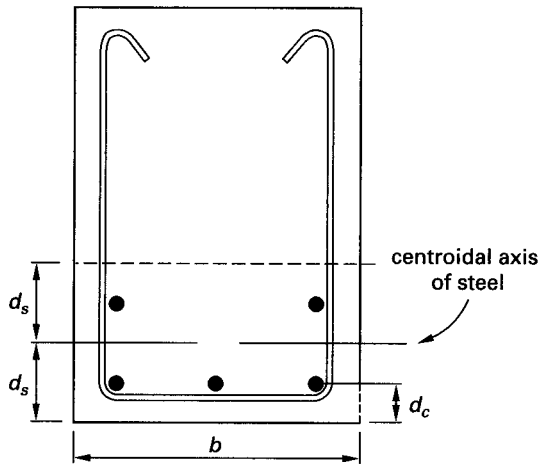


Figure 50.5 *Parameters for Cracking Calculation*

The parameters A and d_c are illustrated in Fig. 50.5. A is the effective tension area per bar, d_c is the distance from the tension surface to the center of the row of reinforcing bars closest to the outside surface, and f_s is the stress in the steel due to service loads. The effective tension area per bar, A, is equal to the area of concrete whose centroid coincides with that of the tension steel divided by the number of bars. If bars of different sizes are present, ACI 318 requires that they all be converted to an equivalent number of the largest size.

$$A = \frac{2d_s b}{\text{no. of bars}} \qquad 50.28$$

d_c is the *concrete cover*: the distance from the center of the bottom steel layer to the bottom of the beam. (ACI 318 Sec. 10 defines the variable d_c as the "thickness of concrete cover measured from extreme tension fiber to center of bar or wire located closest thereto." ACI 318 7.7 specifies the thickness of a concrete layer necessary to provide protection to the steel, but does not give the thickness a symbol. The term "concrete cover" is also used. Although the term "concrete cover" is ambiguous, the symbol d_c used in Eq. 50.29 is not.) For a beam with 1½ in of cover over a stirrup, the cover depth would be

$$d_c = 1.5 \text{ in} + d_{\text{stirrup}} + \frac{d_b}{2} \qquad 50.29$$

Since d_c is controlled by minimum cover requirements and f_s is a function of the applied loads, control of z depends on the area A. Specifically, the larger the number of bars used to provide a certain steel area, the smaller A is.

ACI 318 permits the stress in the tension steel at service conditions to be taken as

$$f_s = 0.6 f_y \qquad 50.30$$

When Eq. 50.30 is used and the limit on z is exceeded, a more accurate computation of f_s may still validate the design. A more accurate value of f_s can be obtained from Eq. 50.31.

$$f_s = \frac{nM_s(d - c_s)}{I_{\text{cr}}} \qquad 50.31$$

I_{cr} is the cracked moment of inertia (Sec. 14), and c_s is the depth of the neutral axis associated with I_{cr}.

14. CRACKED MOMENT OF INERTIA

The *cracked moment of inertia*, also referred to as the *cracked transformed inertia*, is the moment of inertia computed for the section under the assumption that the concrete carries no tension and behaves linearly in compression. Referring to Fig. 50.6, the procedure for computing I_{cr} is as follows.

step 1: Calculate the *modular ratio*, n, the ratio of the moduli of elasticity of the steel and the concrete. The modulus of elasticity for steel is almost always 29,000 kips/in^2 (200 GPa).

$$n = \frac{E_s}{E_c} \qquad 50.32$$

$$E_c = 4700\sqrt{f'_c} \quad \text{[SI]} \qquad 50.33(a)$$

$$E_c = 57{,}000\sqrt{f'_c} \quad \text{[U.S.]} \qquad 50.33(b)$$

step 2: Multiply the tension steel areas by n and the compression steel areas by $n - 1$. This converts the steel areas to equivalent concrete areas. (The "-1" term for the compression steel accounts for the fact that the steel is replacing a concrete area.)

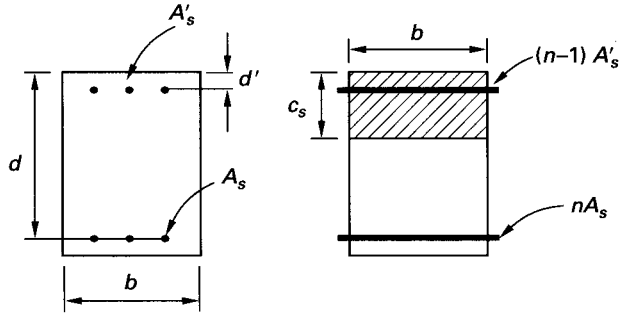
step 3: Determine the distance, c_s, to the neutral axis. All concrete below the neutral axis is assumed to be ineffective.

step 4: Calculate I_{cr} using the parallel axis theorem. The moments of inertia of the steel areas with respect to their local centroid are assumed to be negligible.

There are many cases where the cross section is rectangular and singly reinforced. Closed-form expressions can be derived to simplify the computation of c_s and I_{cr}. Referring to Fig. 50.6,

$$\frac{bc_s^2}{2} = nA_s(d - c_s) \qquad 50.34$$

This is a quadratic equation with the solution



$$c_s = \left(\frac{nA_s}{b}\right)\left(\sqrt{1 + \frac{2bd}{nA_s}} - 1\right) \qquad 50.35$$

Equation 50.35 can also be written in terms of the steel ratio.

$$c_s = n\rho d\sqrt{1 + \frac{2}{n\rho}} - 1 \qquad 50.36$$

The cracked moment of inertia for a rectangular, singly reinforced beam is

$$I_{cr} = \frac{bc_s^3}{3} + nA_s(d - c_s)^2 \qquad 50.37$$

(a) reinforced section (b) transformed section

Figure 50.6 *Parameters for Cracked Moment of Inertia*

15. SERVICEABILITY: DEFLECTIONS

Reinforced concrete beam deflections have two components: (a) an immediate deflection that occurs as a result of the strains induced by the applied loads, and (b) a long-term deflection that develops due to creep and shrinkage of the concrete. Immediate (instantaneous) deflections, Δ_i, are computed using any available general method based on elastic linear response. However, the effect of cracking on the flexural stiffness of the beam must be considered.

Cracking takes place whenever the bending moment at a cross section exceeds the *cracking moment*, M_{cr}. Since moments from the applied loads vary along the beam length, certain portions of the beam will be cracked while others will be uncracked. This makes a rigorous analysis that takes into account the actual variation of the flexural stiffness along the beam length essentially impractical. Therefore, ACI 318 provides a simplified method for obtaining an effective moment of inertia that is assumed to be constant along the entire beam length. The *effective moment of inertia*, I_e, is given by ACI 318 9.5.2.3 as

$$I_e = \left(\frac{M_{cr}}{M_a}\right)^3 I_g + \left(1 - \left(\frac{M_{cr}}{M_a}\right)^3\right) I_{cr} \le I_g \qquad 50.38$$

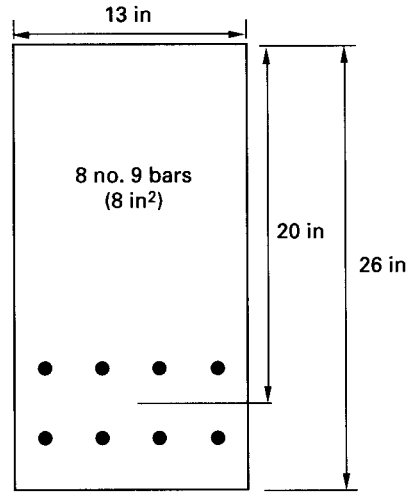
The *cracking moment* is

$$M_{cr} = \frac{f_r I_g}{y_t} \qquad 50.39$$

In Eq. 50.39, I_g is the *gross moment of inertia*, $I_g = bh^3/12$, f_r is the *modulus of rupture* (i.e., the stress at which the concrete is assumed to crack), and y_t is the distance from the neutral axis of the cross section to the extreme tension fiber. For a rectangular cross section, $y_t = h/2$. For stone or gravel concrete (normal-weight concrete), the modulus of rupture is

$$f_r = 0.7\sqrt{f'_c} \quad \text{[SI]} \qquad 50.40(a)$$

$$f_r = 7.5\sqrt{f'_c} \quad \text{[U.S.]} \qquad 50.40(b)$$



For all-lightweight concrete, f_r as calculated from Eq. 50.40 is reduced 25% (i.e., is multiplied by a factor of 0.75). If the fine aggregate is sand but the coarse aggregate is lightweight, f_r is reduced by 15% (i.e., is multiplied by a factor of 0.85).

Since cracking is not reversible, M_a should be taken as the largest bending moment due to service loads. In particular, if an immediate deflection due to the live load is desired, the deflection should be based on the live load, but I_e should be computed from Eq. 50.38 using the value of M_a corresponding to dead plus live load.

When a beam is continuous, the reinforcement will vary along the beam length. Then, the cracked inertia, I_{cr}, will also vary along the length. ACI 318 permits using the value of I_e that corresponds to the positive moment region (with M_s taken also as the maximum positive service moment), or I_e can be taken as the average of the values for the regions of maximum negative and maximum positive moment [ACI 318 9.5.2.4].

Example 50.7

The service moment on the beam shown is 100 ft-kips. The concrete compressive strength is 4000 lbf/in^2, and the modular ratio is 8. Determine the (a) gross, (b) cracked, and (c) effective moments of inertia.

Solution

(a) The gross moment of inertia is

$$I_g = \frac{bh^3}{12} = \frac{(13\text{ in})(26\text{ in})^3}{12}$$
$$= 19{,}041\text{ in}^4$$

(b) Since the section is rectangular, Eqs. 50.36 and 50.37 can be used.

$$\rho = \frac{A_s}{bd} = \frac{8\ \text{in}^2}{(13\ \text{in})(20\ \text{in})}$$
$$= 0.0308$$

$$c_s = n\rho d\sqrt{1 + \frac{2}{n\rho}} - 1$$
$$= (8)(0.0308)(20\ \text{in})\left(\sqrt{1 + \frac{2}{(8)(0.0308)}} - 1\right)$$
$$= 9.95\ \text{in}$$

$$I_{cr} = \frac{bc_s^3}{3} + nA_s(d - c_s)^2$$
$$= \frac{(13\ \text{in})(9.95\ \text{in})^3}{3} + (8)(8\ \text{in}^2)(20\ \text{in} - 9.95\ \text{in})^2$$
$$= 10{,}733\ \text{in}^4$$

The modulus of rupture is given by Eq. 50.40.

$$f_r = 7.5\sqrt{f'_c} = 7.5\sqrt{4000\ \frac{\text{lbf}}{\text{in}^2}}$$
$$= 474\ \text{lbf/in}^2$$

The cracking moment is given by Eq. 50.39.

$$M_{cr} = \frac{f_r I_g}{y_t}$$
$$= \frac{\left(0.474\ \frac{\text{kips}}{\text{in}^2}\right)(19{,}041\ \text{in}^4)}{(13\ \text{in})\left(12\ \frac{\text{in}}{\text{ft}}\right)}$$
$$= 57.86\ \text{ft-kips}$$

$$\left(\frac{M_{cr}}{M_a}\right)^3 = \left(\frac{57.86\ \text{ft-kips}}{100\ \text{ft-kips}}\right)^3 = 0.194$$

The effective moment of inertia is given by Eq. 50.38.

$$I_e = \left(\frac{M_{cr}}{M_a}\right)^3 I_g + \left(1 - \left(\frac{M_{cr}}{M_a}\right)^3\right) I_{cr}$$
$$= (0.194)(19{,}041\ \text{in}^4) + (1 - 0.194)(10{,}733\ \text{in}^4)$$
$$= 12{,}345\ \text{in}^4$$

16. LONG-TERM DEFLECTIONS

Long-term deflection is caused by creep and shrinkage of the concrete. The long-term deformation develops rapidly at first and then slows down, being largely complete after approximately five years. In the procedure specified in ACI 318, the *long-term deformation*, Δ_a, is obtained by multiplying the immediate deflection produced by the portion of the load sustained by an amplification factor. In computing the sustained part of the immediate deflection, judgment is required to decide what fraction of the prescribed service live load can be assumed to be acting continuously. The long-term deflection is taken as

$$\Delta_a = \lambda\Delta_i \qquad 50.41$$

$$\lambda = \frac{\xi}{1 + 50\rho'} \qquad 50.42$$

ρ' is the compression steel ratio (A_s/bd) at midspan for simply supported and continuous beams and at supports for cantilevers. ξ is an empirical factor that accounts for the rate of the additional deflection. ξ is 1.0 at three months, 1.2 at six months, 1.4 at one year, and 2 at five years or more.

The total deflection is the sum of the instantaneous plus the long-term deflections.

17. MINIMUM BEAM DEPTHS TO AVOID EXPLICIT DEFLECTION CALCULATIONS

For nonsupporting beams or those that are attached to nonstructural elements sensitive to deflections, explicit deflection calculations are not required if the beam has been designed with a certain minimum thickness. The minimum thickness, h, is given in Table 50.4.

Table 50.4 *Minimum Beam Thickness Unless Deflections are Computed* ($f_y = 60{,}000\ \text{lbf/in}^2$)[a]

construction	minimum h (fraction of span length)
simply supported	$\frac{1}{16}$
one end continuous	$\frac{1}{18.5}$
both ends continuous	$\frac{1}{21}$
cantilever	$\frac{1}{8}$

[a] Corrections are required for other steel strengths. See Eq. 50.43.
Source: ACI 318 Table 9.5(a)

The values in Table 50.4 apply to normal-weight concrete reinforced with $f_y = 60{,}000\ \text{lbf/in}^2$ (400 MPa) steel. The table values are multiplied by the adjustment factor in Eq. 50.43 for other steel strengths.

$$0.4 + \frac{f_y}{700} \qquad \text{[SI]} \qquad 50.43(a)$$

$$0.4 + \frac{f_y}{100{,}000} \qquad \text{[U.S.]} \qquad 50.43(b)$$

For structural lightweight concrete with a unit weight, w, between 90 and 120 lbf/ft^3 (14.13 and 18.83 kN/m^3), multiply the table values by

$$1.65 - 0.0318w \geq 1.09 \qquad \text{[SI]} \qquad 50.44(a)$$

$$1.65 - 0.005w \geq 1.09 \qquad \text{[U.S.]} \qquad 50.44(b)$$

Structural

Table 50.5 *Maximum Allowable Computed Deflections*

type of member	deflection to be considered	deflection limitation
flat roofs not supporting or attached to nonstructural elements likely to be damaged by large deflections	immediate deflection due to live load	$\frac{1}{180}$
floors not supporting or attached to nonstructural elements likely to be damaged by large deflections	immediate deflection due to live load	$\frac{1}{360}$
roof or floor construction supporting or attached to nonstructural elements likely to be damaged by large deflections	that part of the total deflection that occurs after attachment of the nonstructural elements	$\frac{1}{480}$
roof or floor construction supporting or attached to nonstructural elements not likely to be damaged by large deflections	that part of the total deflection that occurs after attachment of the nonstructural element	$\frac{1}{240}$

Source: ACI 318 Table 9.5(b)

18. MAXIMUM ALLOWABLE DEFLECTIONS

When the minimum thicknesses of Table 50.4 are not used, or if the beam supports nonstructural elements that are sensitive to deformations, the deflections must be explicitly checked by computation. The limits prescribed by ACI 318 for the computed deflections are presented in Table 50.5.

The deflection limits in the first row of Table 50.5 are not intended to safeguard against ponding. Ponding should be checked by deflection calculations, taking into consideration the added deflections due to accumulated ponded water and considering long-term effects of all sustained loads, camber, construction tolerances, and reliability of provisions for drainage.

19. DESIGN OF T-BEAMS

Although a beam can be specifically cast with a T-shaped cross section, that is rarely done. T-beam behavior usually occurs in monolithic beam-slab (one-way) systems. The general beam procedure presented earlier in this chapter applies to the design of T-beams. However, determining the amount of the flange (i.e., the slab) that is effective in resisting compressive loads is code-sensitive. ACI 318 also specifies requirements pertaining to the distribution of the reinforcement.

The compressive stresses in the flange of a T-beam decrease with distance from the centerline of the web. ACI 318 specifies using the *effective width*, which is a width over which the compressive stress is assumed uniform.

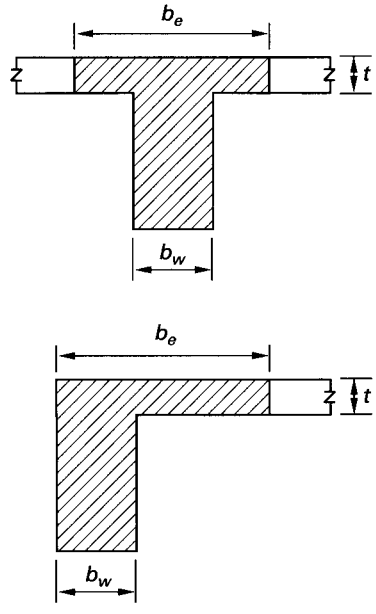


Figure 50.7 *Effective Flange Width (one-way slab systems) [ACI 318 Sec. 8.10]*

It is assumed that a stress of $0.85f'_c$ acting over the effective width provides approximately the same compressive force as that realized from the actual variable stress distribution over the total flange width. The effective width of the flange for T- and L-shaped beams is illustrated in Fig. 50.7. The effective width in each case is the smallest value from the options listed [ACI 318 8.10].

Case 1: Beams with flanges on each side of the web [ACI 318 8.10.2]

Effective width for a T-beam is the minimum of

one fourth of the beam's span length, or

the stem width plus 16 times the thickness of the slab, or

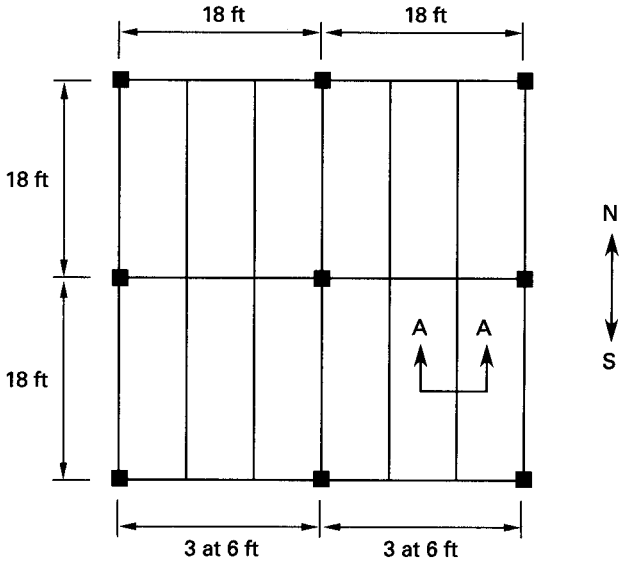
one half of the clear distance between beam webs

Case 2: Beams with an L-shaped flange [ACI 318 8.10.3]

Effective width is the minimum of

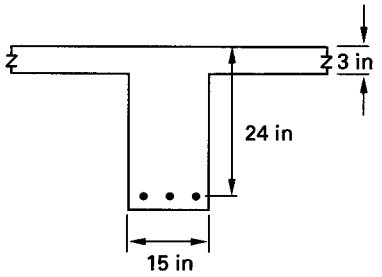
one twelfth of the beam's span length, or

the stem width plus 6 times the thickness of the slab, or



one half of the clear distance between beam webs

Case 3: Isolated T-Beams [ACI 318 8.10.4]



If a T-beam is not part of a floor system but the T-shape is used to provide additional compression area, the flange thickness shall not be less than one half of the width of the web. The effective width of the flange shall not be more than 4 times the thickness of the web.

When a T-beam is subjected to a negative moment, the tension steel must be placed in the flange. ACI 318 10.6.6 requires that this tension steel not all be placed inside the region of the web but that it be spread out into the flange for a distance whose width is the smaller of (a) the effective flange width or (b) one tenth of the span. This provision ensures that cracking on the top surface will be distributed.

If the T-beam is an isolated member, loading will produce bending of the flange in the direction perpendicular to the beam span. Adequate transverse steel must be provided to prevent a bending failure of the flange.

(a)

(b)

Example 50.8

A monolithic slab-beam floor system is supported on a column grid of 18 ft centers as shown. The dimensions of the cross section for the beams running in the north-south direction have been determined. The positive moments in the north-south beams are $M_d = 200$ ft-kips, and $M_l = 340$ ft-kips. $f'_c = 3000$ lbf/in^2, and $f_y = 50{,}000$ lbf/in^2. Design the positive steel reinforcement.

Solution

The effective width of the flange is determined as the smallest of

$$\frac{L}{4} = \frac{(18 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{4} = 54 \text{ in} \quad \text{[controls]}$$

$$b_w + 16t = 15 \text{ in} + (16)(3 \text{ in}) = 63 \text{ in}$$

$$\text{beam spacing} = (6 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right) = 72 \text{ in}$$

The effective flange area is

$$(3 \text{ in})(54 \text{ in}) = 162 \text{ in}^2$$

The factored moment is

$$\begin{aligned} M_u &= 1.4M_d + 1.7M_l \\ &= (1.4)(200 \text{ ft-kips}) + (1.7)(340 \text{ ft-kips}) \\ &= 858 \text{ ft-kips} \end{aligned}$$

Structural

Estimate λ as $(0.1)(24 \text{ in}) = 2.4$ in. The steel area required is given by Eq. 50.19.

$$\begin{aligned} A_s &= \frac{M_u}{\phi f_y (d - \lambda)} \\ &= \frac{(858 \text{ ft-kips})\left(12 \frac{\text{in}}{\text{ft}}\right)}{(0.9)\left(50 \frac{\text{kips}}{\text{in}^2}\right)(24 \text{ in} - 2.4 \text{ in})} \\ &= 10.59 \text{ in}^2 \end{aligned}$$

The area of concrete in compression is given by Eq. 50.17.

$$\begin{aligned} A_c &= \frac{f_y A_s}{0.85 f'_c} \\ &= \frac{\left(50 \frac{\text{kips}}{\text{in}^2}\right)(10.59 \text{ in}^2)}{(0.85)\left(3 \frac{\text{kips}}{\text{in}^2}\right)} \\ &= 207.65 \text{ in}^2 \end{aligned}$$

This area includes the flange plus a depth into the web of

$$\frac{207.65 \text{ in}^2 - 162 \text{ in}^2}{15 \text{ in}} = 3.04 \text{ in}$$

The centroid of the compressed area measured from the top is determined as follows.

$$\begin{aligned} &(162 \text{ in}^2)(1.5 \text{ in}) + (207.65 \text{ in}^2 - 162 \text{ in}^2) \\ &\quad \times \left(3 \text{ in} + \frac{3.04 \text{ in}}{2}\right) = 207.65\lambda \\ &\lambda = 2.16 \text{ in} \end{aligned}$$

The nominal moment capacity is given by Eq. 50.18.

$$\begin{aligned} M_n &= A_s f_y (d - \lambda) \\ &= \frac{(10.59 \text{ in}^2)\left(50 \frac{\text{kips}}{\text{in}^2}\right)(24 \text{ in} - 2.16 \text{ in})}{12 \frac{\text{in}}{\text{ft}}} \\ &= 963.69 \text{ ft-kips} \end{aligned}$$

The design moment capacity is

$$\begin{aligned} \phi M_n &= (0.9)(963.69 \text{ ft-kips}) \\ &= 867.3 \text{ ft-kips} \end{aligned}$$

Since the design moment capacity (867.32 ft-kips) is slightly larger than the factored moment (858 ft-kips), the "exact" steel area required is nominally smaller than the estimated value of 10.59 in^2. An incrementally "better" estimate of the steel area is

$$\begin{aligned} A_s &= \left(\frac{858.0 \text{ ft-kips}}{867.3 \text{ ft-kips}}\right)(10.59 \text{ in}^2) \\ &= 10.48 \text{ in}^2 \end{aligned}$$

Check that the steel does not exceed the maximum allowed. The depth of the rectangular stress block at balanced condition is given by Eq. 50.11.

$$\begin{aligned} a_b &= \beta_1 \left(\frac{87{,}000}{87{,}000 + f_y}\right) d \\ &= (0.85)\left(\frac{87{,}000}{87{,}000 + 50{,}000}\right)(24 \text{ in}) \\ &= 12.95 \text{ in} \end{aligned}$$

The corresponding concrete area is

$$\begin{aligned} A_{\text{cb}} &= (54 \text{ in})(3 \text{ in}) + (12.95 \text{ in} - 3 \text{ in})(15 \text{ in}) \\ &= 311.25 \text{ in}^2 \end{aligned}$$

The balanced steel is obtained from Eq. 51.10.

$$\begin{aligned} A_{\text{sb}} &= \frac{0.85 f'_c A_{\text{cb}}}{f_y} \\ &= \frac{(0.85)\left(3 \frac{\text{kips}}{\text{in}^2}\right)(311.25 \text{ in}^2)}{50 \frac{\text{kips}}{\text{in}^2}} \\ &= 15.87 \text{ in}^2 \end{aligned}$$

The maximum steel is given by Eq. 50.9.

$$\begin{aligned} A_{s,\max} &= 0.75 A_{\text{sb}} = (0.75)(15.87 \text{ in}^2) \\ &= 11.90 \text{ in}^2 \end{aligned}$$

The maximum steel is larger than the required steel area, so the design is adequate. Since the two values are relatively close, the minimum steel requirement is not checked explicitly.

20. SHEAR STRESS

In addition to producing bending moments, beam loads also produce shear forces. Shear forces induce diagonal tension stresses that lead to diagonal cracking. The typical pattern of cracks induced by shear forces is depicted in Fig. 50.8. If a diagonal crack forms and the beam does not contain shear reinforcement, failure will occur abruptly. In order to have ductile beams (where the controlling mechanism is the ductile yielding of the tension steel), shear reinforcement is designed conservatively.

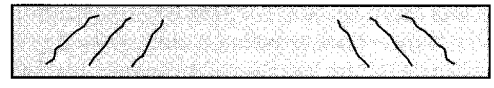


Figure 50.8 *Typical Pattern of Shear Cracks*

The maximum shear at a given location does not necessarily result from placing the live load over the complete beam. For a simple beam, for example, the shear at the centerline is zero if the live load is placed over the full span. If only half the span is loaded, the shear from live load at the center will equal $w_l L/8$.

A *shear envelope* is a plot of the maximum shear that can occur at any given section allowing for a variable position of the live load. In practice, the construction of the exact shear envelope is usually unnecessary since an approximate envelope obtained by connecting the maximum possible shear at the reactions with the maximum possible value at the center of the spans is sufficiently accurate. Of course, the dead load shear must be added to the live load shear envelope.

In the design of beams, it is customary to call out the span length as the distance from the centerline of supports. Although the shear computed is largest immediately adjacent to a reaction, shears corresponding to locations that are within the support width are not physically meaningful. Furthermore, for the typical case where the beam is supported from underneath, the compression induced by the reaction increases the shear strength in the vicinity of the support.

ACI 318 11.1.3 takes this enhanced strength into account by specifying that the region of the beam from a distance d to the face of the support can be designed for the same shear force that exists at a distance d from the support face. For this provision to apply, the reaction must induce compression in the member (i.e., the beam is not hanging from a support), and there must be no concentrated loads acting within the distance d. If concentrated loads exist within this distance, or if the reaction does not induce compression, it is necessary to provide for the actual shear forces occurring all the way to the face of the supports. (See Fig. 50.9.)

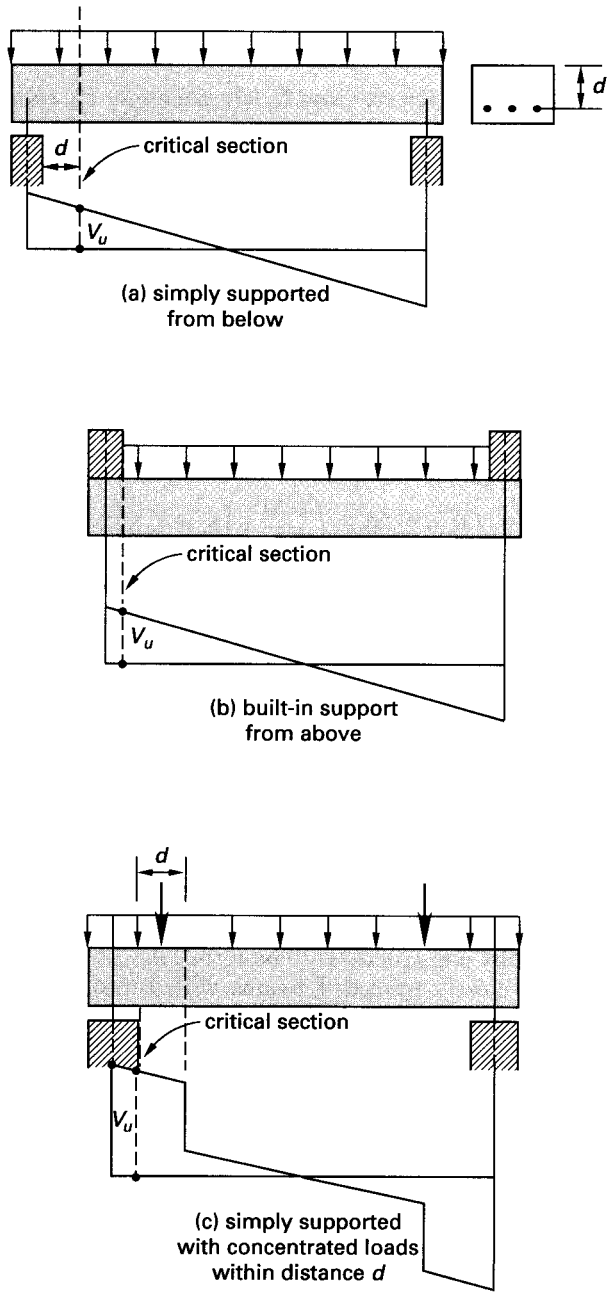

Figure 50.9 *Location of Critical Sections*

21. SHEAR REINFORCEMENT

Shear reinforcement can take several forms. Vertical stirrups are used most often, but stirrups inclined as little as 45° are occasionally seen, as is welded wire fabric. Longitudinal steel that is bent up at 30° or more and enters the compression zone also contributes to shear reinforcement.

In seismically active regions, in order to increase the ductility of beams that are part of lateral load-resisting frames, the concrete in the compression zone must be adequately confined. This confinement is typically attained by providing closely spaced transverse reinforcement in the form of closed ties. These closed ties, which resist shear forces in the same way that stirrups do, are known as *hoops*.

The basic equation governing design for shear forces is given by Eq. 50.45. For shear, $\phi = 0.85$.

$$\phi V_n = V_u \qquad 50.45$$

The beam's shear capacity, V_n, is determined semi-empirically as the sum of the concrete shear capacity, V_c, and the shear capacity that derives from the presence of shear reinforcement, V_s.

$$V_n = V_c + V_s \qquad 50.46$$

(The term *nominal shear strength* is ambiguous in concrete design. The concrete strength, V_c, is often referred to as the *nominal concrete shear strength*. The sum of $V_c + V_s$ is referred to as the *nominal beam shear strength*.) Common usage attributes the term "nominal" to both.

22. SHEAR STRENGTH PROVIDED BY CONCRETE

The shear capacity provided by the concrete, V_c, results from the strength in shear of the uncracked compression zone, a contribution from aggregate interlock across the cracks, and dowel action from the tension steel that crosses the diagonal crack. ACI 318 provides two equations to calculate V_c. One equation is a refined expression that accounts for the effect of the moment and the amount of longitudinal steel on the shear strength.

$$V_c = \left(\frac{\sqrt{f'_c}}{7} + \left(\frac{120}{7} \right) \rho_w \left(\frac{V_u d}{M_u} \right) \right) b_w d \leq 0.29 \sqrt{f'_c} b_w d$$

[SI] *50.47(a)*

$$V_c = \left(1.9 \sqrt{f'_c} + 2500 \rho_w \left(\frac{V_u d}{M_u} \right) \right) b_w d \leq 3.5 \sqrt{f'_c} b_w d$$

[U.S.] *50.47(b)*

The other equation is a simple expression computed solely from the strength of the concrete and the size of the cross section. In practice, the simpler expression is used. If the shear capacity is inadequate, the refined equation can be used.

$$V_c = \tfrac{1}{6} \sqrt{f'_c} b_w d \quad \text{[SI]} \quad \textit{50.48(a)}$$

$$V_c = 2 \sqrt{f'_c} b_w d \quad \text{[U.S.]} \quad \textit{50.48(b)}$$

ACI 318 8.11.8 permits an increase of 10% in the shear force that can be assigned to the concrete in the ribs of floor joist construction. (The term *joist construction* refers to closely spaced T-beams with tapered webs.) To qualify for the 10% increase in V_c, the ribs must be at least 4 in (10 cm) wide, have a depth of no more than 3.5 times the minimum width of the rib, and have a clear spacing not exceeding 30 in (76.2 cm).

23. SHEAR STRENGTH PROVIDED BY SHEAR REINFORCEMENT

The shear capacity provided by the steel reinforcement, V_s, is derived by considering a freebody diagram of the beam with an idealized diagonal crack at 45° and computing the vertical component of the force developed by the reinforcement intersecting the crack. It is assumed that all the steel is yielding when the strength is attained. For the typical case of vertical stirrups, as shown in Fig. 50.10, the shear capacity is

$$V_s = \frac{A_v f_y d}{s} \qquad \textit{50.49}$$

The area A_v includes all of the legs in a single stirrup. For example, for the typical U-shaped stirrup, A_v is twice the area of the stirrup bar. For stirrups inclined at an angle θ from the horizontal, the shear strength contribution is

$$V_s = \frac{A_v f_y (\sin\theta + \cos\theta) d}{s} \qquad \textit{50.50}$$

If the shear reinforcement is provided by a single bar or a single group of parallel bars all bent up at the same distance from the support, the shear strength contribution is

$$V_s = A_v f_y \sin\theta \leq 0.25 \sqrt{f'_c} b_w d \quad \text{[SI]} \quad \textit{50.51(a)}$$

$$V_s = A_v f_y \sin\theta \leq 3 \sqrt{f'_c} b_w d \quad \text{[U.S.]} \quad \textit{50.51(b)}$$

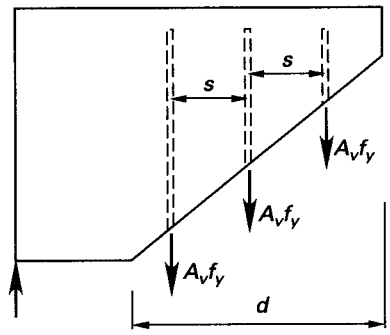

Figure 50.10 *Contribution of Vertical Stirrups to Shear Capacity*

24. SHEAR REINFORCEMENT LIMITATIONS

In order to control the diagonal compressive stresses in the concrete resulting from shear, ACI 318 limits the maximum shear that can be assigned to the shear reinforcement [ACI 318 11.5.6.8].

$$V_s \leq \tfrac{2}{3} \sqrt{f'_c} b_w d \quad \text{[SI]} \quad \textit{50.52(a)}$$

$$V_s \leq 8 \sqrt{f'_c} b_w d \quad \text{[U.S.]} \quad \textit{50.52(b)}$$

The maximum total shear force permitted depends on whether Eq. 50.47 or Eq. 50.48 is used to compute the concrete contribution. For the common case where V_c is computed with the simple expression, the maximum shear force V_u is

$$V_{u,\max} = \tfrac{5}{6} \phi \sqrt{f'_c} b_w d \quad \text{[SI]} \quad \textit{50.53(a)}$$

$$V_{u,\max} = 10 \phi \sqrt{f'_c} b_w d \quad \text{[U.S.]} \quad \textit{50.53(b)}$$

25. STIRRUP SPACING

Whenever stirrups are required, ACI 318 11.5.4 specifies that the spacing, s, shall not be larger than calculated in Eqs. 50.54 and 50.55. This maximum spacing ensures that at least one stirrup crosses each potential diagonal crack. The second limit in Eq. 50.55, which applies when the shear is high, ensures that at least two stirrups cross each potential shear crack.

$$s = \min\{60 \text{ cm or } d/2\} \quad [V_s \leq \tfrac{2}{3} \sqrt{f'_c} b_w d]$$

[SI] *50.54(a)*

$$s = \min\{24 \text{ in or } d/2\} \quad [V_s \leq 4 \sqrt{f'_c} b_w d]$$

[U.S.] *50.54(b)*

$$s = \min\{30 \text{ cm or } d/2\} \quad [V_s > \tfrac{2}{3}\sqrt{f'_c}\,b_w d] \quad \text{[SI]} \quad \textit{50.55(a)}$$

$$s = \min\{12 \text{ in or } d/2\} \quad [V_s > 4\sqrt{f'_c}\,b_w d] \quad \text{[U.S.]} \quad \textit{50.55(b)}$$

Though not specified by the code, the minimum practical spacing is about 3 in (76 mm). If stirrups need to be closer than 3 in (76 mm), a larger bar size should be used. It is common to place the first stirrup at a distance of $s/2$ from the face of the support, but not closer than 2 in (51 mm). However, the first stirrup can be placed a full space from the face.

When a diagonal crack forms, the stress transfers from the concrete to the stirrups. To ensure that the stirrups have sufficient strength (i.e., a minimum strength of at least 50 lbf/in^2 (340 kPa)), ACI 318 11.5.5.3 requires all stirrups to have a minimum area of

$$A_{v,\min} = \frac{b_w s}{3 f_y} \quad \text{[SI]} \quad \textit{50.56(a)}$$

$$A_{v,\min} = \frac{50 b_w s}{f_y} \quad \text{[U.S.]} \quad \textit{50.56(b)}$$

26. NO-STIRRUP CONDITIONS

If the shear force is low enough, the concrete in the compression zone will be able to resist it without the need for shear reinforcement. Logically, shear reinforcement is not needed if $\phi V_c \geq V_u$. However, per ACI 318 11.5.5.1, this criterion can be used only if (a) the depth of the beam is less than 10 in (254 mm), (b) the depth is not larger than 2.5 times the flange thickness, and (c) the depth is not greater than one-half the width of the web. In all other cases, ACI 318 is more conservative by a factor of two. Shear reinforcement can be eliminated only in regions of the beam where

$$\frac{\phi V_c}{2} \geq V_u \quad \textit{50.57}$$

27. SHEAR REINFORCEMENT DESIGN PROCEDURE

The following procedure will design shear reinforcement for an entire beam. Some steps can be omitted when designing for a limited portion of the beam.

step 1: Calculate the shear envelope for the factored loads. If Eq. 50.47 is to be used to compute V_c, the moment diagram is also needed. The shear at any section is V_u.

step 2: Calculate V_c, generally using the simple option.

step 3: Determine the portions of the beam where the factored shear is less than or equal to $\phi V_c/2$. A graphical representation of the shear envelope drawn to scale can be helpful in locating these regions. Stirrups are not required in these regions.

step 4: Use Eq. 50.49 to compute the capacity, $V_{s,\min}$, provided by minimum shear reinforcement. Minimum reinforcement is obtained by setting the spacing of the stirrups to the largest amount allowed by Eq. 50.54 and A_v to the smallest bar choice that will satisfy Eq. 50.56.

step 5: Add V_c from step 2 to $V_{s,\min}$ from step 4 to obtain the shear capacity of the beam with minimum shear reinforcement. Use this minimum reinforcement in regions where $V_c/2 < V_u < V_c + V_{s,\min}$.

step 6: Calculate the spacing of stirrups for the regions of the beam where $V_u > V_c + V_{s,\min}$. At any location, the shear reinforcement needs to supply a strength given by

$$V_{s,\text{req}} = \frac{V_u}{\phi} - V_c \quad \textit{50.58}$$

The maximum value permitted for $V_{s,\text{req}}$ is given by Eq. 50.52. If the value computed in Eq. 50.58 exceeds this limit, adequate shear strength cannot be obtained with shear reinforcement. Either the section size or the concrete strength (or both) must be increased.

Calculate the spacing derived from Eq. 50.49. The spacing from Eq. 50.50 must not exceed the limits presented in Eqs. 50.54 and 50.55.

$$s = \frac{A_v f_y d}{V_{s,\text{req}}} \quad \textit{50.59}$$

28. ANCHORAGE OF SHEAR REINFORCEMENT

ACI 318 requires that the shear reinforcement extend into the compression and tension regions as far as cover requirements and proximity to other bars permit. In order to develop its full capacity, shear reinforcement must be anchored at both ends by one of two means. In a U-shaped stirrup, one end of the shear is bent around the longitudinal steel, anchoring that end. For no. 5 or smaller stirrups and for stirrups constructed of no. 6, no. 7, and no. 8 bars with $f_y \leq 40{,}000$ lbf/in^2 (276 MPa), the other end may be considered to be developed if it is wrapped with a standard hook around longitudinal reinforcement [ACI 318 12.13.2.1].

For no. 6, no. 7, and no. 8 stirrups with $f_y \geq 40{,}000$ psi (276 MPa), the other end may be considered to be developed with a standard hook around longitudinal reinforcement plus an embedment distance between midheight of the member and the outside of the hook given by Eq. 50.60 [ACI 318 12.13.2.2].

$$\text{embedment length} = \frac{0.17 d_b f_y}{\sqrt{f'_c}} \quad \text{[SI]} \quad \textit{50.60(a)}$$

$$\text{embedment length} = \frac{0.014 d_b f_y}{\sqrt{f'_c}} \quad \text{[U.S.]} \quad \textit{50.60(b)}$$

Structural

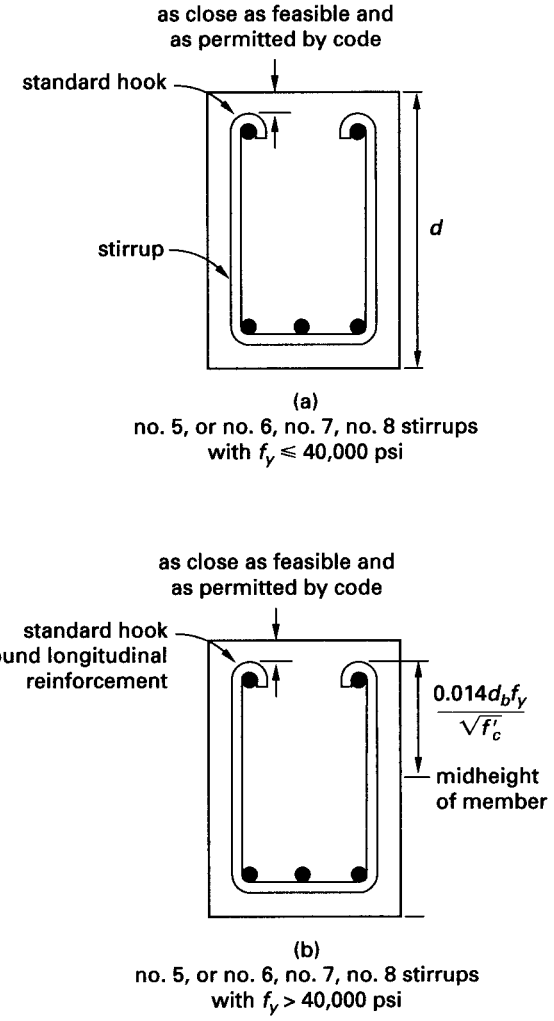

Figure 50.11 *Anchorage Methods for Shear Reinforcement*

29. DOUBLY REINFORCED CONCRETE BEAMS

In singly reinforced beams, steel is used to withstand tensile-only forces. There are instances, however, where it is appropriate to use steel reinforcement to support compressive forces. The most common situation where a doubly reinforced beam is needed is found when the moment capacity of the singly reinforced section, with the maximum area of steel permitted, is not sufficient to carry the applied moment. In such cases, steel can be provided in excess of the maximum allowed for a singly reinforced section if the added tensile force is balanced by steel in compression. Another less common reason for using compression steel is to control long-term deformations. Indeed, the factor λ, which determines the increase in deflection due to creep and shrinkage (see Eq. 50.42), decreases as the percentage of compression steel in the section increases. Sections that have steel in the tension and the compression regions are referred to as *doubly reinforced beams.*

There are also situations where cross sections are doubly reinforced as a result of detailing, not as a result of needing compression steel for strength. For example, in the negative moment region of a typical monolithic beam-slab system the tension steel is at the top of the section, but compression steel is always present regardless of whether it is needed. This is because ACI 318 requires that a certain fraction of the steel used for the positive moment be extended into the support. (ACI 318 12.11.1 requires that at least one third of the reinforcement from a section of maximum moment be extended at least 6 in (15 cm) into a simple support. If the member is continuous, at least one fourth of the reinforcement from the section of maximum positive moment must extend at least 6 in (15 cm) into the support.)

30. STRENGTH ANALYSIS OF DOUBLY REINFORCED SECTIONS

Figure 50.12 illustrates a doubly reinforced concrete section and the profile of strains and stresses when the flexural capacity is attained. The following iterative procedure calculates the nominal moment capacity for a doubly reinforced beam with a known shape and reinforcement.

step 1: Compute the tension force as $T = f_y A_s$.

step 2: Estimate the stress in the compression steel. ($f'_s = 0$ is a valid first estimate.)

step 3: Calculate the area of concrete, A_c, which at a stress of $0.85f'_c$ gives a force equal to $T - A_s f'_s$.

$$A_c = \frac{f_y A_s - f'_s A'_s}{0.85 f'_c} \qquad 50.61$$

The depth of the equivalent compressed area is a. The actual neutral axis is at $c = a/\beta_1$, where β_1 is given by Eq. 50.12.

step 4: Compute the strain in the compression steel as

$$\varepsilon'_s = \left(\frac{0.003}{c}\right)(c - d') \qquad 50.62$$

step 5: Compute the stress in the compression steel as

$$f'_s = E_s \varepsilon'_s \leq f_y \qquad 50.63$$

step 6: Compare the stress assumed in step 2 with the value computed in step 5. If they differ significantly (say, by more than 10%), replace the assumed value with the result from Eq. 50.63 and repeat steps 3 through 5. If they are reasonably close (say, within 10%), go to step 7.

step 7: Locate the centroid of the area A_c.

step 8: The nominal moment capacity is obtained by summing moments of the forces (see Fig. 50.12) about an arbitrary point. This

results in Eq. 50.64. (Equation 50.64 is the general form of Eq. 50.18 for singly reinforced sections with $f'_s = 0$.)

$$M_n = A_s f_y(d - \lambda) + A'_s f'_s(\lambda - d') \quad 50.64$$

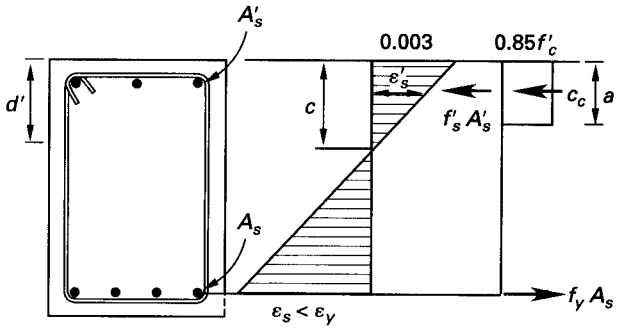

Figure 50.12 *Parameters for Doubly Reinforced Beam*

31. DESIGN OF DOUBLY REINFORCED SECTIONS

The design of a doubly reinforced beam begins by determining the difference between the applied moment and the maximum that can be carried with tension steel. This moment deficit must be provided by a couple formed by a force from additional tension steel ($A_{s,\text{add}} f'_y$) balanced with a force from compression steel ($A'_s f'_s$). It should be noted that, at ultimate, while the steel added in tension will always yield, the compression steel may or may not yield.

The following procedure can be used to design a doubly reinforced beam.

step 1: Calculate the maximum area of tension steel permitted if the section is singly reinforced. (See Eq. 50.9.)

step 2: Calculate the moment capacity for the maximum steel area as singly reinforced. Designate this moment as M_{nc}. For a rectangular cross section, M_{nc} can be conveniently computed using Eq. 50.23 with the steel ratio ρ taken as 75% of Eq. 50.24.

step 3: The nominal moment deficit is

$$M'_n = \frac{M_u}{\phi} - M_{nc} \quad 50.65$$

step 4: Compute the area of tension steel $A_{s,\text{add}}$ that must be added to the area computed in step 1.

$$A_{s,\text{add}} = \frac{M'_n}{f_y(d - d')} \quad 50.66$$

The total tension steel area is

$$A_s = A_{s,\max} + A_{s,\text{add}} \quad 50.67$$

step 5: Compute the stress in the compression steel from Eqs. 50.62 and 50.63. In these formulas, the depth of the neutral axis, c, is that for the singly reinforced section with the area of steel in step 1. For a rectangular cross section, this depth is

$$c = 0.75\left(\frac{600}{600 + f_y}\right)d \quad \text{[SI]} \quad 50.68(a)$$

$$c = 0.75\left(\frac{87{,}000}{87{,}000 + f_y}\right)d \quad \text{[U.S.]} \quad 50.68(b)$$

step 6: Calculate the area of compression steel from Eq. 50.69.

$$A'_s = \left(\frac{f_y}{f'_s}\right)A_{s,\text{add}} \quad 50.69$$

step 7: Complete the design as for a singly reinforced section. (ACI 318 7.11.1 requires that the compression steel be enclosed by ties or stirrups satisfying size and spacing limitations that are the same as for ties in columns.)

Example 50.9

The factored loads acting on a reinforced concrete beam produce a maximum design moment $M_u = 275$ ft-kips. $f'_c = 3000$ lbf/in^2, and $f_y = 60{,}000$ lbf/in^2. The width of the beam is limited to 12 in, and the effective depth must not exceed 18 in. Design the reinforcing steel.

Solution

Determine if the moment that can be resisted with maximum steel as a singly reinforced section is larger than the applied moment M_u. The balanced steel area is obtained from Eq. 50.13(a).

$$\beta_1 = 0.85$$

$$A_{sb} = \left(\frac{0.85\beta_1 f'_c}{f_y}\right)\left(\frac{87{,}000}{87{,}000 + f_y}\right)bd$$

$$= \left(\frac{(0.85)(0.85)\left(3000\ \frac{\text{lbf}}{\text{in}^2}\right)}{60{,}000\ \frac{\text{lbf}}{\text{in}^2}}\right) \times \left(\frac{87{,}000}{87{,}000 + 60{,}000}\right)(12\text{ in})(18\text{ in})$$

$$= 4.62\text{ in}^2$$

The maximum amount of steel as a singly reinforced section is

$$(0.75)(4.62\text{ in}^2) = 3.47\text{ in}^2$$

Structural

The concrete area is given by Eq. 50.10.

$$\begin{aligned}A_c &= \frac{f_y A_s}{0.85 f'_c} \\ &= \frac{\left(60{,}000\ \frac{\text{lbf}}{\text{in}^2}\right)(4.62\ \text{in}^2)}{(0.85)\left(3000\ \frac{\text{lbf}}{\text{in}^2}\right)} \\ &= 92.40\ \text{in}^2\end{aligned}$$

The depth of the equivalent rectangular stress block is

$$a = \frac{92.40\ \text{in}^2}{12\ \text{in}} = 7.70\ \text{in}$$

The centroid of the compressed area is $\lambda = (7.70\ \text{in})/2 = 3.35$ in from the top. The nominal moment capacity with maximum reinforcement is given by Eq. 50.18.

$$\begin{aligned}M_{nc} &= A_s f_y (d - \lambda) \\ &\times \left(\frac{(3.47\ \text{in}^2)\left(60\ \frac{\text{kips}}{\text{in}^2}\right)(18\ \text{in} - 3.35\ \text{in})}{12\ \frac{\text{in}}{\text{ft}}}\right) \\ &= 254.18\ \text{ft-kips}\end{aligned}$$

Since $\phi M_{nc} < M_u$, compression reinforcement is needed. The nominal moment deficit is

$$\begin{aligned}M'_n &= \frac{M_u}{\phi} - M_{nc} \\ &= \frac{275\ \text{ft-kips}}{0.9} - 254.18\ \text{ft-kips} \\ &= 51.38\ \text{ft-kips}\end{aligned}$$

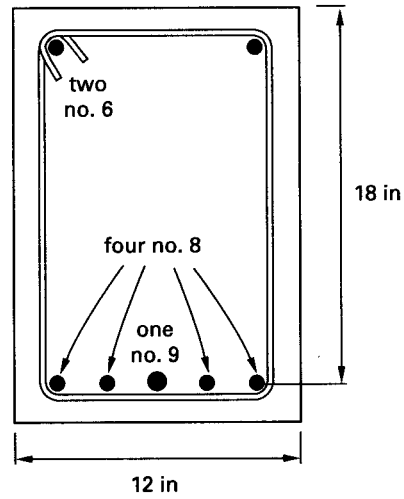
The area of tension steel, $A_{s,\text{add}}$, that must be added to the maximum permitted as a singly reinforced beam is

$$\begin{aligned}A_{s,\text{add}} &= \frac{M'_n}{f_y(d - d')} \\ &= \frac{(51.38\ \text{ft-kips})\left(12\ \frac{\text{in}}{\text{ft}}\right)}{\left(60\ \frac{\text{kips}}{\text{in}^2}\right)(18\ \text{in} - 2.5\ \text{in})} \\ &= 0.66\ \text{in}^2\end{aligned}$$

The total tension steel area is

$$A_s = 3.47\ \text{in}^2 + 0.66\ \text{in}^2 = 4.13\ \text{in}^2$$

In order to find the required compression steel area, it is necessary to determine the strain at the level where the compression steel is to be placed when the beam is reinforced with $A_{s,\max}$. In this problem, assume that the centroid of the compression steel is 2.5 in from the top of the section.



The neutral axis depth is obtained from Eq. 50.68. Since this depth is simply a/β_1, $c = 7.70\ \text{in}/0.85 = 9.06$ in. Using Eqs. 50.62 and 50.63,

$$\begin{aligned}\varepsilon'_s &= \frac{0.003(c - d')}{c} \\ &= \frac{(0.003)(9.06\ \text{in} - 2.5\ \text{in})}{9.06\ \text{in}} \\ &= 0.0022 \\ f'_s &= E_s \varepsilon'_s = \left(29{,}000\ \frac{\text{kips}}{\text{in}^2}\right)(0.0022) \\ &= 63\ \text{kips/in}^2 \le f_y\end{aligned}$$

The steel stress is limited to the yield strength. Therefore, $f'_s = 60{,}000\ \text{lbf/in}^2$. The compression steel area is

$$\begin{aligned}A'_s &= \left(\frac{f_y}{f'_s}\right) A_{s,\text{add}} \\ &= \left(\frac{60{,}000\ \frac{\text{lbf}}{\text{in}^2}}{60{,}000\ \frac{\text{lbf}}{\text{in}^2}}\right)(0.66\ \text{in}^2) \\ &= 0.66\ \text{in}^2\end{aligned}$$

Put four no. 8 bars and one no. 9 bar in the tension region, giving 4.16 in^2 of reinforcement. Put two no. 6 bars in the compression region, giving 0.88 in^2 of area.

32. DEEP BEAMS

Flexural steel for deep beams is designed the same way as for normal-depth beams. For the purpose of shear design, *deep beams* are defined as those for which the ratio of the clear span to the effective depth is less than 5,

that are loaded on one face, and that are supported on the opposite face [ACI 318 11.8.1]. Since the expected orientation of shear cracks in deep beams is more nearly vertical than in shallow beams, horizontal as well as vertical reinforcement is required.

The contribution of the concrete to the shear strength is the same as for normal-depth beams. (See Eq. 50.48.) ACI 318 also provides a refined equation to calculate the shear capacity of deep beams. The refined equation is not, however, the same as the refined equation for normal-depth beams. The same shear reinforcement is used throughout the beam. The spacing is determined from the design shear force, V_u, located at the critical section, as defined by ACI 318. For uniform loading, the critical section is defined to be located a distance l_c from the face of the support [ACI 318 11.8.5].

$$l_c = \min\{0.15l_n, d\} \qquad 50.70$$

For concentrated loading, the location of the critical section is given by Eq. 50.71 in which a is the *shear span*, the distance from the face of the support to the closest concentrated load [ACI 318 11.8.5].

$$l_c = \min\{0.5a, d\} \qquad 50.71$$

If V_n is greater than $V_c/2$, ACI 318 requires a minimum amount of shear reinforcement. (As with regular-depth beams, no shear reinforcement is required if $V_u < V_c/2$. Two types of reinforcement are used: vertical and horizontal. The contribution of the shear reinforcement to the shear strength is given by ACI 318 11.8.8.

$$V_s = \left(\left(\frac{A_v}{s}\right)\left(\frac{1+\frac{l_n}{d}}{12}\right) + \left(\frac{A_{vh}}{s_2}\right)\left(\frac{11-\frac{l_n}{d}}{12}\right) \right) f_y d \qquad 50.72$$

$$A_v \geq 0.0015 b_w s \qquad 50.73$$

$$s \leq \min\{d/5, 45.7 \text{ cm}\} \quad \text{[SI]} \qquad 50.74(a)$$

$$s \leq \min\{d/5, 18 \text{ in}\} \quad \text{[U.S.]} \qquad 50.74(b)$$

$$A_{vh} \geq 0.0025 b_w s_2 \qquad 50.75$$

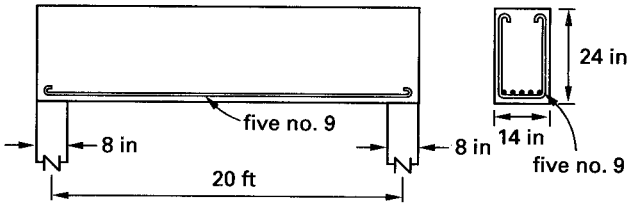
$$s_2 \leq \min\{d/3, 45.7 \text{ cm}\} \quad \text{[SI]} \qquad 50.76(a)$$

$$s_2 \leq \min\{d/3, 18 \text{ in}\} \quad \text{[U.S.]} \qquad 50.76(b)$$

A deep beam's nominal shear strength is computed in the same manner as for normal-depth beams. (See Eq. 50.46.) The maximum shear capacity, however, is not limited in terms of V_s, but is specified directly by ACI 318 11.8.4 as

$$V_n \leq \tfrac{2}{3}\sqrt{f'_c} b_w d \quad [l_n/d \leq 2] \quad \text{[SI]} \qquad 50.77(a)$$

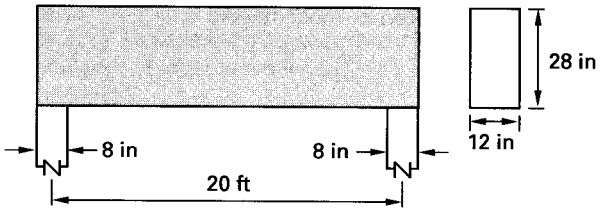
$$V_n \leq 8\sqrt{f'_c} b_w d \quad [l_n/d \leq 2] \quad \text{[U.S.]} \qquad 50.77(b)$$



$$V_n = \tfrac{1}{18}\left(10 + \frac{l_n}{d}\right)\sqrt{f'_c} b_w d \quad [2 \leq l_n/d \leq 5] \quad \text{[SI]} \qquad 50.78(a)$$

$$V_n = \tfrac{2}{3}\left(10 + \frac{l_n}{d}\right)\sqrt{f'_c} b_w d \quad [2 \leq l_n/d \leq 5] \quad \text{[U.S.]} \qquad 50.78(b)$$

PRACTICE PROBLEMS



(Use the ultimate strength method to solve all of these problems.)

1. The simply supported beam shown spans 20 ft and, in addition to its own weight, carries a uniformly distributed service dead load of 1.75 kips/ft and a uniformly distributed live load of 3.0 kips/ft. Five no. 9 bars running the full length of the beam are used as flexural reinforcement. $f'_c = 4000$ lbf/in^2, and $f_y = 60{,}000$ lbf/in^2. No. 3 stirrups are used. (a) Determine the theoretical spacing of stirrups at the critical section using the refined expression for the shear strength of the concrete. (b) Determine the theoretical spacing of the stirrups at the critical section using the simplified expression for the concrete shear strength. (c) Identify the portion of the beam where stirrups are not required.

Answers: (a) 9.0 in, (b) 7.2 in, (c) central 12 in

2. (*Time limit: one hour*) A simply supported reinforced concrete beam spans 20 ft as shown. The beam is subjected to a uniform service dead load equal to 2.0 kips/ft (exclusive of beam weight) and to a uniform service live load of 2.4 kips/ft. $f'_c = 3000$ lbf/in^2, and $f_y = 40{,}000$ lbf/in^2. The depth to the reinforcing is 25.5 in.

Structural

(a) The factored uniform load is most nearly
(A) 6.9 kips/ft
(B) 7.4 kips/ft
(C) 8.0 kips/ft
(D) 9.2 kips/ft

The answer is (B).

(b) The tension steel required at the section of maximum moment is most nearly
(A) 4.5 in^2
(B) 5.0 in^2
(C) 5.6 in^2
(D) 6.1 in^2

The answer is (C).

(c) The maximum area of tension steel permitted is most nearly
(A) 5.6 in^2
(B) 7.7 in^2
(C) 8.5 in^2
(D) 9.2 in^2

The answer is (C).

(d) The minimum area of tension steel permitted is most nearly
(A) 1.0 in^2
(B) 1.3 in^2
(C) 1.5 in^2
(D) 1.8 in^2

The answer is (C).

(e) The maximum uniform factored load that the beam can sustain if no compression steel is used is most nearly
(A) 8.8 kips/ft
(B) 9.0 kips/ft
(C) 10 kips/ft
(D) 13 kips/ft

The answer is (C).

(f) The spacing of no. 3 U-shaped stirrups at the location where the shear is maximum is most nearly
(A) 5.0 in
(B) 5.8 in
(C) 6.6 in
(D) 8.3 in

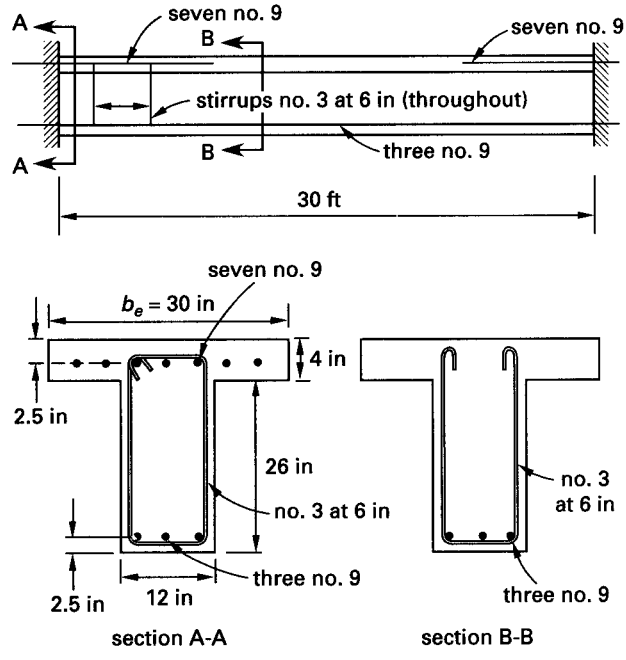
The answer is (C).

(g) The total length of the beam where no shear reinforcement is required is most nearly
(A) 10 in
(B) 12 in
(C) 15 in
(D) 20 in

The answer is (C).

(h) The maximum uniform factored load that the beam can be designed for, with the given dimensions, is most nearly
(A) 16 kips/ft
(B) 17 kips/ft
(C) 18 kips/ft
(D) 20 kips/ft

The answer is (C).



(i) If 50% of the live load is sustained, the service moment that should be used to compute the effective moment of inertia is most nearly
(A) 200 ft-kips
(B) 220 ft-kips
(C) 240 ft-kips
(D) 250 ft-kips

The answer is (C).

(j) The cracking moment is most nearly
(A) 40 ft-kips
(B) 45 ft-kips
(C) 51 ft-kips
(D) 54 ft-kips

The answer is (D).

3. (*Time limit: one hour*) A reinforced concrete T-beam section with a 30 ft span is fixed at both ends and is reinforced as shown. $f'_c = 3000$ lbf/in^2, and $f_y = 60{,}000$ lbf/in^2.

(a) The design moment capacity in the positive moment region is most nearly
(A) 300 ft-kips
(B) 360 ft-kips
(C) 400 ft-kips
(D) 410 ft-kips

The answer is (B).

(b) The stress in the compression steel in the negative moment region is most nearly
(A) 35 kips/in^2
(B) 47 kips/in^2
(C) 52 kips/in^2
(D) 60 kips/in^2

The answer is (D).

(c) The gross moment of inertia is most nearly
(A) 27,000 in^4
(B) 37,000 in^4
(C) 41,000 in^4
(D) 68,000 in^4

The answer is (B).

(d) The cracked moment of inertia in the positive moment region is most nearly
(A) 10,000 in^4
(B) 13,000 in^4
(C) 15,000 in^4
(D) 20,000 in^4

The answer is (C).

(e) The cracking moment in the positive moment region is most nearly
(A) 22 ft-kips
(B) 47 ft-kips
(C) 60 ft-kips
(D) 74 ft-kips

The answer is (D).

(f) The cracking moment in the negative moment region is most nearly
(A) 60 ft-kips
(B) 74 ft-kips
(C) 99 ft-kips
(D) 120 ft-kips

The answer is (C).

(g) If a uniformly distributed service load of 4 kips/ft acts on the beam, the stress in the tension steel in the positive moment region is most nearly
(A) 18 kips/in^2
(B) 23 kips/in^2
(C) 30 kips/in^2
(D) 35 kips/in^2

The answer is (B).

(h) For the service load of 4 kips/ft, the cracking parameter in the positive moment region is most nearly
(A) 86 kips/in
(B) 110 kips/in
(C) 150 kips/in
(D) 160 kips/in

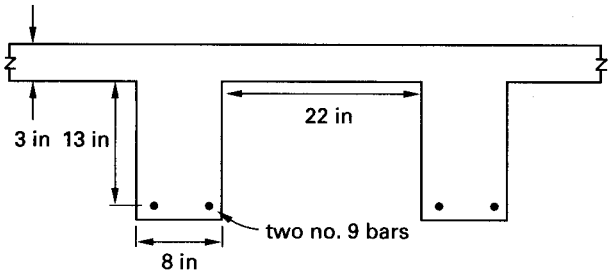
The answer is (A).

(i) The maximum uniform factored load that the beam can sustain as controlled by the shear reinforcement is most nearly
(A) 4.0 kips/ft
(B) 5.9 kips/ft
(C) 6.5 kips/ft
(D) 7.5 kips/ft

The answer is (C).

(j) The maximum uniform factored load that the beam can sustain as governed by the flexural capacity is most nearly
(A) 7.1 kips/ft
(B) 8.2 kips/ft
(C) 9.5 kips/ft
(D) 10 kips/ft

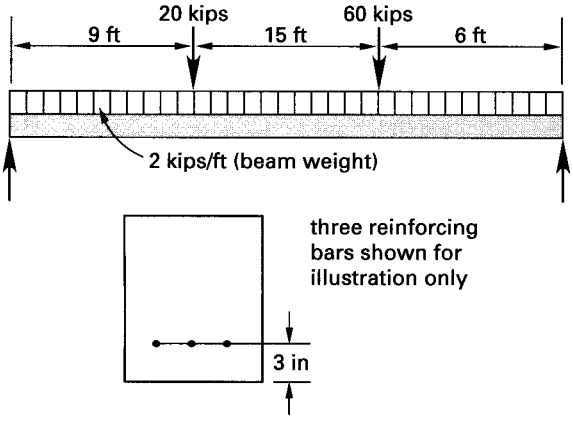
The answer is (C).



4. A singly reinforced rectangular beam carries a moment from dead loads of 50,000 ft-lbf and a moment from live loads of 200,000 ft-lbf. $f'_c = 3000$ lbf/in^2 and $f_y = 50{,}000$ lbf/in^2. No. 4 stirrups are to be used. Design and detail the cross section.

Answer: $b = 15.5$ in, $d = 27$ in, six no. 8 bars, $d_c = 2.5$ in

5. A beam must withstand an ultimate factored moment of 400,000 ft-lbf. $f'_c = 4000$ lbf/in^2, and $f_y = 40{,}000$ lbf/in^2. No. 3 stirrups will be used. (Do not design the shear reinforcement, check for cracking, or check deflection.) (a) Determine the beam width and depth. (b) Determine the required steel area. (c) How many layers of steel are needed? (d) What is the overall beam depth?

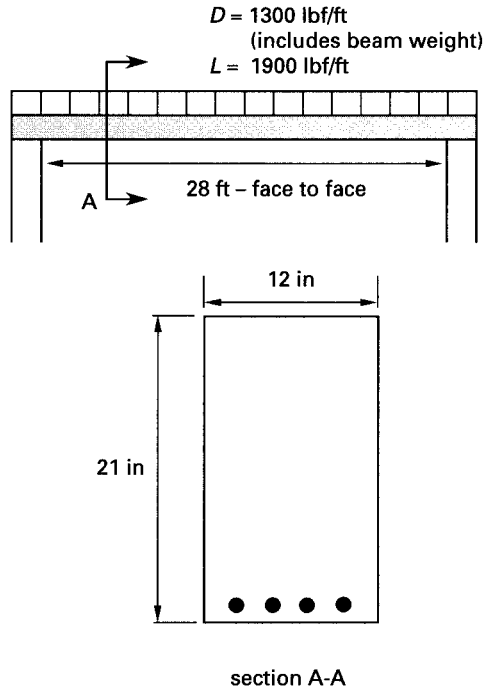


Answers: (There is no unique solution.) (a) $b = 14$ in, $d = 24.5$ in; (b) four no. 11 bars; (c) one layer; (d) 27.5 in

6. The slab shown supports a moment of 20,000 ft-lbf per foot of width. The concrete's unit weight is 145 lbf/ft^3, and f'_c = 3000 lbf/in^2. The response is elastic. Use the transformed area method of evaluating the stresses in the (a) concrete and (b) steel.

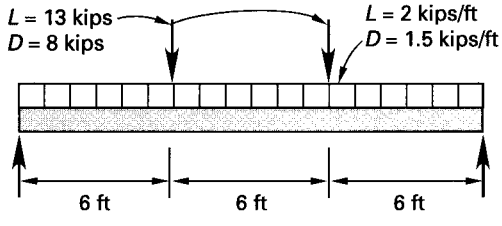
Answers: (a) 720 lbf/in^2; (b) 20,300 lbf/in^2

7. (*Time limit: one hour*) A rectangular, singly reinforced beam is shown. The beam supports two concentrated loads and a self-weight dead load of 2000 lbf/ft. f'_c = 4000 lbf/in^2, and f_y = 60,000 lbf/in^2. No. 11 steel bars must be used. The modular ratio is 8. (Do not design shear reinforcement.) (a) Determine the beam width and depth. (b) Determine the required steel area. (c) How many layers of steel are needed? (d) Check for cracking under exterior conditions.



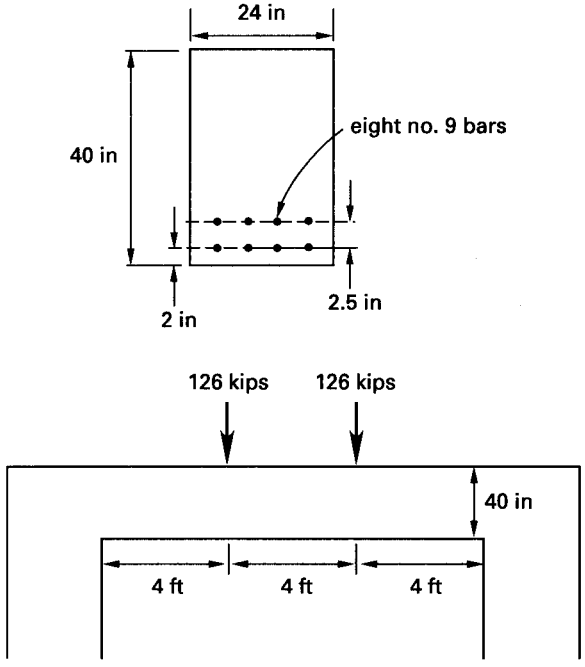
Answers: (There is no unique solution.) (a) b = 16 in, d = 32 in; (b) four no. 11 bars; (c) one layer

8. (*Time limit: one hour*) A simply supported, singly reinforced rectangular concrete beam supporting a roof is needed to span 27 ft. It carries a dead load of 1 kip/ft (which includes the beam weight) and a live load of 2 kips/ft. f'_c = 4000 lbf/in^2, f_y = 60,000 lbf/in^2, and $E_c = 3.6 \times 10^6$ lbf/in^2. The maximum permitted steel reinforcing is to be used. (a) Use no. 11 bars and a beam width of 14 in to design the beam. (b) If the beam has an interior exposure, will cracking be within limits? (c) If 30% of the live load is sustained, calculate the instantaneous and long-term centerline deflections.



Answers: (a) b = 14 in, d = 21 in, four no. 11 bars, h = 24 in; (b) yes; (c) instantaneous, 0.93 in, long-term, 1.9 in

9. (*Time limit: one hour*) The beam shown carries a dead load of 1300 lbf/ft (including its own weight) and a live load of 1900 lbf/ft. f'_c = 3000 lbf/in^2, and f_y = 60,000 lbf/in^2. The clear distance between the two beam supports is 28 ft. The beam's depth to reinforcement, d, is 21 in. (a) What additional shear reinforcement strength is required to be provided by the steel? (b) Over what length of the beam is shear reinforcement not required? (c) Assuming no. 3 bars are used, what stirrup spacing should be used between the face of the support out to a distance of 21 in from the face of the support?



Answers: (a) 45,200 lbf; (b) central 4.64 ft; (c) 6.1 in

10. (*Time limit: one hour*) The simply supported beam shown carries two identical sets of point loads and a set of uniform loadings. The beam has a width of 16 in. f'_c = 3000 lbf/in^2, and f_y = 60,000 lbf/in^2. (a) What is the ultimate moment? (b) Specify the minimum beam depth. (c) Detail the reinforcing steel. (d) Use no. 3 bars to design the shear reinforcing.

Answers: (a) 423 ft-kips; (b) 21.3 in; (c) four no. 10 bars; (d) spacing of 5.75 in; starting 10 in from the face

11. (*Time limit: one hour*) The doubly reinforced, deep concrete beam shown is to support two 126 kip loads, as indicated. $f'_c = 3000$ lbf/in^2, and $f_y = 60{,}000$ lbf/in^2. Disregard self-weight. No. 4 bars are used for vertical shear reinforcing and no. 5 bars are used for horizontal shear reinforcing. (a) What is the concrete shear stress? (b) How much vertical shear reinforcing is required? (c) Design the horizontal shear reinforcing.

Answers: (a) 260 lbf/in^2; (b) 23 kips, no. 4 stirrups with 6 in spacing; (c) no. 5 horizontal bars with 11 in spacing

1. INTRODUCTION

Slabs are structural elements whose lengths and widths are large in comparison to their thicknesses. Shear is generally carried by the concrete without the aid of shear reinforcement (which is difficult to place and anchor in shallow slabs). Longitudinal reinforcement is used to resist bending moments. Slab thickness is typically governed by deflection criteria.

A primary issue associated with the design of slabs is the computation of the moments induced by the applied loads. Since slabs are highly indeterminate two-dimensional structures, an exact analysis to obtain the distribution of moments is impractical. Fortunately, moments can be obtained using simplified techniques. In fact, in many instances, slabs can be designed assuming that all the load is carried by moments in one direction only. These slabs are known as one-way slabs and are discussed in detail starting in Sec. 2. A practical approach for obtaining the distribution of moments in the more general two-dimensional case is presented starting in Sec. 8.

2. ONE-WAY SLABS

Floor slabs are typically supported on all four sides. If the slab length is more than twice the slab width, a uniform load will produce a deformed surface that has little curvature in the direction parallel to the long dimension. Given that moments are proportional to curvature, bending moments will be significant only in the short direction. Slabs designed under the assumption that bending takes place in only one direction are known as *one-way slabs*.

In one-way slabs, the internal forces are computed by taking a strip of unit width and treating it like a beam. The torsional restraint introduced by the supporting beams is typically neglected. For example, the moments per unit width in the short direction for the floor system shown in Fig. 51.1(a) would be obtained by analyzing the four-span continuous beam depicted in Fig. 51.1(b).

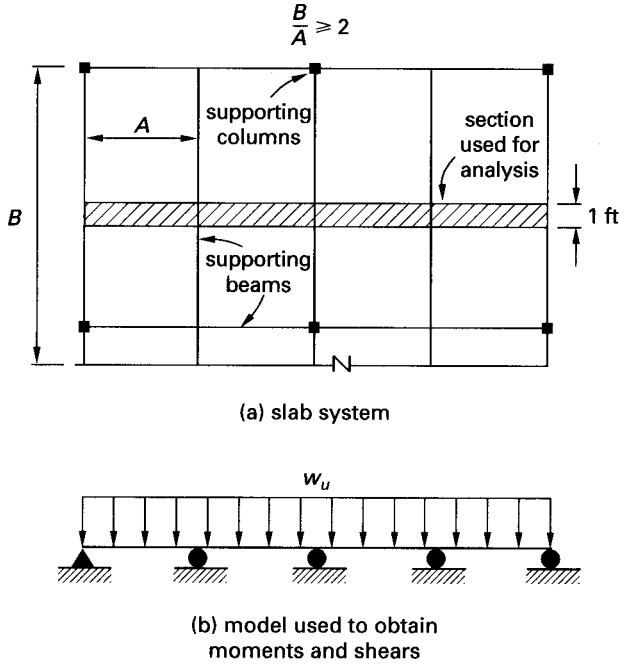

Figure 51.1 *One-Way Slab*

3. TEMPERATURE STEEL

Although one-way slabs are designed to be capable of carrying the full applied load by spanning in a single direction, ACI 318 7.12 requires that reinforcement for shrinkage and temperature stresses be provided normal to the main flexural steel. This is known as *temperature steel*. The minimum reinforcement ratio for shrinkage and temperature control (based on the gross area) is 0.0014 (up to but excluding grade-40 steel), 0.0020 (grade-40 and grade-50 steel), and 0.0018 (grade-60 steel). For steels with yield stresses exceeding 60 kips/in^2 (413.7 MPa), the minimum reinforcement ratio is

$$\rho_t = (0.0018)\left(\frac{413.7}{f_y}\right) \quad \text{[SI]} \qquad 51.1(a)$$

$$\rho_t = (0.0018)\left(\frac{60{,}000}{f_y}\right) \quad \text{[U.S.]} \qquad 51.1(b)$$

Although slabs are typically designed for uniform loads, slabs also experience significant concentrated loads. Temperature steel makes one-way slabs less vulnerable to excessive cracking from moments parallel to the long dimension that are induced by such concentrated loads. Temperature steel must be spaced no farther apart than five times the slab thickness nor 18 in (46.0 cm) (ACI 318 7.12.2.2).

Although no. 3 bars may be used, it is common practice to use no. 4 bars, which are stiffer and, therefore, bend less during construction handling and installation.

4. MINIMUM THICKNESS FOR DEFLECTION CONTROL

Deflections for one-way slabs can be computed using the procedures described for beams in Chap. 50. If the slab is not supporting or attached to partitions that are likely to be damaged by large deflections, the computation of deflections can be obviated if the thickness, h, equals or exceeds the values in Table 51.1.

Table 51.1 *Minimum One-Way Slab Thickness[a,b] (unless deflections are computed)*

construction	minimum thickness, h (fraction of span length[c])
simply supported	$\frac{1}{20}$
one end continuous	$\frac{1}{24}$
both ends continuous	$\frac{1}{28}$
cantilever	$\frac{1}{10}$

[a] ACI 318 Table 9.5
[b] For normal-weight concrete reinforced with $f_y = 60{,}000$ lbf/in^2 (413.7 MPa) steel
[c] For slabs built integrally with supports, the minimum depth can be based on the clear span. For slabs that are not built integrally with supports, the span length (for the purposes of this table) equals the clear span plus the thickness of the slab but need not exceed the centerline-to-centerline distance.

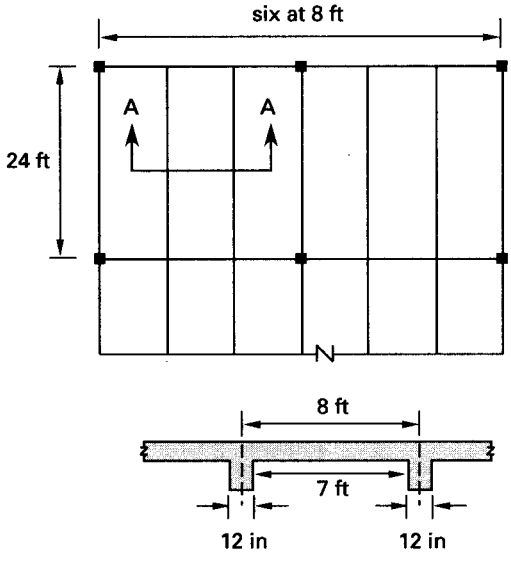
5. ANALYSIS USING ACI COEFFICIENTS

Although the shear and moments in one-way slabs can be computed using standard indeterminate structural analysis, ACI 318 8.3.3 specifies a simplified method that can be used when the following conditions are satisfied: (a) There are two or more spans. (b) Spans are approximately equal, with the longer of two adjacent spans not longer than the shorter by more than 20%. (c) The loads are uniformly distributed. (d) The ratio of live to dead loads is no more than 3. (e) The slab has a uniform thickness. The formulas for calculating moments and shears when these conditions apply were presented in Chap. 47.

6. SLAB DESIGN FOR FLEXURE

The procedure for selecting steel reinforcement is identical to that for beams, except that moments per unit width are used. Designating the required area of steel

Table 51.2 *Average Steel Area per Foot of Width*



bar size number	nominal diameter (in)	spacing of bars in inches													
		2	$2\frac{1}{2}$	3	$3\frac{1}{2}$	4	$4\frac{1}{2}$	5	$5\frac{1}{2}$	6	7	8	9	10	12
3	0.375	0.66	0.53	0.44	0.38	0.33	0.29	0.26	0.24	0.22	0.19	0.17	0.15	0.13	0.11

(Multiply in by 25.4 to obtain mm.)
(Multiply in^2 by 645 to obtain mm^2.)

per unit width as A_{sr} and the area of one bar as A_b, the spacing of the reinforcement, s, is given by Eq. 51.2. The maximum spacing for the main steel is three times the slab thickness but no more than 18 in (46 cm) (ACI 318 7.6.5). The smallest bar size typically used for flexural resistance is no. 4. Table 51.2 can be used to select the steel reinforcement if the steel area per foot of width is known.

$$s = \frac{A_b}{A_{sr}} \qquad 51.2$$

Although the design procedures for beams and slabs are similar, there are some differences. (a) The minimum cover for the steel is 3/4 in (19 mm). (b) The minimum steel ratio is equal to that used for shrinkage and temperature. The equations for minimum steel used in beams do not apply.

section A-A

7. SLAB DESIGN FOR SHEAR

Due to the small thickness, shear reinforcement is difficult to anchor and is seldom used in one-way slabs. Because one-way slabs are wide members, the requirement for no shear reinforcement is strictly $\phi V_c \geq V_u$. As in beams, the critical section for shear is at a distance d from the face of the support if the support induces compression in the vertical direction.

Example 51.1

A floor system with columns in a 24 ft grid is shown. Beams in the north-south direction spaced at 8 ft on centers are used to create one-way slab action. The floor is subjected, in addition to its own weight, to dead and live loads of 20 lbf/ft^2 and 50 lbf/ft^2, respectively. $f'_c = 3000$ lbf/in^2, and $f_y = 60{,}000$ lbf/in^2. No. 4 bars are used for flexural reinforcement, and no. 3 bars are to be used for temperature steel. Select the thickness of the slab and design the flexural reinforcement.

Solution

Begin by determining the required thickness. From Table 51.1, for an edge panel,

$$h \geq \frac{l}{24}$$

$$= \frac{(7 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{24} = 3.5 \text{ in} \quad \text{[say 4 in]}$$

(The interior panels could be made thinner than the edge panels.)

The slab weight is

$$\frac{\left(150 \frac{\text{lbf}}{\text{ft}^3}\right)(4 \text{ in})}{12 \frac{\text{in}}{\text{ft}}} = 50 \text{ lbf/ft}^2$$

The factored load is

$$\begin{aligned} U &= 1.4D + 1.7L \\ &= (1.4)\left(50\ \frac{\text{lbf}}{\text{ft}^2} + 20\ \frac{\text{lbf}}{\text{ft}^2}\right) + (1.7)\left(50\ \frac{\text{lbf}}{\text{ft}^2}\right) \\ &= 183\ \text{lbf/ft}^2 \end{aligned}$$

Next, obtain the factored moments using moment coefficients with Eq. 47.42 and shear coefficients with Eq. 47.43. Consider a 1 ft wide strip.

The exterior negative moment is

$$\begin{aligned} \frac{w_u l_n^2}{24} &= \frac{\left(0.183\ \frac{\text{kip}}{\text{ft}}\right)(7\ \text{ft})^2}{24} \\ &= 0.374\ \text{ft-kip} \end{aligned}$$

The interior negative moment is

$$\begin{aligned} \frac{w_u l_n^2}{12} &= \frac{\left(0.183\ \frac{\text{kip}}{\text{ft}}\right)(7\ \text{ft})^2}{12} \\ &= 0.747\ \text{ft-kip} \end{aligned}$$

The positive moment in the exterior span is

$$\begin{aligned} \frac{w_u l_n^2}{14} &= \frac{\left(0.183\ \frac{\text{kip}}{\text{ft}}\right)(7\ \text{ft})^2}{14} \\ &= 0.641\ \text{ft-kip} \end{aligned}$$

The positive moment in the interior spans is

$$\begin{aligned} \frac{w_u l_n^2}{16} &= \frac{\left(0.183\ \frac{\text{kip}}{\text{ft}}\right)(7\ \text{ft})^2}{16} \\ &= 0.560\ \text{ft-kip} \end{aligned}$$

The maximum shear is

$$\begin{aligned} \frac{1.15 w_u l_n}{2} &= \frac{(1.15)\left(0.183\ \frac{\text{kip}}{\text{ft}}\right)(7\ \text{ft})}{2} \\ &= 0.737\ \text{kip} \end{aligned}$$

Compute the effective depth. Using no. 4 bars,

$$\begin{aligned} d &= h - \text{cover} - 0.25\ \text{in} = 4\ \text{in} - 0.75\ \text{in} - 0.25\ \text{in} \\ &= 3\ \text{in} \end{aligned}$$

Check the shear capacity.

$$\begin{aligned} V_c &= 2\sqrt{f'_c}\, b_w d \\ &= \frac{2\sqrt{3000\ \frac{\text{lbf}}{\text{in}^2}}(12\ \text{in})(3\ \text{in})}{1000\ \frac{\text{lbf}}{\text{kip}}} \\ &= 3.94\ \text{kips} \\ \phi V_c &= (0.85)(3.94\ \text{kips}) \\ &= 3.35\ \text{kips} > 0.737\ \text{kip} \quad \text{[OK]} \end{aligned}$$

Design the flexural reinforcement. The interior negative moment is the largest. As with beams, initially estimate λ.

$$\begin{aligned} \lambda &= 0.1d = (0.1)(3\ \text{in}) \\ &= 0.3\ \text{in} \end{aligned}$$

From Chap. 50, Eq. 50.19,

$$\begin{aligned} A_s &= \frac{M_u}{\phi f_y (d - \lambda)} \\ &= \frac{(0.747\ \text{ft-kip})\left(12\ \frac{\text{in}}{\text{ft}}\right)}{(0.9)\left(60\ \frac{\text{kips}}{\text{in}^2}\right)(3\ \text{in} - 0.3\ \text{in})} \\ &= 0.0615\ \text{in}^2 \end{aligned}$$

The minimum steel is $(0.0018)(12\ \text{in})(4\ \text{in}) = 0.0864\ \text{in}^2$, which is larger than the steel required to resist the maximum moment. Therefore, the minimum steel controls at all locations.

The maximum bar spacing is (3)(4 in) = 12 in. Since the area of a no. 4 is 0.2 in^2, the maximum spacing controls. Use no. 4 bars on 12 in centers for positive and negative moments.

Temperature steel is required parallel to the long direction. Using no. 3 bars, the required spacing is

$$\begin{aligned} s = \frac{A_b}{A_{sr}} &= \frac{(0.11\ \text{in}^2)\left(12\ \frac{\text{in}}{\text{ft}}\right)}{0.0864\ \frac{\text{in}^2}{\text{ft}}} \\ &= 15.28\ \text{in} \end{aligned}$$

The maximum spacing for temperature steel is the minimum of five times the slab thickness: (5)(4 in) = 20 in or 18 in. Use no. 3 bars on 15 in centers in the long direction as temperature reinforcement.

8. TWO-WAY SLABS

Slabs are classified as *two-way slabs* when the ratio of long-to-short sides is less than 2. A two-way slab supported on a column grid without the use of beams (Fig. 51.2(a)) is known as a *flat plate*. A modified version of a flat plate, where the shear capacity around the columns is increased by thickening the slab in those regions, is known as a *flat slab* (Fig. 51.2(b)). The thickened part of the flat plate is known as a *drop panel*. Another two-way slab often used without beams between column lines is a *waffle-slab* (Fig. 51.2(c)). In a waffle-slab, the forms used to create the voids are omitted around the columns to increase resistance to punching shear. A two-way slab system supported on beams is illustrated in Fig. 51.2(d).

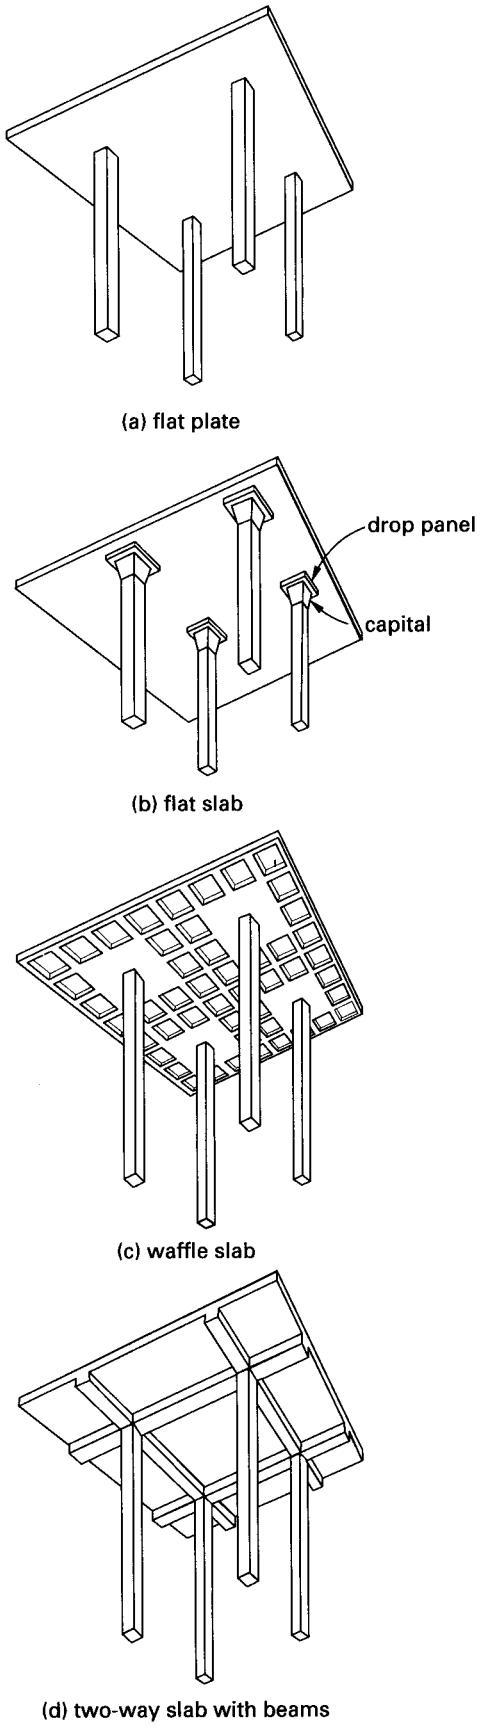

Figure 51.2 *Two-Way Slabs*

The moments used to design the reinforcement in two-way slabs, whether with or without beams, are obtained in the same manner as for beams and one-way slabs: The slab system and supporting columns are reduced to a series of one-dimensional frames running in both directions. As Fig. 51.3 illustrates, the beams in the frames are wide elements whose edges are defined by cuts midway between the columns. In ACI 318, the dimensions associated with the direction in which moments are being computed are identified by the subscript 1 and the those in the transverse direction by the subscript 2. Note from Fig. 51.3 that the width of the wide beam is the average of the transverse panel dimensions on either side of the column line. For the edge frames, the width is half the width (centerline-to-centerline) of the first panel.

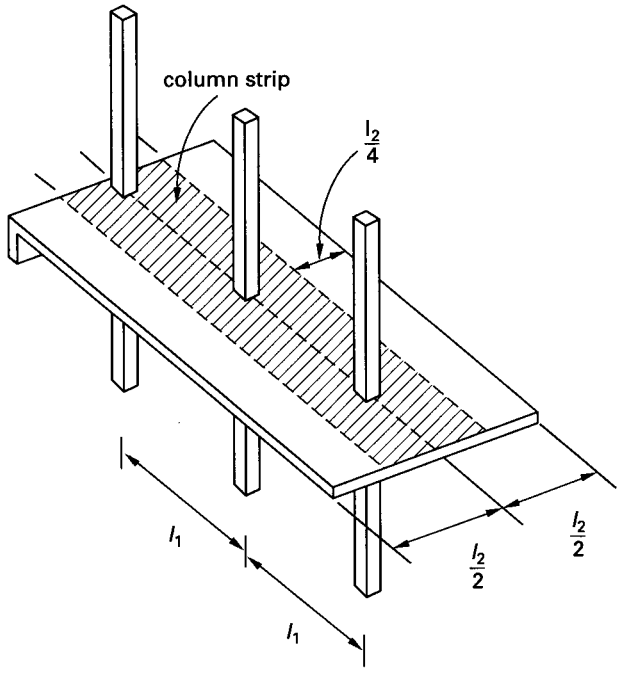

Figure 51.3 *Wide Beam Frame (used in the analysis of two-way slabs)*

If the small effect of edge panels is neglected, and if the slab system is assumed to be uniformly loaded (from symmetry), the vertical shears and torques in the edges of the wide beams will be zero. There are two steps in the analysis of two-way slabs using the procedure in ACI 318: (a) calculating the longitudinal distribution of the moments (variation in the direction l_1), and (b) distributing the moment at any cross section across the width of the wide beams.

ACI 318 provides two alternative methods for computing the longitudinal distribution of moments. In the *equivalent frame method* (EFM), the moments are obtained from a structural analysis of the wide beam frame. In this analysis, it is customary to treat the columns as fixed one level above and below the level

Structural

Table 51.3 *Distribution of Moments in Exterior Spans*

	exterior edge unrestrained	slab with beams between all supports	slabs without beams between interior supports: without edge beam	slabs without beams between interior supports: with edge beam	exterior edge fully restrained
interior negative factored moment	0.75	0.70	0.70	0.70	0.65
positive factored moment	0.63	0.57	0.52	0.50	0.35
exterior negative factored moment	0	0.16	0.26	0.30	0.65

being considered. (Special provisions that apply to the definition of the stiffness of the elements in the equivalent frame, and to other related aspects, are presented in ACI 318 13.7.) In the second alternative, known as the *direct design method* (DDM), the moments are obtained using a simplified procedure conceptually similar to that introduced for one-way slabs [ACI 318 13.6].

The procedure to distribute the moment computed at any section of the wide beam across the width of the wide beam is not dependent on whether the EFM or the DDM is used.

9. DIRECT DESIGN METHOD

The DDM can be used when the following conditions are met: (a) There are a minimum of three spans. (b) Panels are rectangular with a ratio of long-to-short side (center-to-center of supports) of no more than 2. (c) Successive span lengths do not differ by more than one third of the longest span. (d) Columns are not offset by more than 10% of the span in the direction of the offset.[1] (e) The loading consists of uniformly distributed gravity loads. (f) The service live load does not exceed two times the dead load. (g) If beams are present, the relative stiffness in two perpendicular directions, $\alpha_1 l_2^2/\alpha_2 l_1^2$, is not less than 0.2 nor greater than 5.0.

The following steps constitute the direct design method.

step 1: Divide the floor system in each direction into wide beams as shown in Fig. 51.3.

step 2: Calculate the total statical moment in each span from Eq. 51.3 [ACI 318 13.6.2.2].

$$M_o = \frac{w_u l_2 l_n^2}{8} \qquad 51.3$$

This moment is the maximum moment in a simple beam of span l_n that carries the total load ($w_u l_2$). In Eq. 51.3, the span l_2 refers to the width of the wide beam being considered. l_n is measured face-to-face of columns or other supports. However, $l_n \geq 0.65 l_1$. For the computation of minimum thickness in two-way slabs, l_n is taken as the distance face-to-face of supports in slabs without beams and face-to-face of beams or other supports in other cases.

step 3: Divide the total moment, M_o, in each span into positive and negative moments. For interior spans, the negative factored moment is calculated as $0.65M_o$, and the positive factored moment is $0.35M_o$. The total moment in end (exterior) spans is distributed according to the coefficients in Table 51.3.

step 4: Divide the width of the wide beam into column-strip and middle-strip regions. A *column strip* is a design strip with a width of each side of the column centerline equal to $0.25l_2$ or $0.25l_1$, whichever is less. A *middle strip* is a design strip bounded by two column strips.

step 5: Design the column strip for the percentages of the moment at each section according to Table 51.4.

step 6: Design the middle strip for the percentages of the moment at each section not assigned to the column strip.

10. FACTORED MOMENTS IN SLAB BEAMS

A "beam," for the purpose of designing two-way slabs, is illustrated in Fig. 51.4. A beam includes the portion of the slab on each side extending a distance equal to the projection of the beam above or below the slab, whichever is largest, but not greater than four times the slab thickness.

[1]For design purposes, the moments are computed neglecting the column offsets. This procedure will lead to an adequate design if the column offset does not exceed the limit specified. For larger offsets, neither the DDM nor the EFM apply. It is customary in these cases to calculate the moments in the slab using a finite element model.

The distribution of moments in two-way slabs depends on the relative stiffness of the beams (with respect to the slab without beams). ACI 318 designates this relative stiffness as α, which is the ratio of the flexural stiffness of the beam (as defined in Fig. 51.4) to the flexural stiffness of a slab of width equal to that of the wide beam.

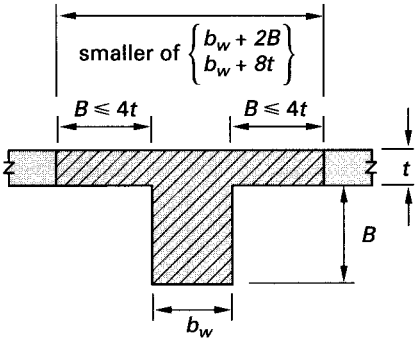
$$\alpha = \frac{E_{cb} I_b}{E_{cs} I_s} \qquad 51.4$$

When beams are part of the column strip, they are proportioned to resist 85% of the column strip moment if $\alpha_1 l_2/l_1 \geq 1$. For values of $\alpha_1 l_2/l_1$ between 0 and 1, linear interpolation is used to select the moment to be assigned to the beam, with zero percent assigned when $\alpha_1 l_2/l_1 = 0$. The value of l_2 in the previous expressions refers to the average of the values for the panels on either side of the column line (i.e., to the width of the wide beam).

Table 51.4 *Distribution of Moments in Column Strips*[a,b]

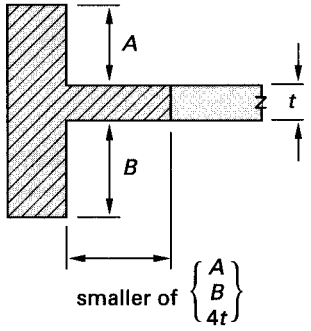
(a) *interior negative moment*

$\frac{l_2}{l_1}$	0.5	1.0	2.0
$\alpha_1 \frac{l_2}{l_1} = 0$ (no beams)	75	75	75
$\alpha_1 \frac{l_2}{l_1} \geq 1$	90	75	40



(b) *exterior negative moment*

$\frac{l_2}{l_1}$		0.5	1.0	2.0
$\alpha_1 \frac{l_2}{l_1} = 0$	$\beta_t = 0$	100	100	100
$\alpha_1 \frac{l_2}{l_1} = 0$	$\beta_t \geq 2.5$	75	75	75
$\alpha_1 \frac{l_2}{l_1} \geq 1$	$\beta_t = 0$	100	100	100
$\alpha_1 \frac{l_2}{l_1} \geq 1$	$\beta_t \geq 2.5$	90	75	45



(c) *positive factored moment*

$\frac{l_2}{l_1}$	0.5	1.0	2.0
$\alpha_1 \frac{l_2}{l_1} = 0$ (no beams)	60	60	60
$\alpha_1 \frac{l_2}{l_1} \geq 1$	90	75	45

[a]Linear interpolation is used between the values shown.
[b]Middle strips are designed for the fraction of the moment not assigned to the column strip.

(a) interior

(b) exterior

Figure 51.4 *Slab Beams (monolithic or fully composite construction) [ACI 318 13.2.4]*

11. COMPUTATION OF β_t

The distribution of the negative moment across the width of a slab at the exterior edge depends not only on the relative beam stiffness and the ratio l_2/l_1, but also on the stiffness in the torsion of edge beams. ACI 318 uses the parameter β_t to quantify the relative torsional stiffness of the edge beam.

$$\beta_t = \frac{E_{cb} C}{2 E_{cs} I_s} \qquad 51.5$$

$$C = \sum \left(1 - 0.63 \left(\frac{x}{y}\right)\right) \left(\frac{x^3 y}{3}\right) \qquad 51.6$$

The summation in Eq. 51.6 is taken over all of the separate rectangles that make up the edge beam (which is typically L-shaped as illustrated in Fig. 51.4). The division into separate rectangles that leads to the largest value of C should be used.

12. DEFLECTIONS IN TWO-WAY SLABS

Accurate estimates of deflections in two-way slabs are difficult to obtain. In practice, rather than attempting to calculate deflections accurately, two-way slabs should be sized to satisfy the minimum thickness values given in ACI 318 9.5.3.

Structural

Table 51.5 *Minimum Thickness for Slabs Without Interior Beams (longest clear span divided by value given)*

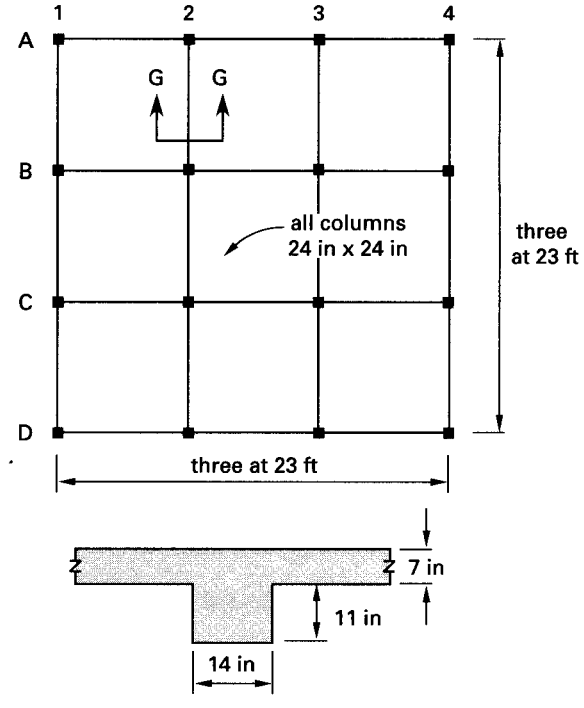
	without drop panels			with drop panels		
	exterior panels (in)		interior panels (in)	exterior panels (in)		interior panels (in)
yield strength (lbf/in^2)	without edge beams	with edge beams		without edge beams	with edge beams	
40,000	33	36	36	36	40	40
60,000	30	33	33	33	36	36
75,000	28	31	31	31	34	34

For slabs without beams or whose beams are only placed between exterior columns (i.e., slabs without beams between interior supports), minimum thickness is specified as the largest clear span (face-to-face of supports) divided by the values listed in Table 51.5. For the values in Table 51.5 to be useful, drop panels must project below the slab at least one-quarter of the slab thickness beyond the drop and must extend in each direction at least one-sixth the length of the corresponding span. The thickness of the slab without drop panels may not be less than 5 in. Slabs with drop panels may not be less than 4 in thick.

For the purpose of calculating minimum thickness in slabs with beams between interior supports, there are three possibilities. For $\alpha_m \leq 0.2$, the minimum thickness is computed neglecting the beams. For $0.2 < \alpha_m \leq 2.0$, the minimum thickness is

$$h = \frac{l_n\left(0.8 + \frac{f_y}{200{,}000}\right)}{36 + 5\beta(\alpha_m - 0.2)} \geq 5 \text{ in} \qquad 51.7$$

For $\alpha_m > 2.0$, the minimum thickness is

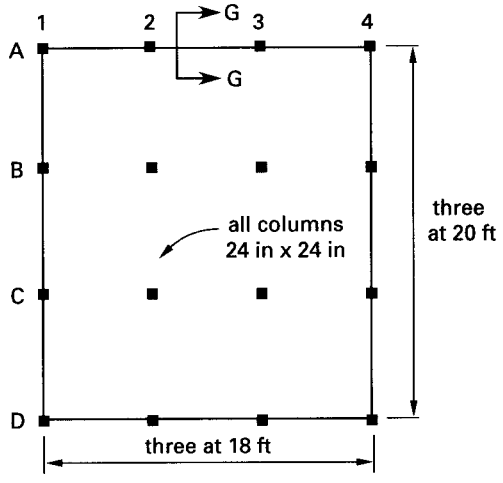


$$h = \frac{l_n\left(0.8 + \frac{f_y}{200{,}000}\right)}{36 + 9\beta} \geq 3.5 \text{ in} \qquad 51.8$$

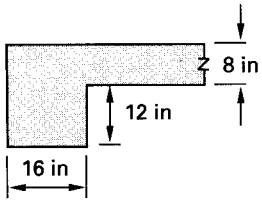
When the stiffness ratio α of the edge beam is less than 0.8, the minimum thickness in the edge panel shall be at least 10% larger than the value obtained from Eqs. 51.7 and 51.8.

PRACTICE PROBLEMS

One-Way Slabs



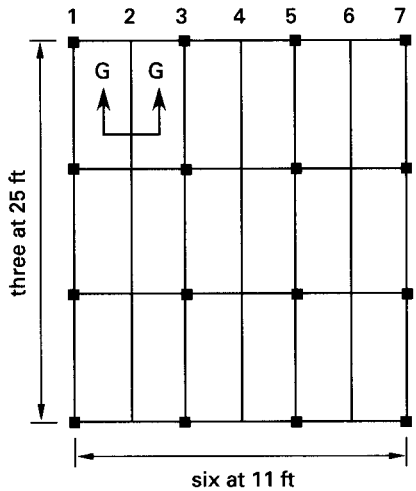
1. A plan of a floor system supported on beams is shown. In addition to its own weight, the floor is subjected to uniformly distributed dead and live loads of 30 lbf/ft^2 and 50 lbf/ft^2, respectively. Material properties are $f'_c = 4000$ lbf/in^2 and $f_y = 60{,}000$ lbf/in^2. (a) Calculate the relative beam stiffness for beam A2-B2. (b) Determine if the thickness of the slab is adequate for deflection control. (c) Design the steel reinforcement for positive moment in beam A2-B2.

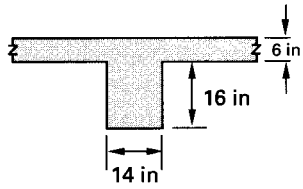


section G-G

Answers: (a) 1.31; (b) adequate; (c) three no. 7 bars per ft

2. A flat plate with an edge beam is shown. In addition to its own weight, the floor slab is subjected to uniformly distributed dead and live loads of 20 lbf/ft^2 and 50 lbf/ft^2, respectively. Material properties are f'_c = 4000 lbf/in^2 and f_y = 40,000 lbf/in^2. (a) Determine the torsional constant, C, for the edge beam in span A2-A3. (b) Determine the adequacy of the slab thickness for deflection control. (c) Design the positive reinforcement needed in the column strip whose center lies on the axis A2-B2.





section G-G

Answers: (a) 14,732 in^4; (b) adequate; (c) fourteen no. 4 bars per ft

3. (*Time limit: one hour*) The floor system shown is subjected, in addition to its own weight, to uniformly distributed dead and live loads of 20 lbf/ft^2 and 80 lbf/ft^2, respectively. Material properties are f'_c = 3000 lbf/in^2 and f_y = 40,000 lbf/in^2.

section G-G

(a) Assuming a single slab depth is used throughout, the minimum thickness required for deflection control is most nearly

(A) 5.0 in
(B) 5.5 in
(C) 6.0 in
(D) 7.5 in

The answer is (A).

For parts (b) through (j), assume the slab thickness is 6 in.

(b) The factored uniform load is most nearly

(A) 130 lbf/ft^2
(B) 160 lbf/ft^2
(C) 270 lbf/ft^2
(D) 300 lbf/ft^2

The answer is (C).

(c) The maximum live load that the slab can carry, as limited by shear, is most nearly

(A) 400 lbf/ft^2
(B) 470 lbf/ft^2
(C) 500 lbf/ft^2
(D) 600 lbf/ft^2

The answer is (C).

Structural

(d) The required spacing of no. 3 bars parallel to the N-S direction is most nearly

(A) 7 in
(B) 8 in
(C) 9 in
(D) 10 in

The answer is (C).

(e) The maximum positive moment in this floor system is most nearly

(A) 1.5 ft-kip/ft
(B) 1.6 ft-kip/ft
(C) 1.9 ft-kip/ft
(D) 2.1 ft-kip/ft

The answer is (C).

(f) The maximum negative moment in this floor system is most nearly

(A) 2.5 ft-kip/ft
(B) 2.6 ft-kip/ft
(C) 2.9 ft-kip/ft
(D) 3.1 ft-kip/ft

The answer is (B).

(g) The spacing of no. 4 bars for negative moment normal to axis 2 is most nearly

(A) 9 in
(B) 10 in
(C) 12 in
(D) 14 in

The answer is (C).

(h) The spacing of no. 6 bars for positive moment in the span between axes 2 and 3 is most nearly

(A) 12 in
(B) 16 in
(C) 18 in
(D) 27 in

The answer is (C).

(i) The spacing of no. 4 bars for positive moment in the span between axes 2 and 3 is most nearly

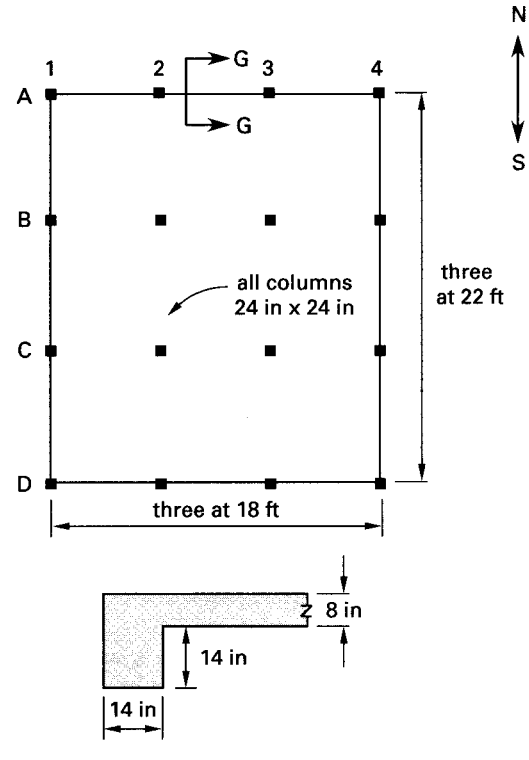
(A) 14 in
(B) 17 in
(C) 19 in
(D) 20 in

The answer is (B).

(j) The load per foot that should be used to design the beam located on axis 2 is most nearly

(A) 2.8 kips/ft
(B) 3.0 kips/ft
(C) 3.2 kips/ft
(D) 3.5 kips/ft

The answer is (D).



Two-Way Slabs

4. (*Time limit: one hour*) A flat plate is supported on 24 in by 24 in columns that are spaced 18 ft in the E-W and 22 ft in the N-S direction. In addition to its own weight, the floor is subjected to uniformly distributed dead and live loads of 20 lbf/ft^2 and 50 lbf/ft^2, respectively. Material properties are $f'_c = 4000$ lbf/in^2 and $f_y = 60{,}000$ lbf/in^2.

(a) The torsional constant C for the edge beam is most nearly

(A) 9000 in^4
(B) 12,000 in^4
(C) 14,000 in^4
(D) 34,000 in^4

The answer is (C).

section G-G

(b) The minimum thickness for deflection control is most nearly

(A) 6.0 in
(B) 7.3 in
(C) 8.0 in
(D) 8.5 in

The answer is (B).

(c) The minimum thickness if the edge beam is eliminated is most nearly

(A) 6.0 in
(B) 7.5 in
(C) 8.0 in
(D) 8.5 in

The answer is (C).

(d) The relative torsional stiffness, β_t, for the edge beam spanning in the E-W direction is most nearly

(A) 0.50
(B) 0.75
(C) 1.00
(D) 1.3

The answer is (B).

(e) The maximum positive moment in the column strip that runs from B2 to C2 is most nearly

(A) 40 ft-kips
(B) 48 ft-kips
(C) 52 ft-kips
(D) 62 ft-kips

The answer is (B).

(f) The maximum positive moment in the column strip that runs from B1 to C1 is most nearly

(A) 24 ft-kips
(B) 26 ft-kips
(C) 28 ft-kips
(D) 31 ft-kips

The answer is (A).

(g) The maximum positive moment in the N-S middle strips in panel B2-B3-C2-C3 is most nearly

(A) 28 ft-kips
(B) 32 ft-kips
(C) 38 ft-kips
(D) 40 ft-kips

The answer is (B).

(h) If drop panels that meet ACI 318 requirements are provided, the minimum thickness for deflection control (outside the drop panel) is most nearly

(A) 5.5 in
(B) 6.7 in
(C) 7.5 in
(D) 8.0 in

The answer is (B).

(i) The required total thickness for the drop panels is most nearly

(A) 7.0 in
(B) 7.5 in
(C) 8.5 in
(D) 9.0 in

The answer is (C).

(j) The minimum dimension in the E-W direction for interior drop panels is most nearly

(A) 3 ft
(B) 5 ft
(C) 6 ft
(D) 7 ft

The answer is (C).

1. INTRODUCTION

Columns are vertical members whose primary purpose is to transfer axial compression to lower members. In many practical situations, columns are subjected not only to axial compression but also to significant bending moments. Another factor sometimes increasing column loads is the P-Δ effect. The P-Δ effect refers to the increase in moment that results when the column sways, adding eccentricity. Columns where the P-Δ effect is significant are known as *long columns*. In this chapter we focus on the design of *short columns* only, that is, columns where the P-Δ effect can be neglected. (Long columns are covered in Chap. 53.)

Columns that are part of braced structures are considered to be short columns if Eq. 52.1 holds. The quantity $k_b l_u / r$ is the column's *slenderness ratio*. M_1 is the smaller (in absolute value) of the two end moments acting on a column. M_2 is the larger (in absolute value) of the two end moments acting on a column. The ratio M_1/M_2 cannot be less than -0.5. In Eq. 52.1, it is always conservative to take $k_b = 1$.

$$\frac{k_b l_u}{r} \leq 34 - 12\left(\frac{M_1}{M_2}\right) \qquad 52.1$$

Columns that are part of unbraced structures are considered to be short columns if Eq. 52.2 holds.

$$\frac{k_u l_u}{r} \leq 22 \quad [k_u > 1] \qquad 52.2$$

The effective length factors, k_b and k_u, used in Eqs. 52.1 and 52.2, are discussed in Chap. 53. (ACI 318 uses the notation k to represent both k_b and k_u.)

2. TIED COLUMNS

Reinforced concrete columns with transverse reinforcement in the form of individually tied hoops are known as *tied columns*. Figure 52.2 illustrates a number of typical configurations. The following construction details are specified by ACI 318 for tied columns.

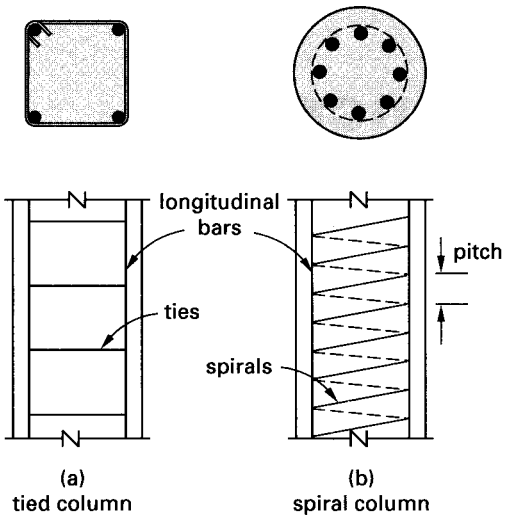

Figure 52.1 *Tied and Spiral Columns*

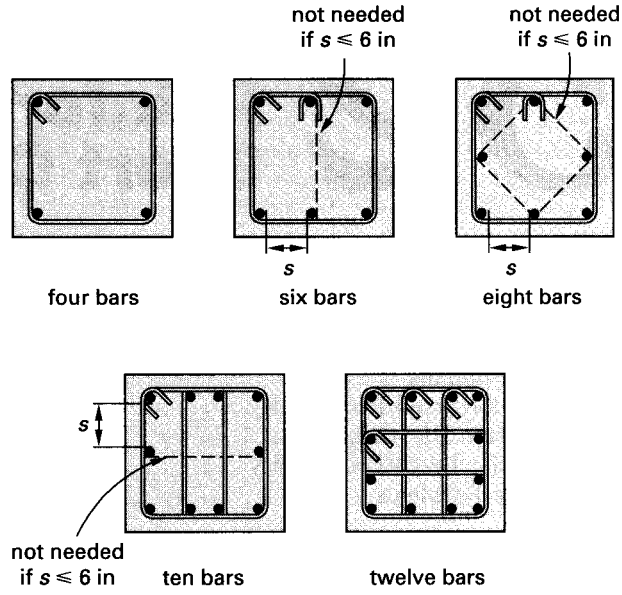

Figure 52.2 *Types of Tied Columns*

- Longitudinal bars must have a clear distance between bars of at least 1.5 times the bar diameter, but not less than 1.5 in [ACI 318 7.6.3].
- Ties must be at least no. 3 if the longitudinal reinforcement consists of bars no. 10 in size or smaller. For bars larger than no. 10, or when bundles are used in the longitudinal reinforcement, the minimum tie size is no. 4 [ACI 318 7.10.5.1]. (The maximum practical tie size is normally no. 5.)
- The concrete cover must be at least 1.5 in over the outermost surface of the tie steel [ACI 318 7.7.1].
- At least four longitudinal bars are needed for columns with square or circular ties [ACI 318 10.9.2].
- The ratio of longitudinal steel area to the gross column area (see Eq. 52.12) must be between 0.01 and 0.08 [ACI 318 10.9.1]. (The lower limit keeps the column from being designed as all-concrete. The upper limit keeps the column from being too slender.)

$$0.01 \leq \rho_g \leq 0.08 \qquad 52.3$$

- Center-to-center spacing of ties must not exceed the smallest of 16 longitudinal bar diameters, 48 diameters of the tie, or the smaller exterior column dimension [ACI 318 7.10.5.2].
- Every corner and alternating longitudinal bar must be supported by a tie corner. The included angle of the tie cannot be more than 135° [ACI 318 7.10.5.3]. (Tie corners are not relevant to tied columns with longitudinal bars placed in a circular pattern.)
- No longitudinal bar can be more than 6 in away from a bar that is properly restrained by a corner [ACI 318 7.10.5.3].

3. SPIRAL COLUMNS

Reinforced concrete columns with transverse reinforcement in the form of a continuous spiral are known as *spiral columns*. The following construction details are specified by ACI 318 for spiral columns.

- Longitudinal bars must have a clear distance between bars of at least 1.5 times the bar diameter but not less than 1.5 in [ACI 318 7.6.3].
- The minimum spiral wire diameter is $^3/_8$ in [ACI 318 7.10.4.2]. (The maximum practical spiral diameter is $^5/_8$ in.)
- The clear distance between spirals cannot exceed 3 in nor be less than 1 in [ACI 318 7.10.4.3].
- The concrete cover should be at least 1.5 in from the outermost surface of the spiral steel [ACI 318 7.7.1].
- At least six longitudinal bars are to be used for spiral columns [ACI 318 10.9.2].
- The ratio of the longitudinal steel area to the gross column area must be between 0.01 and 0.08 [ACI 318 10.9.1].

ACI 318 also requires that the ratio of the volume of spiral reinforcement to the volume of the column core (concrete placed inside the spiral) be no less than the value in Eq. 52.4. A_c is the area of the core, measured to the outside surface of the spiral reinforcement, and A_g is the gross section area.

$$\rho_s = 0.45\left(\frac{A_g}{A_c} - 1\right)\left(\frac{f'_c}{f_y}\right) \qquad 52.4$$

Once the spiral wire diameter is selected, the spiral pitch needed to satisfy Eq. 52.4 can be easily computed from Eq. 52.5, where A_{sp} is the area of the spiral wire and D_c is the diameter of the core measured to the outside surface of the spiral.

$$s \approx \frac{4A_{sp}}{\rho_s D_c} \qquad 52.5$$

The clear distance between the spirals is related to the spiral pitch, s, by Eq. 52.6 where d_{sp} is the diameter of the spiral wire.

$$\text{clear distance} = s - d_{sp} \qquad 52.6$$

The design of spiral reinforcing consists of the following steps: (a) Select a wire size. (A starting estimate for a spiral wire size can be obtained from Table 52.1.) (b) Evaluate Eqs. 52.4 and 52.5 to determine the required pitch. (c) Compute the clear spacing from Eq. 52.6. (d) Make sure the limit on clear spacing is satisfied.

Table 52.1 *Typical Spiral Wire Sizes*[a]

column diameter	spiral wire size (in)
up to 15 in, using no. 10 bars or smaller	$\frac{3}{8}$
up to 15 in, using bars larger than no. 10	$\frac{1}{2}$
16 to 22 in	$\frac{1}{2}$
23 in and larger	$\frac{5}{8}$

(Multiply in by 25.4 to obtain mm.)
[a]The ACI code does not specify spiral wire size.

4. DESIGN FOR SMALL ECCENTRICITY

The relative importance of bending and axial compression in the design of a column is measured by the *normalized eccentricity*. This parameter is defined as the ratio of the maximum moment acting on the column to the product of the axial load and the dimension of the column perpendicular to the axis of bending, $M_u/P_u h$.

Limits on normalized eccentricity are no longer part of ACI 318, but they can still be used to obtain approximate estimates of the maximum moment that will not affect the design for a given axial load. In an exact solution, the eccentricity limit will be a function of the percent of steel used and the type of reinforcement pattern. As described in Sec. 6, when the normalized eccentricity is less than approximately 0.1 for tied columns or 0.05 for spiral columns, the column can be designed without explicit consideration of flexural effects.

Design of a column for small eccentricity is based on Eq. 52.7. For tied columns, $\phi = 0.70$ and $\beta = 0.80$. For spiral columns, $\phi = 0.75$ and $\beta = 0.85$. (ACI 318 does not actually use the symbol β as a parameter for columns. ACI 318 10.3.5.3 prescribes the values without specifying a symbol.)

$$\phi\beta P_o \geq P_u \qquad 52.7$$

In Eq. 52.7, P_o is the nominal axial load strength at zero eccentricity. The product $\phi\beta P_o$ is known as the *design strength* for a column with small eccentricity. This strength is computed by assuming that, at the attainment of maximum capacity, the concrete is stressed to $0.85f'_c$ and the steel is stressed to f_y.

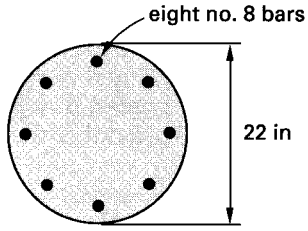
$$P_o = 0.85f'_c(A_g - A_{st}) + f_y A_{st} \qquad 52.8$$

Although the nominal capacity, P_o, is the same for tied and spiral columns, their behavior is different once the peak capacity is attained. In particular, while tied columns fail in a relatively brittle manner, spiral columns, having better confinement of the core, undergo significant deformation before significant deterioration of the load-carrying capacity ensues. ACI 318 takes into consideration the increased reliability of spiral columns by providing higher values for ϕ and β. The ultimate load, P_u, is determined by structural analysis.

$$P_u = 1.4\ (\text{dead load axial force}) + 1.7\ (\text{live load axial force}) \qquad 52.9$$

The basic design expression for columns with small eccentricity is obtained by substituting Eq. 52.9 into Eq. 52.7. Passing ϕ and β to the right-hand side,

$$0.85f'_c(A_g - A_{st}) + A_{st}f_y = \frac{P_u}{\phi\beta} \qquad 52.10$$



A convenient form of Eq. 52.10 is obtained by expressing the steel area as a function of the reinforcement ratio, ρ_g. If the column size is not known, a value of ρ_g between the limits of 0.01 and 0.08 is selected, and Eq. 52.11 is solved for the required gross column area, A_g. (Larger values of ρ_g decrease the gross column area. Typical starting values of ρ_g are approximately 0.02 to 0.025.) If the section size is known and only the steel reinforcement needs to be obtained, then the equation is solved for ρ_g, and the area of steel is obtained from Eq. 52.12.

$$A_g\left(0.85f'_c(1 - \rho_g) + \rho_g f_y\right) = \frac{P_u}{\phi\beta} \qquad 52.11$$

$$\rho_g = \frac{A_{st}}{A_g} \qquad 52.12$$

Example 52.1

Calculate the design strength of the short spiral column shown. Assume the loading has a low eccentricity. $f'_c = 3500$ lbf/in^2, and $f_y = 40{,}000$ lbf/in^2.

Solution

The gross area of the column is

$$A_g = \frac{\pi D_g^2}{4} = \frac{\pi(22\text{ in})^2}{4} = 380.1\text{ in}^2$$

Since there are eight no. 8 bars, the area of steel is

$$A_{st} = (8)(0.79\text{ in}^2) = 6.32\text{ in}^2$$

Substitute into Eq. 52.11.

$$\begin{aligned} P_o &= 0.85f'_c(A_g - A_{st}) + f_y A_{st} \\ &= \left((0.85)\left(3500\ \frac{\text{lbf}}{\text{in}^2}\right)(380.1\text{ in}^2 - 6.32\text{ in}^2)\right. \\ &\quad \left. + \left(40{,}000\ \frac{\text{lbf}}{\text{in}^2}\right)(6.32\text{ in}^2)\right)\left(\frac{1}{1000\ \frac{\text{lbf}}{\text{kip}}}\right) \\ &= 1364.8\text{ kips} \end{aligned}$$

The design strength is

$$\phi\beta P_o = (0.75)(0.85)(1364.8\text{ kips}) = 870.06\text{ kips}$$

Example 52.2

Design a spiral column to carry a factored load of 375 kips. Use $f'_c = 3000\text{ lbf/in}^2$ and $f_y = 40{,}000\text{ lbf/in}^2$.

Assume $\rho_g = 0.02$, which is within the allowable range. Use Eq. 52.11.

$$\begin{aligned} A_g &= \frac{P_u}{\phi\beta(0.85f'_c(1-\rho_g) + f_y)} \\ &= \frac{375\text{ kips}}{(0.75)(0.85)\left((0.85)\left(3\ \frac{\text{kips}}{\text{in}^2}\right)(1-0.02)\right.} \\ &\quad \left. + (0.02)\left(40\ \frac{\text{kips}}{\text{in}^2}\right)\right) \\ &= 178.3\text{ in}^2 \end{aligned}$$

The outside diameter is

$$\begin{aligned} D_g &= \sqrt{\frac{4A_g}{\pi}} = \sqrt{\frac{(4)(178.3\text{ in}^2)}{\pi}} \\ &= 15.07\text{ in} \quad \text{[say 15.25 in]} \end{aligned}$$

With 1.5 in of cover, the diameter of the core is

$$D_c = 15.25\text{ in} - 3\text{ in} = 12.25\text{ in}$$

From Eq. 52.12, the area of steel is

$$A_{st} = (0.02)(178.3\text{ in}^2) = 3.57\text{ in}^2$$

ACI 318 requires at least six bars to be used. Several possibilities exist. For example, six no. 7 bars, nine no. 6 bars, or twelve no. 5 bars would all give the required area. Choose nine no. 6 bars after checking the clear spacing (not shown here).

The required spiral reinforcement ratio is obtained from Eq. 52.4.

$$\begin{aligned} \rho_s &= 0.45\left(\frac{A_g}{A_c} - 1\right)\left(\frac{f'_c}{f_y}\right) \\ &= (0.45)\left(\frac{15.25\text{ in}^2}{12.25\text{ in}^2} - 1\right)\left(\frac{3000\ \frac{\text{lbf}}{\text{in}^2}}{40{,}000\ \frac{\text{lbf}}{\text{in}^2}}\right) \\ &= 0.0186 \end{aligned}$$

Assume a 3/8 in spiral wire. The maximum pitch is obtained from Eq. 52.5.

$$\begin{aligned} s &= \frac{4A_{sp}}{\rho_s D_c} = \frac{(4)(0.11\text{ in}^2)}{(0.0186)(12.25\text{ in})} \\ &= 1.93\text{ in} \end{aligned}$$

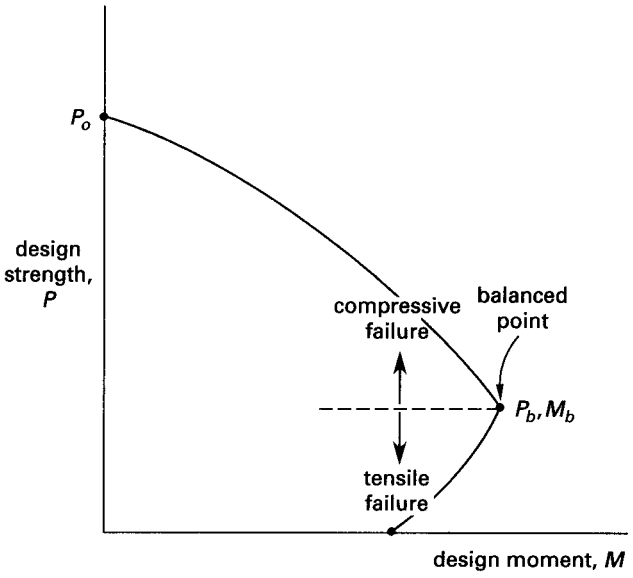
Use a spiral pitch equal to 1.75 in.

The clear space between spirals is 1.75 in − 0.375 in = 1.375 in. This is between 1 and 3 in and satisfies ACI 318 7.10.4.3.

5. INTERACTION DIAGRAMS

Based on approximate eccentricity limits, when the maximum moment acting on a column is larger than approximately $0.1P_u h$ for tied columns or $0.05P_u h$ for spiral columns, the design must account explicitly for the effect of bending. In practice, design of columns subjected to significant moments is based on interaction diagrams. An *interaction diagram* is a plot of the values of moment and axial force for which the capacity of a reinforced concrete section is exceeded.

Fig. 52.4 illustrates that, for small compressive loads, the moment capacity initially increases, then at a certain axial load it reaches a maximum and subsequently decreases, becoming zero when the axial load equals P_o from Eq. 52.8. The point in the interaction diagram where the moment is maximum is referred to as the *balanced point* because the associated strain diagram is the same as that used to compute the amount of balanced steel in beams.



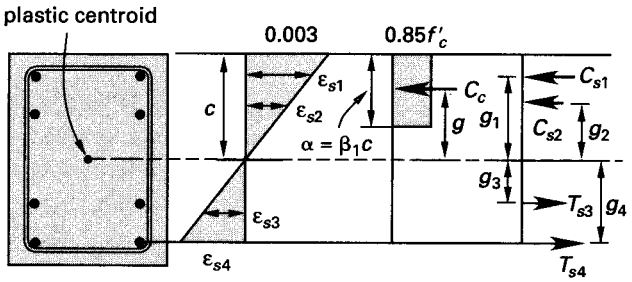


Figure 52.3 *Nominal Interaction Diagram*

An approximate and conservative nominal interaction diagram can be sketched by drawing straight lines between the balanced point at (P_b, M_b) and P_o, and between P_o and the nominal moment capacity for pure bending.

$$P_n = C_c + C_{s1} + C_{s2} - T_{s3} - T_{s4}$$

$$M_n = C_c g + C_{s1} g_1 + C_{s2} g_2 + T_{s3} g_3 + T_{s4} g_4$$

Figure 52.4 *Calculation of Points on a Nominal Interaction Diagram*

Points on a *nominal interaction diagram* are obtained from the following procedure. (Refer to Figs. 52.4 and 52.5.)

step 1: Assume an arbitrary neutral axis depth, c. (For $c > c_b$, points above the balanced condition will be obtained.)

step 2: Calculate $a = \beta_1 c$ and the associated area of concrete in compression, A_c. (β_1 is specified in Chap. 51.) The force in the concrete is $0.85f'_c A_c$.

step 3: Compute the forces in the steel bars (or layers). This is done by computing the strain from the geometry of the strain diagram, obtaining the associated stress, and multiplying by the appropriate steel area.

step 4: Compute the nominal axial load, P_n, as the sum of all the forces in the cross section. (For a sufficiently small neutral axis depth, the axial force resultant will be tensile. Although the portion of the interaction diagram corresponding to tension is not usually of interest, points on the negative side need not be discarded since they can help in drawing the interaction diagram.)

step 5: Compute the nominal moment, M_n, by summing moments of all the forces about the plastic centroid. The *plastic centroid* is the location of the resultant force when all the concrete is compressed at $0.85f'_c$ and all the steel is yielding. This corresponds to the point where the line of action of P_o intersects the section. For the typical case of rectangular or circular column sections, the plastic centroid coincides with the centroid of the section.

A *design interaction diagram* can be constructed from the nominal interaction diagram in two steps: (a) Multiply by the appropriate values of ϕ. (b) Limit the maximum allowable compression to $\beta\phi P_o$. Although ϕ is constant (either 0.70 or 0.75 for most of the diagram), consistency with the design of beams requires that a transition to 0.9 be made as the axial load approaches zero. In the typical case where $f_y \leq 60{,}000$ lbf/in^2 (457 GPa) and $(h - d' - d_s)/h \geq 0.7$, ACI 318 9.3.2.2 indicates that the transition (which is a linear function of P_u) begins when $P_u = 0.1f'_c A_g$. For other conditions, the transition starts at $P_u = 0.1f'_c A_g$ or $P_u = \phi P_b$, whichever is smallest.

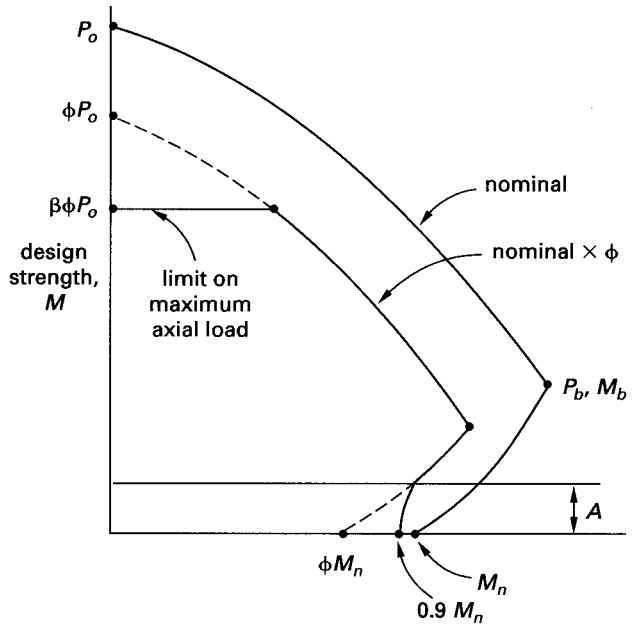

Figure 52.5 illustrates the conversion of a nominal interaction diagram to the design interaction diagram. Note that the ϕ transition is easily implemented (with sufficient accuracy) by joining the last value where ϕ is constant to 0.9 times the nominal pure bending strength.

6. DESIGN FOR LARGE ECCENTRICITY

Although interaction diagrams for columns with unusual shapes need to be drawn on a case-by-case basis, routine design of rectangular or circular columns is carried out using dimensionless interaction diagrams from the ACI (or other sources). Typical dimensionless interaction diagrams are presented in App. 52.A. (A complete collection is published by ACI as ACI SP-17.)

The use of dimensionless interaction diagrams is straightforward. In App. 52.A, each diagram includes eight envelope lines, each line corresponding to a percent of steel from the minimum of 1% to the maximum of 8%. Each diagram corresponds to a particular set of material properties and to a particular value of γ that is the ratio of the gross dimension perpendicular to the neutral axis to the parallel distance between the outer

Structural

$$A = 0.1f'_cA_g \qquad \left[F_y \leq 60{,}000\ \frac{\text{lbf}}{\text{in}^2} \text{ and } \frac{h-d'-d_s}{d} \geq 0.7\right]$$

$$A = \text{smallest of } \begin{cases} 0.1f'_cA_g \\ \phi P_b \end{cases} \qquad \text{[otherwise]}$$

Figure 52.5 *Relation Between Nominal and Design Interaction Diagrams*

steel layers. For practical purposes, γ can be estimated as $(h-5)/h$, where h is in inches. For rectangular cross sections, there is also a need to determine if the steel is to be placed on the two faces parallel to the neutral axis or if a uniform distribution around the column is to be used. In this regard, it is worth noting that the circles represent only the reinforcing pattern, not the exact positioning.

The following procedure can be used to design columns for large eccentricity using standard interaction diagrams.

step 1: If the column size is not known, an initial estimate can be obtained from Eq. 52.11 using an arbitrarily selected value of ρ_g between the limits allowed. Since the moment will increase the steel demand above that for no moment, a value of ρ_g somewhat smaller than the desired target should be selected.

step 2: Select the type of reinforcement pattern desired and estimate the value of γ. Choose the appropriate interaction diagram. Using a diagram for a γ value smaller than the actual leads to conservative results.

step 3: Evaluate the coordinates P_u/A_g and M_u/A_gh and plot this point in the diagram. If the point is outside the last curve for $\rho_g = 0.08$, the section size is too small. In that case, the section size should be increased and this step repeated. If the point is inside the curve for $\rho_g = 0.01$, the section is oversized. In that case, the dimensions should be reduced and this step should be repeated.

Once the size and steel reinforcement are selected, the design is completed by selecting the transverse reinforcement. This step is carried out exactly the same as in the case of columns with small eccentricity. Although seldom an issue in the design of columns, the adequacy of the cross section in shear should also be checked when significant bending moments exist.

PRACTICE PROBLEMS

1. (*Time limit: one hour*) A short column in a building is subjected to a factored axial load of 600 kips. Moments are negligible. Material properties are $f'_c = 4000$ lbf/in^2 and $f_y = 60{,}000$ lbf/in^2. Design the column as a square tied column using a reinforcement ratio of 4%.

Answer: 14 in square; eight no. 9 bars

2. A short column is subjected to an axial load of $P_u = 650$ kips and a moment $M_u = 250$ ft-kips. Material properties are $f'_c = 4000$ lbf/in^2 and $f_y = 60{,}000$ lbf/in^2. Design a tied square column with approximately 3% steel. Use steel distributed in all four faces.

Answer: 18 in square; twelve no. 9 bars

3. (*Time limit: one hour*) A short column is subjected to a factored axial load of $P_u = 850$ kips. Material properties are $f'_c = 4000$ lbf/in^2 and $f_y = 60{,}000$ lbf/in^2.

(a) Assume moments are negligible. If the column is designed as a tied column, the minimum gross cross-sectional area is most nearly

(A) 170 in^2
(B) 190 in^2
(C) 210 in^2
(D) 220 in^2

The answer is (B).

(b) Assume moments are negligible. If the column is designed as a spiral column, the minimum gross cross-sectional area is most nearly

(A) 150 in^2
(B) 170 in^2
(C) 180 in^2
(D) 190 in^2

The answer is (B).

(c) If the column is an 18 in by 18 in square tied column, the required area of steel is most nearly

(A) 6.0 in^2
(B) 7.5 in^2
(C) 8.5 in^2
(D) 9.0 in^2

The answer is (B).

(d) If the column is an 18 in by 18 in square tied column, the maximum moment that can act without affecting the design (for pure axial loading) is most nearly

(A) 50 ft-kips
(B) 130 ft-kips
(C) 200 ft-kips
(D) 250 ft-kips

The answer is (B).

(e) If the column is an 18 in by 18 in square tied column and no. 9 bars are used for the longitudinal reinforcement, the maximum spacing of no. 3 ties is most nearly

(A) 14 in
(B) 16 in
(C) 18 in
(D) 20 in

The answer is (C).

(f) If the column is a spiral circular column with an outside diameter of 20 in, the required area of steel is most nearly

(A) 4.4 in^2
(B) 4.7 in^2
(C) 5.0 in^2
(D) 5.2 in^2

The answer is (B).

(g) If the column is a circular spiral column with an outside diameter of 20 in, the maximum moment that can act without affecting the design (for pure axial loading) is most nearly

(A) 50 ft-kips
(B) 60 ft-kips
(C) 70 ft-kips
(D) 140 ft-kips

The answer is (C).

(h) If the column is a spiral circular column with an outside diameter of 20 in and the diameter of the spiral wire is $\frac{3}{8}$ in, the maximum spiral pitch is most nearly

(A) 1.8 in
(B) 2.3 in
(C) 2.5 in
(D) 3.0 in

The answer is (B).

(i) When minimum reinforcement is used, the gross cross-sectional area for a tied column is most nearly

(A) 330 in^2
(B) 350 in^2
(C) 380 in^2
(D) 410 in^2

The answer is (C).

(j) When minimum reinforcement is used, the gross cross-sectional area for a spiral column is most nearly

(A) 310 in^2
(B) 340 in^2
(C) 380 in^2
(D) 410 in^2

The answer is (B).

4. (*Time limit: one hour*) A 20 in by 20 in tied column is built with $f'_c = 4000$ lbf/in^2 and $f_y = 60{,}000$ lbf/in^2.

(a) The maximum axial load that can be designed for is most nearly

(A) 1600 kips
(B) 1800 kips
(C) 2000 kips
(D) 2100 kips

The answer is (B).

(b) Assume moments are negligible. For $P_u = 1000$ kips, the required steel area is most nearly

(A) 5.0 in^2
(B) 6.5 in^2
(C) 7.5 in^2
(D) 8.5 in^2

The answer is (C).

(c) For $P_u = 800$ kips, the largest moment that does not affect the design is most nearly

(A) 65 ft-kips
(B) 130 ft-kips
(C) 200 ft-kips
(D) 260 ft-kips

The answer is (B).

(d) For $P_u = 800$ kips and $M_u = 400$ ft-kips, the required steel area is most nearly

(A) 10 in^2
(B) 14 in^2
(C) 18 in^2
(D) 22 in^2

The answer is (C).

(e) When the steel ratio equals 4%, the maximum moment that can be resisted when $P_u = 800$ kips is most nearly

(A) 300 ft-kips
(B) 380 ft-kips
(C) 480 ft-kips
(D) 500 ft-kips

The answer is (B).

(f) When the steel ratio is 4%, the axial load at which the moment capacity is largest is most nearly

(A) 300 kips
(B) 400 kips
(C) 500 kips
(D) 600 kips

The answer is (B).

(g) Assuming the column is unbraced and the effective length factor is 1.5, the maximum clear height for which the column is short is most nearly

(A) 6 ft
(B) 8 ft
(C) 9 ft
(D) 10 ft

The answer is (A).

(h) If the column is reinforced with no. 11 bars, the appropriate transverse reinforcement is most nearly

(A) no. 3 ties at 20 in
(B) no. 4 ties at 20 in
(C) no. 3 ties at 18 in
(D) no. 4 ties at 24 in

The answer is (B).

(i) If the column is reinforced with eight no. 8 bars placed in four bundles of two bars at each corner, the appropriate transverse reinforcement is most nearly

(A) no. 3 ties at 20 in
(B) no. 4 ties at 20 in
(C) no. 3 ties at 18 in
(D) no. 4 ties at 24 in

The answer is (B).

(j) If the steel ratio is 3%, the maximum eccentricity for a load $P_u = 800$ kips is most nearly

(A) 3.0 in
(B) 4.6 in
(C) 5.5 in
(D) 6.5 in

The answer is (B).

5. Design a short spiral column to carry an axial dead load of 175 kips and an axial live load of 300 kips. Use $f'_c = 3000$ lbf/in^2 and $f_y = 40{,}000$ lbf/in^2.

Answer: 21.5 in gross diameter; twelve no. 7 bars

6. Design a short square tied column to carry an axial dead load of 100 kips and an axial live load of 125 kips. Use $f'_c = 3500$ lbf/in^2 and $f_y = 40{,}000$ lbf/in^2. Use no. 5 bars or larger for the longitudinal reinforcement. Specify the ties.

Answer: 13 in square; eight no. 6 bars; no. 3 ties at 12 in spacing; no additional crossties

1. INTRODUCTION

A typical assumption used in the calculation of internal forces in structures is that the change in geometry resulting from deformations is sufficiently small to be neglected. This type of analysis, known as a *first-order analysis*, is an approximation that is often sufficiently accurate. There are other instances, however, where the changes in geometry resulting from the structural deformations have a notable effect and must be considered.

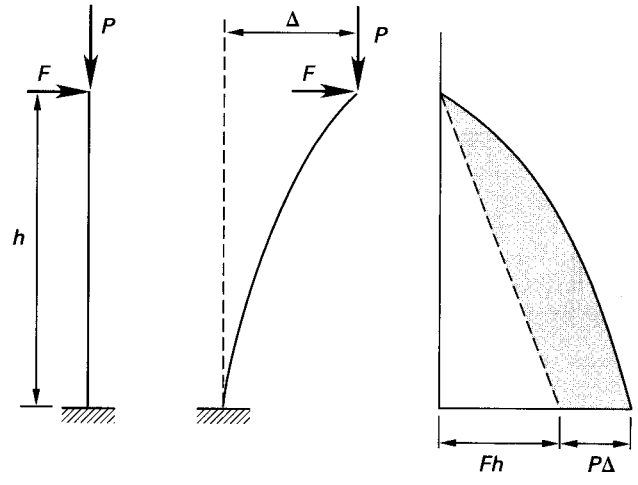

Figure 53.1 *Effect of Deformation on Internal Forces*

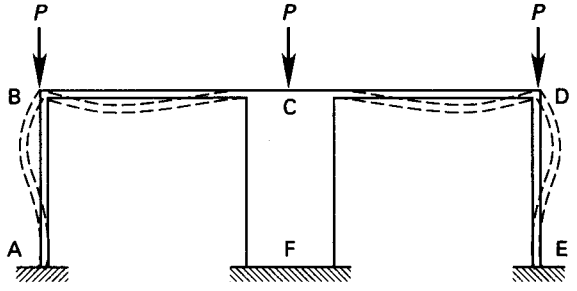
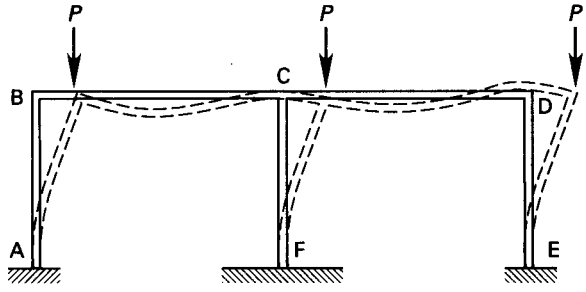
To illustrate how the deformations of a structure affect the internal forces, consider the cantilever column subjected to compressive and lateral loads shown in Fig. 53.1. The moment at the base of the column in a first-order solution is the product of the lateral load F times the height h. (The actual moment at the base, however, is $Fh + P\Delta$, where Δ is the deflection at the tip of the cantilever due to the combined action of both F and P.) An unconservative design results if the moment $P\Delta$ is significant (in comparison to Fh) and is neglected in the design. Although the changes in geometry have an influence in the axial forces also, these effects are typically small and are neglected in design.



The rigorous evaluation of second-order moments in large structures is generally considered too involved for routine design. A practical alternative, however, is to estimate the true moments by multiplying the first-order solution by appropriately defined amplification factors—this is the approach taken by the ACI Code in its treatment of long columns.

ACI 318 contains simplified criteria for determining when slenderness amplification factors do not have to be calculated. These criteria were presented in Chap. 52.



2. BRACED AND UNBRACED COLUMNS

A fundamental determination that has to be made in the process of computing the amplification formulas for columns is whether the column is part of a braced or an unbraced structure. The magnitude of the vertical load required to induce buckling when sway is possible is typically much smaller than when sway is restrained.

Conceptually, a column is considered braced if its buckling mode shape does not involve translation of the end points. It is important to recognize that a structure may be braced even though *diagonal bracing* is not provided. For example, if the frame in Fig. 53.2(a) is assumed elastic and the vertical loading is progressively increased, columns AB and DE will eventually buckle without joint translation.

(a) frame braced by wall

(b) unbraced frame

Figure 53.2 *Braced and Unbraced Frames*

Wall CF provides the necessary bracing in this case. When the wall is replaced by a column, however, buckling takes place with lateral translation of the joints so the structure must be considered unbraced, as in Fig. 53.2(b). Note that because floor systems are essentially rigid against distortions in their own plane, it is not even necessary for a wall to be located in the same plane of a column to provide adequate bracing. The only requirement is that the arrangement of walls be such that significant torsional stiffness is provided so that the slab cannot rotate about a wall while a certain frame buckles.

There are instances where inspection is not sufficient to establish the distinction between braced and unbraced structures. For example, as the size of the wall CF in Fig. 53.2 is reduced, the condition passes from braced to unbraced. It is difficult to determine when the transition occurs. ACI 318 provides the following two quantitative methods to distinguish between braced and unbraced conditions. In particular, columns in any given level of a building can be treated as braced when either one of the following two criteria are satisfied.

(1) The ratio of the moment from a second-order analysis to the first-order moment is less than or equal to 1.05.

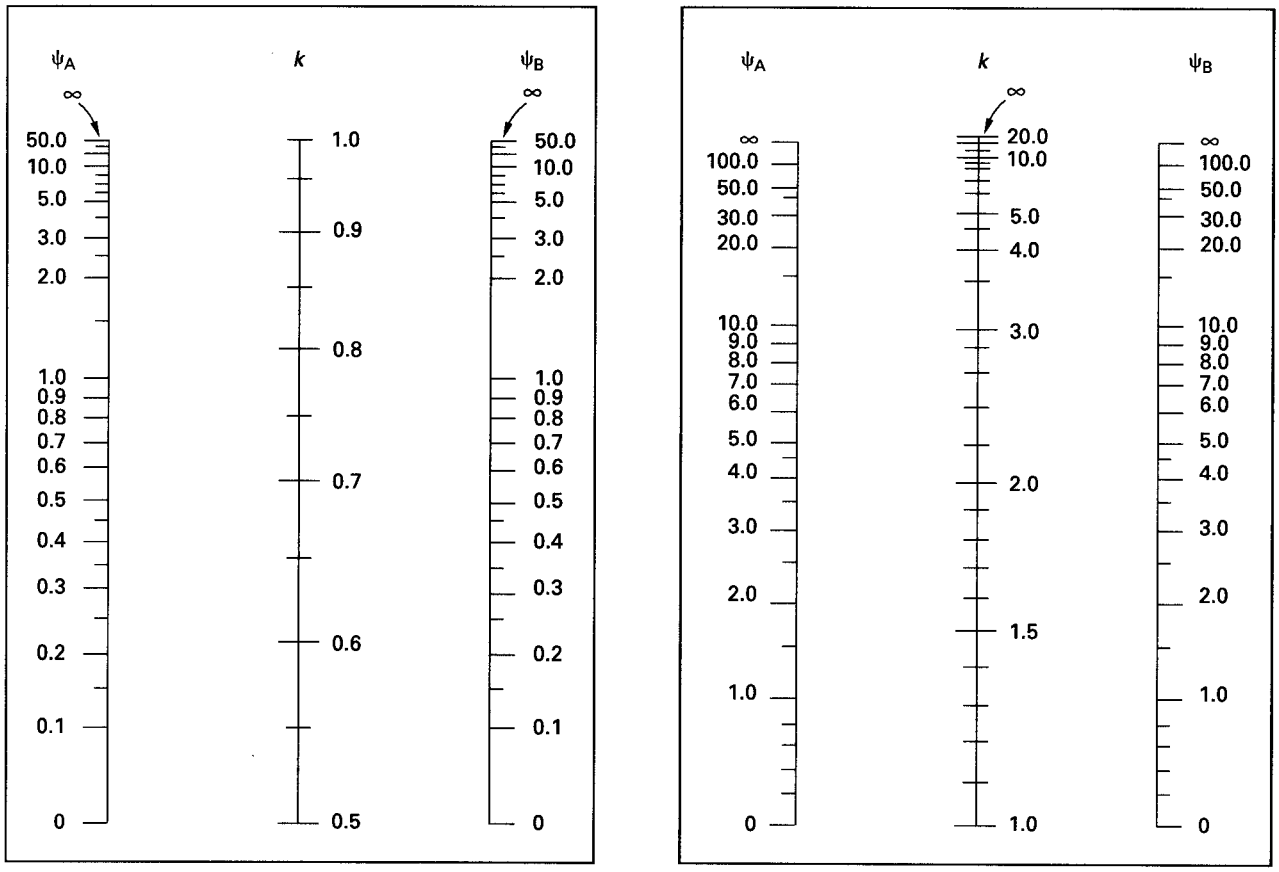
(2) The *stability coefficient*, Q, is less than or equal to 0.05, where Q is given by

$$Q = \frac{\sum P_u \Delta_o}{V_u l_c} \qquad 53.1$$

$\sum P_u$ is the sum of the axial forces in the columns at the level in question, Δ_o is the *story drift* (the relative displacement between the floor and the roof of the story), V_u is the shear force in the story, and l_c is the column height measured from centerline-to-centerline of the joints (essentially the same as the story height).

From a practical standpoint, Eq. 53.1 is the simplest criterion since it can be checked without the need to perform a second-order analysis of the structure.

3. EFFECTIVE LENGTH



The buckling load of a column is dependent on how the ends are supported. The end-restraint conditions affect the column's *effective length*. The effective length is calculated as the product of an effective length factor, k, times the actual length of the column.

$$\text{effective length} = kl_u \qquad 53.2$$

The *effective length factor* depends on the relative stiffness of the columns and beams at the ends of the column and also on whether the column is part of a braced or an unbraced frame. ACI 318 uses the symbol k to identify the effective length factor for both braced and unbraced conditions. However, it is clearer to use k_b for the braced condition and k_u for unbraced condition.

A convenient way to obtain the effective length factor is by using a *Jackson and Moreland alignment chart*, Fig. 53.3. The effective length is obtained by connecting the values of the relative stiffness parameter, Ψ, for each end of the column.

$$\Psi = \frac{\sum_{\text{columns}} \frac{EI}{l_c}}{\sum_{\text{beams}} \frac{EI}{l}} \qquad 53.3$$

Figure 53.3 *Effective Length Factors (Jackson and Moreland chart)*

4. SECTION PROPERTIES

Since second-order moments depend on the actual deformations, it is important to use section properties that reflect the influence of cracking and the effect of the duration of the loads on the stiffness of the structure. ACI 318 10.11.1 recommends the following values in the absence of a more detailed analysis. (Values for walls are also provided in this section of the ACI.)

modulus of elasticity of concrete	$57{,}000\sqrt{f'_c}$
area	A_g
moments of inertia of columns	$0.70I_g$
moments of inertia of beams	$0.35I_g$
moments of inertia of plates and slabs	$0.25I_g$

I_g for T-beams and one-way beam-slab systems is computed using the effective flange sections shown in Fig. 50.7 [ACI 318 8.10]. I_g for two-way beam-slab systems is computed using the effective flange sections shown in Fig. 53.4 [ACI 318 13.2.4].

For the unusual situation where a building is subjected to sustained lateral loads (from earth pressure, for example) the moments of inertia are divided by the factor $1+\beta_d$. β_d is defined as the ratio of the sustained fraction of the factored lateral load to the total factored lateral load.

5. EFFECTIVE FLEXURAL STIFFNESS

To evaluate the buckling load of a column, the effective length (kl_u) and the *flexural stiffness* EI are needed. This last term must include possible reductions due to cracking, nonlinear effects in the stress-strain curve and, in the case of sustained loads, the increase in curvatures that occur as a result of creep deformations. ACI 318 provides two formulas that provide conservative estimates of the flexural stiffness. Equation 53.5 is typically used since it can be evaluated without knowing the steel reinforcement.

$$EI = \frac{0.2E_cI_g + E_sI_{se}}{1+\beta_d} \qquad 53.4$$

$$EI = \frac{0.4E_cI_g}{1+\beta_d} \qquad 53.5$$

In Eq. 53.4, I_{se} is the moment of inertia of the steel bars in a column cross section, calculated as the sum of the products of areas times the square of the distances to the neutral axis.

Structural

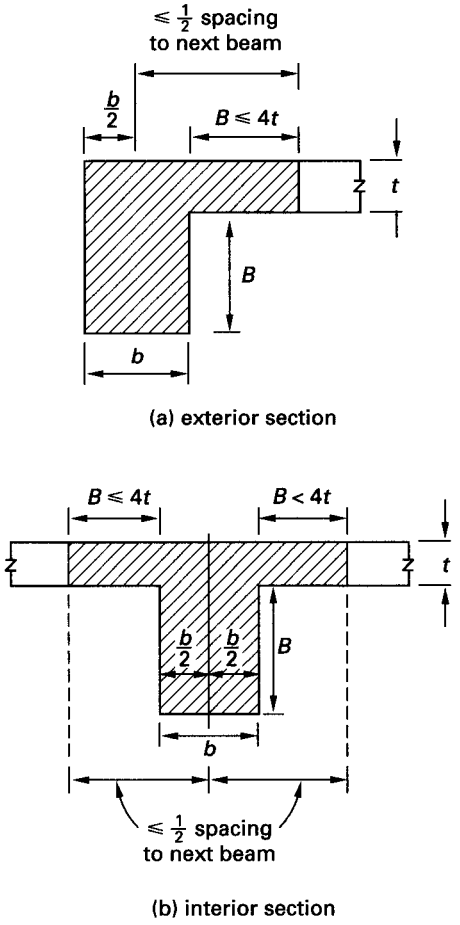

Figure 53.4 *Slab Sections Considered as Beams*

There are two cases for evaluating β_d: (a) When the internal forces are from gravity loads only, β_d is the ratio of the permanent fraction of factored axial force to the total factored axial force. (b) When the internal forces are derived from gravity and lateral loads, β_d is the ratio of the permanent fraction of factored lateral load to the total factored lateral load. Thus, for load combinations that include wind or earthquake loads, $\beta_d = 0$.

6. BUCKLING LOAD

The column *buckling load* for a slender column is given by the Euler formula. The values of flexural stiffness and effective length previously determined in Secs. 3 and 5 must be used.

$$P_c = \frac{\pi^2 EI}{(kl_u)^2} \qquad 53.6$$

7. COLUMNS IN BRACED STRUCTURES

When the columns in a story are braced, the design is carried out for the factored axial load obtained from a first-order analysis and for a moment M_c given by Eq. 53.7. M_2 is the larger factored end moment from a first-order solution.

$$M_c = \delta_{ns} M_2 \qquad 53.7$$

The amplification factor is

$$\delta_{ns} = \frac{C_m}{1 - \dfrac{P_u}{0.75P_c}} \geq 1.0 \qquad 53.8$$

The buckling load, P_c, is obtained from Eq. 53.6 with $k = k_b$ and EI given by either Eq. 53.4 or 53.5.

The parameter C_m is used to account for the shape of the first-order moment diagram. For columns with transverse loads between the endpoints, $C_m = 1$. For columns without transverse loads between the endpoints, Eq. 53.9 can be used. (When $M_1 = M_2 = 0$, use $M_1/M_2 = 1$.) [ACI 318 10.12.3.2]

$$C_m = 0.6 + 0.4\left(\frac{M_1}{M_2}\right) \geq 0.4 \qquad 53.9$$

ACI 318 10.12.3.2 provides the minimum value for the moment M_2 given by Eq. 53.10.

$$M_{2,\min} = P_u(0.6 + 0.03h) \quad [h \text{ in inches}] \qquad 53.10$$

8. COLUMNS IN UNBRACED STRUCTURES

Columns in unbraced structures should be designed for the axial load computed from a first-order analysis and for the end moments M_1 and M_2, which are computed as

$$M_1 = M_{1,ns} + \delta_s M_{1s} \qquad 53.11$$

$$M_2 = M_{2,ns} + \delta_s M_{2s} \qquad 53.12$$

The amplification factor, δ_s, is given by

$$\delta_s = \frac{1}{1 - \dfrac{\sum P_u}{0.75 \sum P_c}} \geq 1.0 \qquad 53.13$$

Alternatively, if $Q \leq 1/3$,

$$\delta_s = \frac{1}{1 - Q} \geq 1 \qquad 53.14$$

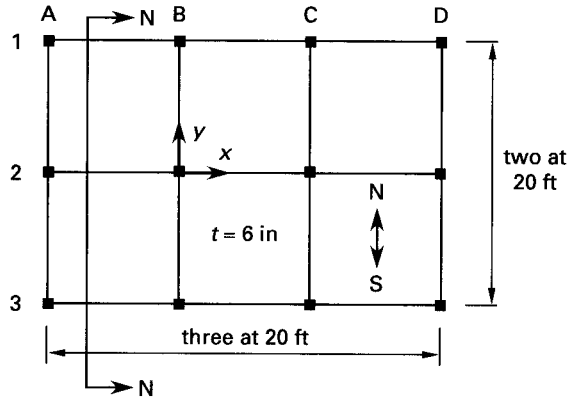
The amplification factor, δ_s, is not computed for a single given column but rather for all the columns in a given story. This is because all of the columns in a story must buckle with sway if any one does.

The value of each one of the buckling loads, P_c in Eq. 53.13, is obtained using Eq. 53.6 with the effective length factor taken as k_u.

While Eqs. 53.11 and 53.12 give the amplified moments at the column ends in an unbraced structure, the moment may be even larger at some point along the height of the column. In fact, the moments within the column height cannot be obtained from the moments at the ends alone. The deflection of the column with respect to its chord affects the moments within the length.

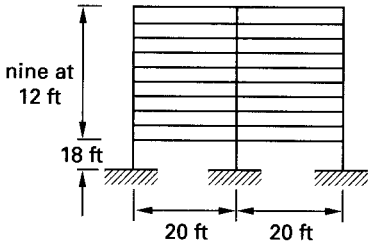
ACI 318 10.13.5 indicates when further moment checking is necessary. When the condition of Eq. 53.15 is satisfied, an explicit check on other moments is necessary. In that case, the moment within the length is computed by assuming that the column is braced and has the end moments given by Eqs. 53.11 and 53.12.

$$\frac{l_u}{r} \geq \frac{35}{\sqrt{\frac{P_u}{f'_c A_g}}} \qquad 53.15$$



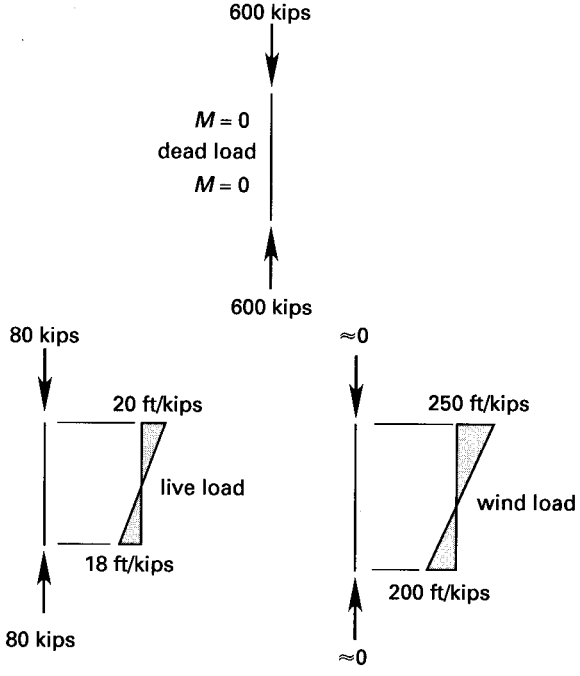
To ensure that the safety margin against global instability is adequate in unbraced frames, ACI 318 requires that the maximum amplification factor, δ_s (computed using an axial load corresponding to $U = 1.4D + 1.7L$) be less than or equal to 2.5 [ACI 318 10.13.6]. (In checking stability under a maximum vertical load, the value of β_d is taken as the ratio of the axial force for the factored dead load to the total factored axial load.)

Example 53.1



A 10 story reinforced concrete building is supported on 20 in by 20 in columns located on a 20 ft by 20 ft rectangular grid. The stories are 12 ft in height with the exception of the first story, which is 18 ft high. The first story column height can be taken as 17 ft. The effective length factor, k_u, for column B2 is 1.5. The slab thickness is 6 in. The actions in column B2 for dead load, live load, and wind loading in the N-S direction are as shown. The moments from the live load shown are obtained by positioning the live load on the panels located to the north of column B2 only. Moments in the E-W direction (about the y-y axis) are negligible.

To account for the low probability of all stories above being fully loaded, the live load over all the stories above is assumed to be 40% of the nominal value for the purpose of computing the amplification δ_s at level 1. To account for the fact that their effective lengths are longer as a result of having only one beam framing into their joints in the direction of the analysis, the critical load of the columns in axes 1-1 and 3-3 is assumed to be 0.75 times the critical load of the columns in axis 2-2.



Compute the design axial load and moment in the first level for column B2. Consider the load combination $U = 0.75(1.4D + 1.7L + 1.7W)$.

(a) column plan view

(b) elevation

(c) dead, live, and wind load
(reductions considered)

Solution

The amplification factor δ_s is given by Eq. 53.13. $\sum P_u$ is the total factored load above the level in question. Taking into consideration the reduction of the live load,

$$\sum P_u = (0.75)\left((1.4)\left(0.15\,\frac{\text{kip}}{\text{ft}^2}\right) + (1.7)(0.4)\left(0.05\,\frac{\text{kip}}{\text{ft}^2}\right)\right) \times \left((9)(60\text{ ft})(40\text{ ft})\right) = 3952.8\text{ kips}$$

$\sum P_c$ is the sum of the buckling loads of all the columns in the level. Compute this for the columns in axis 2-2.

$$E_c = \frac{57{,}000\sqrt{4000\,\frac{\text{lbf}}{\text{in}^2}}}{1000\,\frac{\text{lbf}}{\text{kip}}} = 3605\text{ kips/in}^2$$

$$I_g = \frac{bh^3}{12} = \frac{(20\text{ in})(20\text{ in})^3}{12} = 13{,}333\text{ in}^4$$

$$\beta_d = 0$$

$$EI = \frac{0.4E_cI_g}{1+\beta_d} = (0.4)\left(3605\,\frac{\text{kips}}{\text{in}^2}\right)(13{,}333\text{ in}^4) = 19.23 \times 10^6\text{ kip-in}^2$$

Substitute into Eq. 53.6.

$$P_c = \frac{\pi^2 EI}{(kl_u)^2} = \frac{\pi^2(19.23 \times 10^6\text{ kip-in}^2)}{\left((1.5)(17\text{ ft})\left(12\,\frac{\text{in}}{\text{ft}}\right)\right)^2} = 2026.9\text{ kips}$$

Taking the reduction in axial loading into account,

$$\sum P_c = \big((0.75)(8)+4\big)(2026.9\text{ kips}) = 20{,}269\text{ kips}$$

The amplification factor is computed from Eq. 53.13.

$$\delta_s = \frac{1}{1 - \frac{\sum P_u}{0.75\sum P_c}} = \frac{1}{1 - \frac{3952.8\text{ kips}}{(0.75)(20{,}269\text{ kips})}} = 1.35$$

$$M_{1,ns} = (0.75)(1.7)(18\text{ ft-kips}) = 23.0\text{ ft-kips}$$

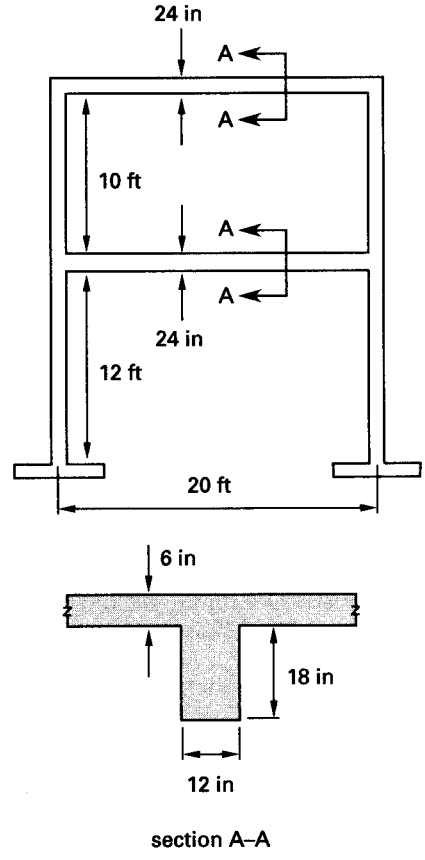
$$M_{2,ns} = (0.75)(1.7)(20\text{ ft-kips}) = 25.5\text{ ft-kips}$$

$$M_{1,s} = (0.75)(1.7)(200\text{ ft-kips}) = 255.0\text{ ft-kips}$$

$$M_{2,s} = (0.75)(1.7)(250\text{ ft-kips}) = 318.8\text{ ft-kips}$$

Using Eqs. 53.11 and 53.12, the amplified moments at the column ends are

$$M_1 = M_{1,ns} + \delta_s M_{1,s} = 23\text{ ft-kips} + (1.35)(255.0\text{ ft-kips}) = 344.3\text{ ft-kips}$$



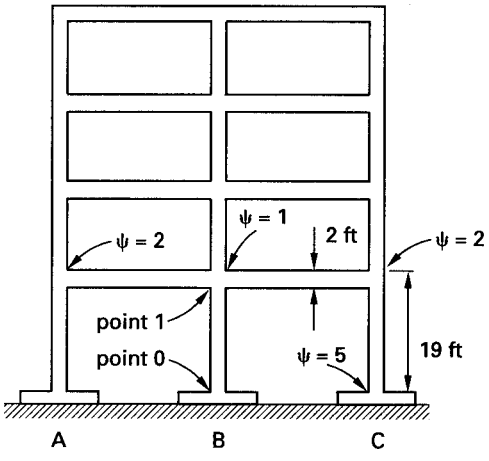
$$M_2 = M_{2,ns} + \delta_s M_{2,s} = 25.5\text{ ft-kips} + (1.35)(318.8\text{ ft-kips}) = 455.9\text{ ft-kips}$$

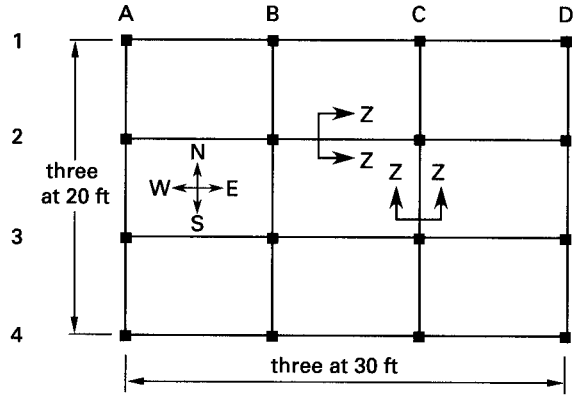
The design axial force is

$$P_u = (0.75)\big((1.4)(600\text{ kips}) + (1.7)(80\text{ kips})\big) = 732.0\text{ kips}$$

PRACTICE PROBLEMS

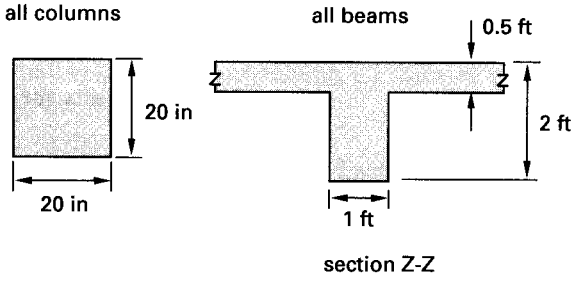
1. The frame shown is one of several parallel frames in an unbraced building. The frames are spaced on 20 ft centers and are constructed using 4000 lbf/in^2 concrete. All columns are 18 in by 18 in. All slabs are two-way. Compute the effective length factor k_u for the columns on the second story.





section A–A

(A) 1.1
(B) 1.2
(C) 1.5
(D) 1.8



The answer is (C).

2. The frame shown is part of a building that can be considered braced by the presence of stiff concrete walls surrounding the elevator shafts. The soil under the footings is soft, and a relative stiffness of $\Psi = 5$ is considered appropriate at the base. Other values of Ψ have been computed and are given in the illustration. Structural loadings for column B between points 0 and 1 are 400 kips dead load and 100 kips live load. The concrete modulus of elasticity, E_c, is 4000 kips/in^2. All columns are 16 in × 16 in square.

(a) plan view

(b) column construction (c) beam construction

(a) Calculate the buckling load for column B.

(A) 1200 kips
(B) 1500 kips
(C) 2200 kips
(D) 2800 kips

The answer is (B).

(b) Calculate the moment that should be used to design column B in the first story.

(A) 120 ft-kips
(B) 140 ft-kips
(C) 170 ft-kips
(D) 200 ft-kips

The answer is (D).

3. (*Time limit: one hour*) A reinforced concrete building is supported on columns placed on a grid spaced 30 ft in the E-W direction and 20 ft in the N-S direction. The story height, measured from the top of one slab to the top of the slab above, is 14 ft. At the first level, the distance from the top of the footings to the top of the first story slab is 18 ft. The columns are 20 in by 20 in. Columns are connected in both directions by beams with an overall depth of 2 ft and a web width of 1 ft. The slab thickness is 6 in. All slabs are two-way. 4000 lbf/in^2 concrete is used throughout.

(a) For the computation of the relative stiffness parameter, Ψ, the moment of inertia of the beams is most nearly

(A) 4800 in^4
(B) 6100 in^4
(C) 8600 in^4
(D) 14,000 in^4

The answer is (C).

In parts (b) through (h), assume the building is unbraced.

(b) The effective length factor for bending about the W-E axis in column B2 at the third level is most nearly

(A) 0.85
(B) 1.0
(C) 1.5
(D) 2.0

The answer is (C).

(c) The effective length factor for bending about the W-E axis in column B1 at the third level is most nearly

(A) 0.9
(B) 1.0
(C) 1.5
(D) 1.9

The answer is (D).

Structural

(d) Assuming the footing provides complete fixity at the base and using $\beta_d = 0$, the effective length for bending about the W-E axis in column B2 at the first level is most nearly

(A) 14 ft
(B) 16 ft
(C) 19 ft
(D) 21 ft

The answer is (C).

(e) The buckling load about W-E for column B2 in the first level is most nearly

(A) 3500 kips
(B) 4000 kips
(C) 4900 kips
(D) 5600 kips

The answer is (B).

(f) Assume the dead load is 0.1 kip/ft^2 and the live load is 0.06 kips/ft^2. Consider the load combination $U = 0.75(1.4D + 1.7L + 1.7W)$. Neglecting reductions in the live load, the $\sum P_u$ term used for the calculation of δ_s in the first level is most nearly

(A) 1100 kips
(B) 4500 kips
(C) 4900 kips
(D) 5200 kips

The answer is (C).

(g) Assume the unfactored wind load is 30 lbf/ft^2 and the load combination is $U = 0.75(1.4D + 1.7L + 1.7W)$. The first-story column's radius of gyration for horizontal sway of the building in the N-S direction is 30% of the column gross dimension. The value of Q at this level is most nearly

(A) 0.015
(B) 0.032
(C) 0.15
(D) 0.20

The answer is (B).

(h) The maximum axial load in the columns of the first level for which the maximum moment can be safely assumed to occur at one of the two ends is most nearly

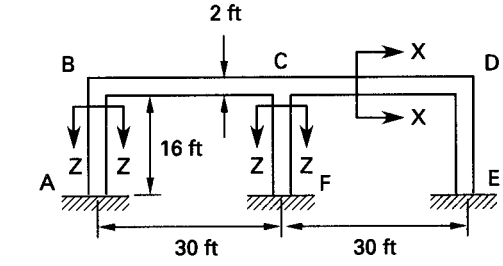
(A) 989 kips
(B) 1600 kips
(C) 1900 kips
(D) 2400 kips

The answer is (C).

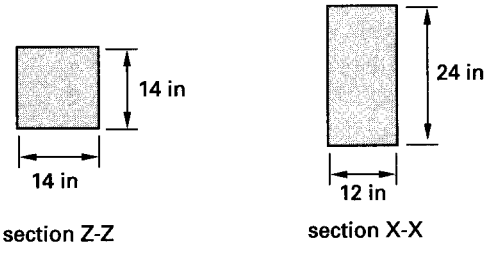
For parts (i) and (j), assume walls are added so that the building is braced.

(i) The effective length factor for bending about W-E in column B2 at the first level is most nearly

(A) 0.75
(B) 0.87
(C) 1.0
(D) 1.2

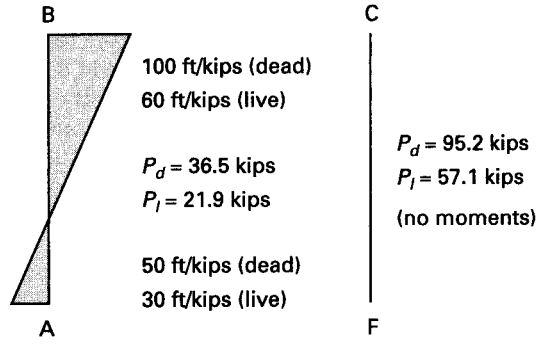


The answer is (B).



(j) Assume the unfactored axial forces from dead and live loads on a particular column are 200 kips and 50 kips, respectively. The value of β_d for the load combination $U = 1.4D + 1.7L$ is most nearly

(A) 0.50
(B) 0.77
(C) 0.80
(D) 1.0



The answer is (B).

4. (*Time limit: one hour*) The single-story frame shown is built with concrete having a modulus of elasticity, E_c, of 3605 kips/in^2. The actions in the columns due to dead and live load are as shown.

section Z-Z section X-X

In parts (a) through (e), assume the frame is part of a building that is braced. Assume the load combination is $U = 1.4D + 1.7L$.

(a) The moment $M_{2,ns}$ in column AB is most nearly
(A) 120 ft-kips
(B) 140 ft-kips
(C) 160 ft-kips
(D) 240 ft-kips

The answer is (D).

(b) The effective length for column AB is most nearly
(A) 9.0 ft
(B) 11 ft
(C) 12 ft
(D) 13 ft

The answer is (C).

(c) The effective length of column BC is most nearly
(A) 10 ft
(B) 11 ft
(C) 13 ft
(D) 15 ft

The answer is (B).

(d) The factor β_d that should be used to compute the buckling load for column AB is most nearly
(A) 0
(B) 0.45
(C) 0.58
(D) 0.65

The answer is (C).

(e) The buckling load for column AB is most nearly
(A) 1200 kips
(B) 1400 kips
(C) 1500 kips
(D) 1800 kips

The answer is (B).

(f) The parameter C_m for column AB (used to compute the amplification factor δ_{ns}) is most nearly
(A) 0.3
(B) 0.4
(C) 0.5
(D) 0.6

The answer is (B).

(g) The parameter C_m for column CF (used to compute the amplification factor δ_{ns}) is most nearly
(A) 0.4
(B) 0.5
(C) 0.6
(D) 1.0

The answer is (D).

(h) The buckling load for column CF is most nearly
(A) 1000 kips
(B) 1300 kips
(C) 1600 kips
(D) 2200 kips

The answer is (C).

(i) The amplification factor δ_{ns} in column CF is most nearly
(A) 0.9
(B) 1.0
(C) 1.2
(D) 1.5

The answer is (C).

(j) The amplification factor δ_{ns} in column AB is most nearly
(A) 0.44
(B) 1.0
(C) 1.1
(D) 1.3

The answer is (B).

1. NONBEARING WALLS

Nonbearing walls support their own weight and, occasionally, lateral wind and seismic loads. The following minimum details are specified by ACI 318 for designing nonbearing walls.

Minimum vertical reinforcement (ACI 318 14.3.2):

(1) 0.0012 times the gross concrete area for deformed no. 5 bars or smaller and $f_y > 60{,}000$ psi

(2) 0.0015 times the gross concrete area for other deformed bars

(3) 0.0012 times gross concrete area for smooth or welded wire fabric not larger than W31 or D31

Minimum horizontal reinforcement (ACI 318 14.3.3):

(1) 0.0020 times the gross concrete area for deformed no. 5 bars or smaller and $f_y > 60{,}000$ psi

(2) 0.0025 times the gross concrete area for other deformed bars

(3) 0.0020 times the gross concrete area for smooth or welded wire fabric not larger than W31 or D31

Number of reinforcing layers (ACI 318 14.3.4):

(1) Wall thickness > 10 in: two layers; one layer containing from 1/2 to 2/3 of the total steel placed in the exterior surface not less than 2 in and not more than $1/3h$; the other layer placed in the interior surface at a distance not less than 3/4 in and no more than $1/3h$.

(2) Wall thickness < 10 in: ACI 318 does not specify two layers of reinforcement.

Structural

Spacing of vertical and horizontal reinforcement (ACI 318 14.3.5):

The spacing of vertical and horizontal reinforcement may not exceed three times the wall thickness or 18 in.

Need for ties (ACI 318 14.3.6):

The vertical reinforcement does not have to be enclosed by ties unless the vertical reinforcement is greater than 0.01 times the gross concrete area or if the vertical reinforcement is not required as compression reinforcing.

Thickness (ACI 318 14.6.1):

Thickness cannot be less than 4 in or $^1/_{30}$ times the least distance between members that provide lateral support.

2. BEARING WALLS: EMPIRICAL METHOD

The majority of concrete walls in buildings are *bearing walls* (*load-carrying walls*). In addition to their own weights, bearing walls support vertical and lateral loads. There are two methods for designing bearing walls. They may be designed (a) by the ACI Empirical Design Method, or (b) as compression members using the strength design provisions for flexure and axial loads. The minimum design requirements for nonbearing walls must also be satisfied for bearing walls.

The empirical method may be used only if the resultant of all factored loads falls within the middle third of the wall thickness. This is the case with short vertical walls with approximately concentric loads. The empirical design equation is

$$P_u \le \phi P_{n,w} \le 0.55\phi f'_c A_g \left(1 - \left(\frac{kl_c}{32h}\right)^2\right) \qquad 54.1$$

The capacity factor, ϕ, is 0.70 for bearing on concrete. The *effective length factor*, k, depends on the end conditions of the wall. According to ACI 318 14.5.3.1, $k = 0.8$ for walls braced at the top and bottom against lateral translation and restrained against rotation at the top and/or bottom. $k = 1.0$ for walls braced at the top and bottom against lateral translation and not restrained against rotation at either end. $k = 2.0$ for walls not braced against lateral translation.

Use of the ACI empirical equation is further limited to the following design conditions: (a) The wall thickness, h, must not be less than $^1/_{25}$ times the supporting length or height, whichever is shorter, nor may it be less than 4 in. Exterior basement walls and foundation all must be at least 7.5 in thick. (b) Walls must contain both horizontal and vertical reinforcement. The area of horizontal reinforcement must not be less than 0.0025 times the gross concrete area. The area of vertical reinforcement must not be less than 0.0015 times the gross concrete area. (c) To be considered effective for beam reaction, the length of the wall must not exceed the center-to-center distance between reactions or the width of bearing plus four times the wall thickness. (d) The wall must be anchored to the floors or to columns and other structural elements of the building.

3. BEARING WALLS: STRENGTH DESIGN METHOD

If the wall has a nonrectangular cross section (as in ribbed wall panels) or if the eccentricity of the force resultant is greater than one sixth of the wall thickness, the wall must be designed as a column subject to axial loading and bending. Moreover, if the effective slenderness ratio (kl_u/r) is greater than 100, theoretical analysis involving axial loads, moments, deflections, and creep should be performed. Design aids such as those published by the Portland Cement Association are useful for such cases, since the procedure is complex.

4. SHEAR WALLS

Shear walls are designed to resist lateral wind and seismic loads. Reinforced concrete walls have high in-plane stiffness, making them suitable for resisting lateral forces. The ductility provided by the reinforcing steel ensures a ductile-type failure. Ductile failure is the desirable failure mode because it gives warning and enough time for the occupants of the building to escape prior to total collapse. Since lateral forces can come from any direction, shear walls should be reinforced on both vertical sides.

5. DESIGN OF RIGID RETAINING WALLS

Retaining walls are essentially vertical cantilever beams, with the additional complexities of nonuniform loading and soil-to-concrete contact. The wall is designed to resist moments from the lateral earth pressure. The following procedure can be used to design the structural reinforcement.

step 1: Gather information needed to design the wall.

H	wall height
B	base length
t_b	thickness of base
b	batter decrement (change in stem width per unit height)
$R_{a,h}$	horizontal active earth pressure resultant per unit wall width
y_a	height of the active earth pressure resultant
$R_{a,y}$	vertical active earth pressure resultant per unit wall width

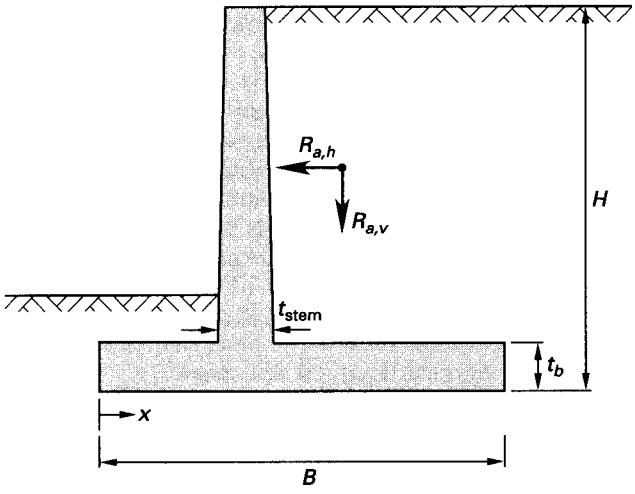

Figure 54.1 *Retaining Wall Dimensions (step 1)*

step 2: Select a reinforcement ratio to control deflections.

$$\rho \approx \tfrac{1}{2}\rho_{\max} = 0.375\rho_{\text{balanced}} \qquad 54.2$$

step 3: Calculate a trial coefficient of resistance for the stem.

$$R_{u,\text{trial}} = \rho f_y \left(1 - \left(\frac{\rho f_y}{(2)(0.85)f'_c}\right)\right) \qquad 54.3$$

step 4: Calculate the factored moment, $M_{u,\text{stem}}$, at the base of the stem per unit width, w, from the active earth pressure resultant. Include forces from surcharge loads, but disregard reductions from passive distributions.

$$M_{u,\text{stem}} = 1.7R_{a,h}y_a \qquad 54.4$$

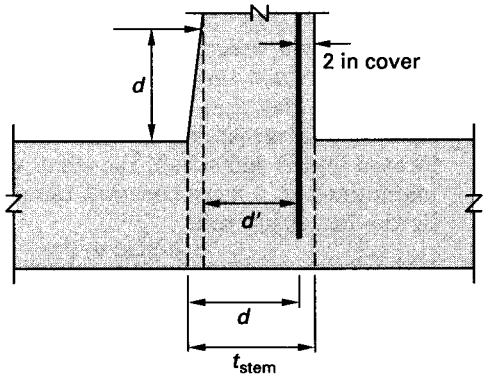

Figure 54.2 *Base of Stem Details (step 4)*

step 5: Calculate the required stem thickness at the base. Since the ultimate moment is per unit wall width, w will be the width of that unit (e.g., 12 in for moments per foot). $\phi = 0.90$ for flexure. If ρ has been selected arbitrarily, the stem thickness will not be unique.

$$d = \sqrt{\frac{M_{u,\text{stem}}}{\phi R_u w}} \qquad 54.5$$

2 in of cover are required for no. 6 bars or larger when exposed to earth or weather. The total thickness of the stem at the base is

$$t_{\text{stem}} = d + \text{cover} + \tfrac{1}{2}d_b \qquad 54.6$$

step 6: Calculate the factored shear, $V_{u,\text{stem}}$, on the stem per unit width at the critical section. Include all of the active and surcharge pressure loading from the top of the retaining wall down to the critical section, a distance d from the base.

$$V_{u,\text{stem}} = 1.7V_{\text{active}} + 1.7V_{\text{surcharge}} \qquad 54.7$$

step 7: Calculate the unreinforced concrete shear strength for a unit wall width, w. $\phi = 0.85$ for shear at the critical section a distance d from the bottom of the stem. d' is the thickness of the compression portion of the stem a distance d from the bottom of the stem. (One-way shear is assumed.) $d' = d$ when the batter decrement is zero.

$$\phi V_n = 2\phi w d' \sqrt{f'_c} \qquad 54.8$$

step 8: If $\phi V_n \geq V_{u,\text{stem}}$, only minimum shear reinforcement is needed and the stem can be designed as a slab. Otherwise, select vertical reinforcing to carry the deficit. (See step 10.)

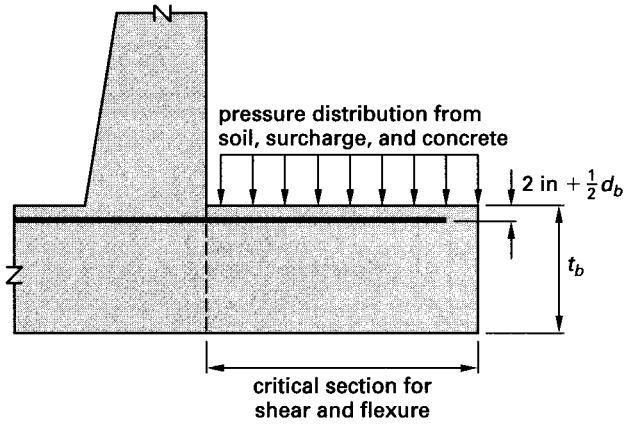

Figure 54.3 *Heel Details (step 8)*

step 9: If the base design is not known, design the base heel as a cantilever beam. The procedure is similar to the previous steps. The

critical section for shear checking is located at the face of the stem. (Since tension occurs in the heel, the critical section cannot be assumed to occur a distance d from the face of the stem. The entire heel contributes to V_u [ACI 318 11.1.3]). Include shear for a unit width of base from the vertical active pressure, the surcharge, and the heel's self-weight. Disregard the upward pressure distribution as well as any effect the key has on the pressure distributions.

$$V_{u,\text{base}} = 1.4V_{\text{soil}} + 1.4V_{\text{heel weight}} + 1.7V_{\text{surcharge}} \quad 54.9$$

$$M_{u,\text{base}} = 1.4M_{\text{soil}} + 1.4M_{\text{heel weight}} + 1.7M_{\text{surcharge}} \quad 54.10$$

Since the base is cast against the earth, a cover of 3 in is required for reinforcing steel. If the base thickness, t_b, is significantly different from what was used to calculate M_u, a second iteration may be necessary.

Complete the heel reinforcement design by calculating the development length. The distance from the face of the stem to the end of the heel reinforcement must equal or exceed the development length. The heel reinforcement must also extend a distance equal to the development length past the stem reinforcement into the toe.

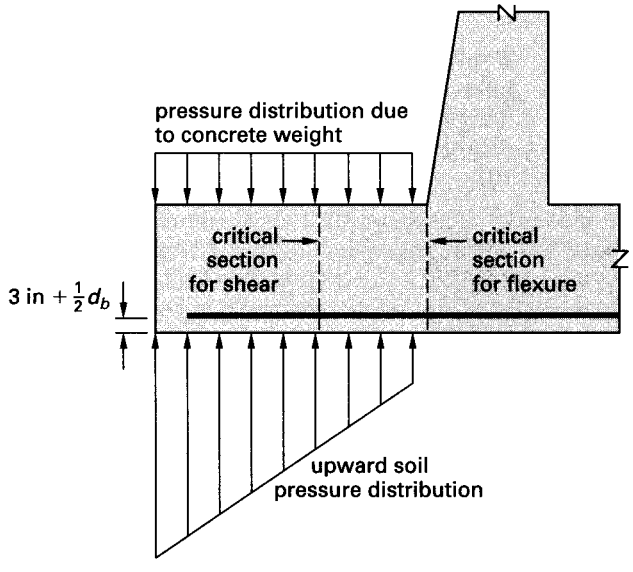

Figure 54.4 *Toe Details (step 9)*

step 10: The procedure for designing the toe is similar to that for the heel. The toe loading is assumed to be caused by the toe self-weight and the upward soil pressure distribution. The passive soil loading is disregarded. For one-way shear, the critical section is located a distance d from the outer face of the stem. For flexure, the critical section is at the outer face of the stem. (ACI 318 9.2.4 specifies a factor of 1.4 for concrete and soil dead loads, and the factor is 1.7 for earth pressure. The toe soil pressure distribution is the result of the horizontal active earth pressure, so a factor of 1.7 is used.) It is likely that shear will determine the toe thickness.

$$V_{u,\text{toe}} = 1.7V_{\text{toe pressure}} - 1.4V_{\text{toe weight}} \quad 54.11$$

$$M_{u,\text{toe}} = 1.7M_{\text{toe pressure}} - 1.4M_{\text{toe weight}} \quad 54.12$$

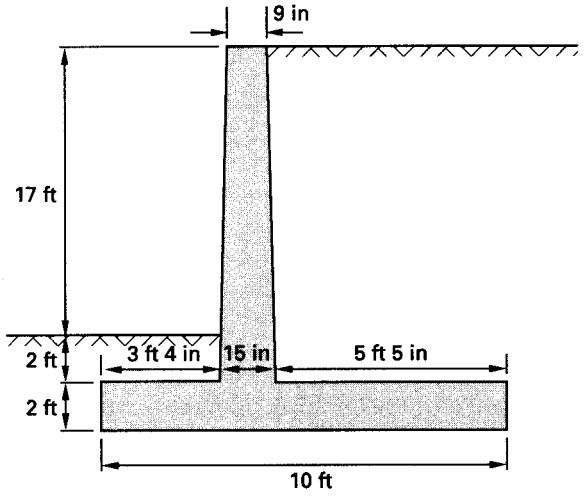
step 11: Calculate the required coefficient of resistance for the base of the stem. Solve for the reinforcement ratio, ρ, and the steel area, A_s. Select reinforcement to meet distribution requirements.

$$R_{u,\text{required}} = \frac{M_{u,\text{stem}}}{\phi w d^2} \quad 54.13$$

$$\rho_{\text{required}} = \rho_{\text{trial}}\left(\frac{R_{u,\text{required}}}{R_{u,\text{trial}}}\right) \quad 54.14$$

step 12: As the stem goes up, less reinforcement is required. Similar calculations should be performed at one or two other heights above the base to obtain a curve of M_u versus height. Select reinforcement to meet the moment requirements.

step 13: Check the development length of the stem reinforcement. The vertical stem height should be adequate without checking. However, it may be difficult to achieve full development in the base. The reinforcement can be extended into the key, if present. Otherwise hooks, bends, or smaller bars should be used.



step 14: Calculate the temperature and shrinkage reinforcement from H and w. Allocate two thirds of this reinforcement to the outside stem face, since that surface is alternately exposed to day and night temperature extremes. The remaining one third should be located on the soil side of the stem, which is maintained at a more constant temperature by the insulating soil.

step 15: If the design assumed a drained backfill, provide for drainage behind the wall. Weep holes should be placed regularly.

Example 54.1

The cantilever retaining wall shown supports 17 ft of earth above the toe of a cut. The backfill is level and has a unit weight of 100 lbf/ft^3. The angle of internal friction is 35°. The allowable soil pressure under service loading is 5000 lbf/ft^2. The coefficient of friction

between the concrete and soil is 0.60. 3500 psi concrete and 60,000 psi steel are used. (a) What is the equivalent fluid pressure behind the wall? (b) What is the active earth pressure resultant? (c) What is the overturning moment? (d) What is the resisting moment? (e) What is the factor of safety against overturning? (f) What is the factor of safety against sliding? (g) Is any part of the heel soil in tension? (h) What is the maximum pressure below the toe? (i) Specify the stem reinforcement. (j) Investigate the development length of the stem bars in the base. (k) Design the temperature steel for the stem. (l) Design the bending steel for the heel. (m) Design the temperature steel for the heel.

Solution

(a) The active earth pressure coefficient is

$$k_a = \frac{1-\sin\phi}{1+\sin\phi} = \frac{1-\sin 35^\circ}{1+\sin 35^\circ} = 0.271$$

$$\gamma_{\text{equivalent}} = k_a\gamma_{\text{soil}} = (0.271)\left(100\ \frac{\text{lbf}}{\text{ft}^3}\right) = 27.1\ \text{lbf/ft}^3$$

(b) The active height is

$$H = 17\ \text{ft} + 2\ \text{ft} + 2\ \text{ft} = 21\ \text{ft}$$

$$R_a = \tfrac{1}{2}k_a\gamma H^2 = \frac{(0.5)(0.271)\left(100\ \frac{\text{lbf}}{\text{ft}^3}\right)(21\ \text{ft})^2}{1000\ \frac{\text{lbf}}{\text{kip}}} = 5.976\ \text{kips/ft}$$

(c) The overturning moment from the active resultant is

$$M = R_a y_a = R_a\left(\frac{H}{3}\right) = \left(5.976\ \frac{\text{kips}}{\text{ft}}\right)\left(\frac{21\ \text{ft}}{3}\right) = 41.83\ \text{ft-kips/ft}$$

(d) Determine the weights per unit width (1 ft) and their moment arms (from the toe). Area 1 is the soil above the heel.

$$W_1 = \frac{(5\frac{5}{12}\ \text{ft})\,(19\ \text{ft})\left(100\ \frac{\text{lbf}}{\text{ft}^3}\right)}{1000\ \frac{\text{lbf}}{\text{kip}}} = 10.29\ \text{kips/ft}$$

$$x_1 = 10\ \text{ft} - \left(\tfrac{1}{2}\right)\left(5\tfrac{5}{12}\right)\ \text{ft} = 7.29\ \text{ft}$$

$$M_1 = W_1 x_1 = (10.29\ \text{kips})(7.29\ \text{ft}) = 75.02\ \text{ft-kips/ft}$$

The other weights are found similarly.

area	weight (kips/ft)	moment arm (ft)	moment (ft-kips/ft)
1: heel soil	10.29	7.29	75.02
2: batter soil	0.48	4.42	2.12
3: batter stem	0.72	4.25	3.06
4: 9 in stem	2.14	3.71	7.92
5: base	3.0	5.00	15.0
totals	16.63 kips/ft		103.12 ft-kips/ft

(e) The factor of safety against overturning is

$$\text{FS}_{\text{OT}} = \frac{103.12\ \frac{\text{ft-kips}}{\text{ft}}}{41.83\ \frac{\text{ft-kips}}{\text{ft}}} = 2.46 \quad [> 1.5, \text{ so OK}]$$

(f) The friction force resisting sliding is

$$R_{\text{SL}} = f\sum W_i = (0.60)\left(16.63\ \frac{\text{kips}}{\text{ft}}\right) = 9.98\ \text{kips/ft}$$

$$\text{FS}_{\text{SL}} = \frac{9.98\ \frac{\text{kips}}{\text{ft}}}{5.976\ \frac{\text{kips}}{\text{ft}}} = 1.67 \quad [> 1.5, \text{ so OK}]$$

(g) Locate the resultant from the toe.

$$x_R = \frac{M_R - M_{\text{OT}}}{\sum W_i} = \frac{103.12\ \frac{\text{ft-kips}}{\text{ft}} - 41.83\ \frac{\text{ft-kips}}{\text{ft}}}{16.63\ \frac{\text{kips}}{\text{ft}}} = 3.68\ \text{ft}$$

Structural

Since the resultant acts in the middle third, there is no uplift on the footing. The heel soil is not in tension.

(h) The eccentricity is

$$\epsilon = \frac{10 \text{ ft}}{2} - 3.68 \text{ ft} = 1.32 \text{ ft}$$

Perform all calculations per foot of base width.

$$P = \sum W_i = 16.63 \text{ kips/ft}$$

$$A = 10 \text{ ft}^2/\text{ft}$$

$$M = (1.32 \text{ ft})(16.63 \text{ kips}) = 21.95 \text{ ft-kips/ft}$$

$$c = 1 \text{ ft/ft}$$

$$I = \frac{bh^2}{6} = \frac{(1 \text{ ft})(10 \text{ ft})^2}{6} = 16.67 \text{ ft}^4/\text{ft}$$

$$q = \frac{P}{A} \pm \frac{Mc}{I}$$

$$= \frac{16.63 \frac{\text{kips}}{\text{ft}}}{10 \frac{\text{ft}^2}{\text{ft}}} \pm \frac{\left(21.95 \frac{\text{ft-kips}}{\text{ft}}\right)\left(1 \frac{\text{ft}}{\text{ft}}\right)}{16.67 \frac{\text{ft}^4}{\text{ft}}}$$

$$= 1.663 \frac{\text{kips}}{\text{ft}^2} \pm 1.32 \frac{\text{kips}}{\text{ft}^2}$$

$$q_{\text{toe}} = 1.66 \frac{\text{kips}}{\text{ft}^2} + 1.32 \frac{\text{kips}}{\text{ft}^2} = 2.98 \frac{\text{kips}}{\text{ft}^2}$$

$$q_{\text{heel}} = 1.66 \frac{\text{kips}}{\text{ft}^2} - 1.32 \frac{\text{kips}}{\text{ft}^2} = 0.35 \frac{\text{kip}}{\text{ft}^2}$$

(i) Subtracting 2 in of cover for a formed surface, the effective depth of the wall is

$$d = 15 \text{ in} - 2 \text{ in} = 13 \text{ in}$$

The distance from the base to the critical stem section is also 13 in. Calculate the factored shear from the top to the critical section.

$$V_u = (1.7)\left(\tfrac{1}{2}\right)\gamma_{\text{equivalent}} L^2$$

$$= (1.7)\left(\tfrac{1}{2}\right)\left(27.1 \frac{\text{lbf}}{\text{ft}^3}\right)\left(21 \text{ ft} - 2 \text{ ft} - \frac{13 \text{ in}}{12 \frac{\text{in}}{\text{ft}}}\right)^2$$

$$= 7394 \text{ lbf/ft}$$

Use Eq. 54.8.

$$\phi V_n = 2\phi w d' \sqrt{f'_c}$$

$$= (2)(0.85)(12 \text{ in})(13 \text{ in})\sqrt{3500 \frac{\text{lbf}}{\text{in}^2}}$$

$$= 15{,}690 \text{ lbf}$$

Since $\phi V_n > V_u$, the stem thickness is acceptable. The moment at the base of the stem is

$$M_u = (1.7)\left(\tfrac{1}{2}\right)\gamma_{\text{equivalent}}(H - t_b)^2 \times \left(\frac{H - t_b}{3}\right)$$

$$= \frac{(1.7)\left(\tfrac{1}{2}\right)\left(27.1 \frac{\text{lbf}}{\text{ft}^3}\right) \times (21 \text{ ft} - 2 \text{ ft})^3}{3}$$

$$= 52{,}666 \text{ ft-lbf}$$

$$R_u = \frac{M_u}{bd^2} = \frac{(52{,}666 \text{ ft-lbf})\left(12 \frac{\text{in}}{\text{ft}}\right)}{(12 \text{ in})(13 \text{ in})^2}$$

$$= 311 \text{ lbf/in}^2$$

$$R_u = \phi f'_c \omega(1 - 0.59\omega)$$

$$\frac{R_u}{\phi f'_c} = \omega - 0.59\omega^2$$

$\phi = 0.90$ for moments.

$$\frac{311 \frac{\text{lbf}}{\text{in}^2}}{(0.90)\left(3500 \frac{\text{lbf}}{\text{in}^2}\right)} = \omega - 0.59\omega^2$$

This is a quadratic equation. ω has the values of 1.58 and 0.11. Disregard 1.58.

$$\rho = \frac{\omega f'_c}{f_y}$$

$$= \frac{(0.11)\left(3500 \frac{\text{lbf}}{\text{in}^2}\right)}{60{,}000 \frac{\text{lbf}}{\text{in}^2}}$$

$$= 0.0064$$

The required steel area per foot of wall width is

$$A_s = \rho b d = (0.0064)(12 \text{ in})(13 \text{ in}) = 1.00 \text{ in}^2/\text{ft}$$

This area can be provided with no. 9 bars at 12 in spacing.

(j) Check the development length. Refer to ACI 318. 12.2.2. $\alpha = 1$ (vertical bars), $\beta = 1$ (uncoated), and $\lambda = 1$ (normal weight concrete).

$$l_d = \frac{d_b f_y \alpha \beta \lambda}{20\sqrt{f'_c}}$$

$$= \frac{(1.125 \text{ in})\left(60{,}000 \frac{\text{lbf}}{\text{in}^2}\right)(1)(1)(1)}{20\sqrt{f'_c}}$$

$$= 57 \text{ in}$$

This is greater than the footing thickness. Either the footing thickness should be increased, hooks should be used on the ends of the stem bars, or a smaller-diameter bar should be used. A more sophisticated analysis can also be performed.

(k) The temperature steel required in the stem is

$$\begin{aligned}A_{s,\text{temperature}} &= 0.0018bt_s \\ &= (0.0018)(12\text{ in})(15\text{ in}) = 0.32\text{ in}^2/\text{ft}\end{aligned}$$

Give two thirds of this to the front face and one third to the back face.

$$\left(\tfrac{2}{3}\right)\left(0.32\ \frac{\text{in}^2}{\text{ft}}\right) = 0.22\text{ in}^2/\text{ft}$$

Use no. 4 bars spaced at 12 in.

$$\left(\tfrac{1}{3}\right)\left(0.32\ \frac{\text{in}^2}{\text{ft}}\right) = 0.10\text{ in}^2/\text{ft}$$

Use no. 3 bars spaced at 12 in.

(l) Disregard the soil pressure under the heel. The factored uniform load above the heel is

$$\begin{aligned}w_u &= (1.4)\left((17\text{ ft})\left(100\ \frac{\text{lbf}}{\text{ft}^3}\right) + (2\text{ ft})\left(150\ \frac{\text{lbf}}{\text{ft}^3}\right)\right) \\ &\quad \times \left(1000\ \frac{\text{lbf}}{\text{kip}}\right) \\ &= 2.8\text{ kips/ft}\end{aligned}$$

The distance from the vertical stem steel to heel edge is

$$\begin{aligned}L &= (5\text{ ft }5\text{ in}) + 3\text{ in} = 5\text{ ft }8\text{ in }(5.67\text{ ft}) \\ M_u &= \tfrac{1}{2}w_uL^2 = \left(\tfrac{1}{2}\right)\left(2.8\ \frac{\text{kips}}{\text{ft}}\right)(5.67\text{ ft})^2 \\ &= 45\text{ ft-kips}\end{aligned}$$

The heel extension (from the stem's soil face) is

$$\begin{aligned}L &= 5\text{ ft }5\text{ in }(5.42\text{ ft}) \\ V_u &= w_uL = \left(2.8\ \frac{\text{kips}}{\text{ft}}\right)(5.42\text{ ft}) \\ &= 15.2\text{ kips}\end{aligned}$$

The heel thickness is 2 ft. The heel depth is

$$\begin{aligned}d &= t_{\text{heel}} - \text{cover} - \frac{d_b}{2} \\ &= (2\text{ ft})\left(12\ \frac{\text{in}}{\text{ft}}\right) - 2\text{ in} - \frac{1\text{ in}}{2} \\ &= 21.5\text{ in} \\ \phi V_n &= 2\phi bd\sqrt{f'_c} \\ &= \frac{(2)(0.85)(12\text{ in})(21.5\text{ in}) \times \sqrt{3500\ \frac{\text{lbf}}{\text{in}^2}}}{1000\ \frac{\text{lbf}}{\text{kip}}} \\ &= 26.0\text{ kips} \quad \left[\begin{array}{c}> V_u = 15.2\text{ kips,} \\ \text{so OK}\end{array}\right] \\ R_u &= \frac{M_u}{bd^2} \\ &= \frac{(45\text{ ft-kips})\left(12\ \frac{\text{in}}{\text{ft}}\right)\left(1000\ \frac{\text{lbf}}{\text{kip}}\right)}{(12\text{ in})(21.5\text{ in})^2} \\ &= 97\text{ lbf/in}^2 \\ R_u &= \phi f'_c\omega(1 - 0.59\omega) \\ \frac{R_u}{\phi f'_c} &= \omega - 0.59\omega^2 \\ \frac{97\ \frac{\text{lbf}}{\text{in}^2}}{(0.90)\left(3500\ \frac{\text{lbf}}{\text{in}^2}\right)} &= \omega - 0.59\omega^2 \\ \omega &= 0.0315 \\ \rho &= \frac{\omega f'_c}{f_y} \\ &= \frac{(0.0315)\left(3500\ \frac{\text{lbf}}{\text{in}^2}\right)}{60{,}000\ \frac{\text{lbf}}{\text{in}^2}} \\ &= 0.00184\end{aligned}$$

The minimum reinforcement ratio is

$$\rho_{\min} = \frac{200}{f_y} = \frac{200}{60{,}000\ \frac{\text{lbf}}{\text{in}^2}} = 0.0033$$

The required steel area per foot of wall width is

$$A_s = \rho bd = (0.0033)(12\text{ in})(21.5\text{ in}) = 0.85\text{ in}^2$$

This can be provided with no. 9 bars with 12 in spacing.

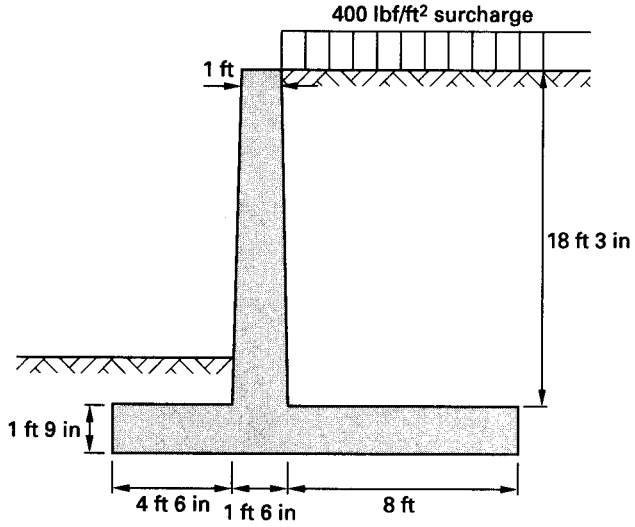
(m) $$\begin{aligned}A_{s,\text{temperature,heel}} &= (0.0018)wt_{\text{heel}} \\ &= (0.0018)(12\text{ in})(24\text{ in}) \\ &= 0.52\text{ in}^2/\text{ft}\end{aligned}$$

Structural

Half of this is given to the top of the heel and half to the bottom of the heel.

Use no. 6 bars spaced at 18 in, top and bottom.

PRACTICE PROBLEMS



1. A 14 ft high concrete bearing wall supports concrete roof beams spaced on 7 ft centers. Using the tributary area method, each end reaction is found to carry a dead load of 25 kips and a live load of 20 kips. The bearing width of the beam is 12 in. Both the top and bottom of the wall are restrained against translation and rotation. The concrete strength and the yield strength of steel are 4000 psi and 60,000 psi, respectively. The wall weight can be neglected. The ACI empirical formula is to be used. (a) What is the required wall thickness? (b) Is the bearing strength adequate if the wall is 7 in thick? (c) What is the vertical load capacity of a 7-in wall? (d) Design the vertical reinforcing steel. (e) Design the horizontal reinforcing steel.

Answers: (a) 7 in; (b) yes; (c) 276 kips; (d) no. 4 bars at 18 in; (e) no. 4 bars at 12 in

2. (a) What is the vertical capacity of the wall described in Prob. 1 if the wall is not restrained against rotation at the top or bottom? Assume the wall thickness is 7 in. (b) Is the wall capacity still adequate?

Answer: (a) 189 kips; (b) yes

3. *(Time limit: one hour)* The retaining wall shown supports a 400 lbf/ft^2 surcharge in addition to the active backfill loading. 3000 psi concrete and 60,000 psi steel are used. The specific weights of the backfill and the concrete are 100 lbf/ft^3 and 150 lbf/ft^3, respectively. The active earth pressure coefficient is 0.5. The passive earth pressure coefficient is 2.0. (a) What is the factor of safety against overturning? (b) What is the minimum theoretical heel depth? (c) Using a heel depth of 30 in and no. 8 reinforcing bars, what bar spacing is required in the heel?

Answers: (a) 2.09; (b) 30 in; (c) 9 in

1. INTRODUCTION

Footings are designed in two steps: (a) selecting the footing area, and (b) selecting the footing thickness and reinforcement. The footing area is chosen so that the soil contact pressure is within limits. The footing thickness and the reinforcement are chosen to keep the shear and bending stresses in the footing within permissible limits.

Although the footing area is obtained from the unfactored service loads, the footing thickness and reinforcement are calculated from factored loads. This is because the weight of the footing and the overburden contribute to the contact stress, but these forces do not induce shears or bending moments in the footing.

For the general case of a footing with dimensions L and B (see Fig. 55.1), carrying a vertical (downward) axial service load, P_s, and a service moment, M_s, the service soil pressure is

$$q_s = \frac{P_s}{A_f} + \gamma_c h + \gamma_s (H - h) \pm \frac{M_s \left(\frac{B}{2}\right)}{I_f} \leq q_a \quad [55.1]$$

$$I_f = \tfrac{1}{12} L B^3 \quad [55.2]$$

Structural

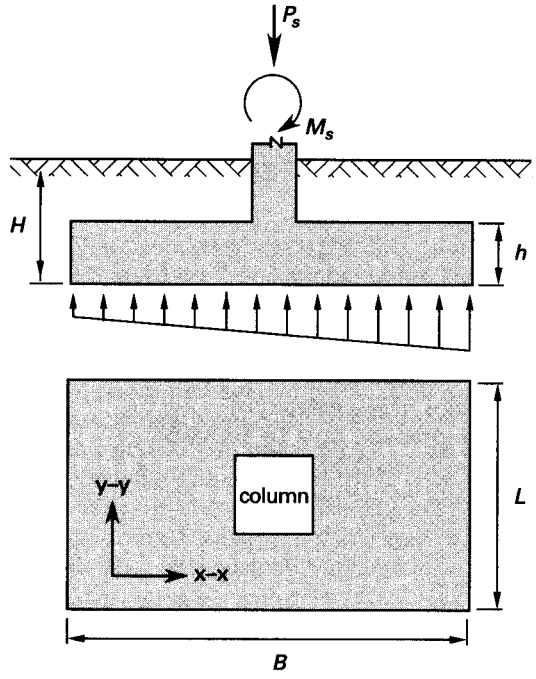

Figure 55.1 *General Footing Loading*

2. WALL FOOTINGS

For a wall footing, the factored load per unit length is

$$q_u = \frac{P_u}{B} \qquad 55.3$$

$$P_u = 1.4P_d + 1.7P_l \qquad 55.4$$

The critical plane for shear is assumed to be located a distance d (the effective footing depth) from the wall face, where d is measured to the center of the flexure steel layer. The thickness of wall footings is selected to satisfy the shear stress requirement of Eq. 55.5. v_u is the shear stress at a distance d from the face of the wall, v_c is the shear strength capacity of the concrete, and $\phi = 0.85$.

$$\phi v_c \leq v_u \qquad 55.5$$

$$v_c = 2\sqrt{f'_c} \qquad 55.6$$

Referring to Fig. 55.2, the shear from the critical section to the footing edge is

$$v_u = \left(\frac{q_u}{d}\right)\left(\frac{B-t}{2} - d\right) \qquad 55.7$$

Combining Eqs. 55.5 and 55.7,

$$d = \frac{q_u(B-t)}{2(q_u + \phi v_c)} \qquad 55.8$$

In a wall footing, the main (y-y) steel resists flexure and is perpendicular to the wall. Temperature and shrinkage steel (x-x) runs parallel to the wall and is placed on top of and in contact with the main steel. The total thickness of the wall footing is

$$h = d + \tfrac{1}{2}(\text{diameter of x-x bars}) + \text{diameter of y-y bars} + \text{cover} \qquad 55.9$$

The minimum cover (below the bars) for cast-in-place concrete against and permanently exposed to earth is 3 in (ACI 318 7.7.1). The minimum depth above the bottom reinforcement is 6 in (ACI 318 15.7). Therefore, the minimum total thickness of a footing is

$$h \geq 6 \text{ in} + \text{diameter of x-x bars} + \text{diameter of y-y bars} + 3 \text{ in} \qquad 55.10$$

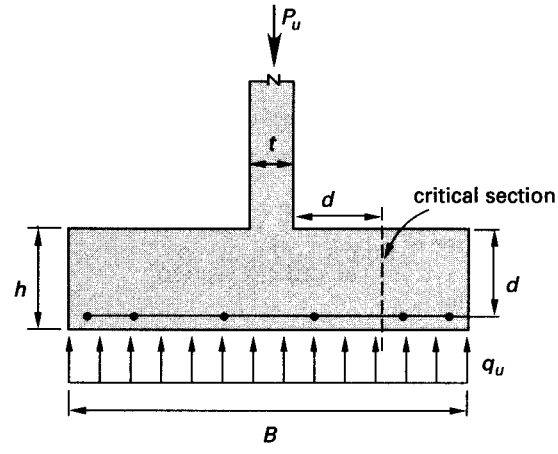

Figure 55.2 *Critical Section for Wall Footing*

3. COLUMN FOOTINGS

The effective depth, d (and thickness, h), of column footings is controlled by shear strength. Two shear failure mechanisms are considered: one-way shear and two-way shear. The footing depth is taken as the larger of the two values calculated. In the majority of cases, the required depth is controlled by two-way shear.

For *one-way shear* (also known as *single-action shear* and *wide-beam shear*), the critical sections are a distance d from the face of the column. Equation 55.11 applies for the case of uniform pressure distribution (i.e., where there is no moment). The section with the largest values of e controls.

$$v_u = \frac{q_u e}{d} \qquad 55.11$$

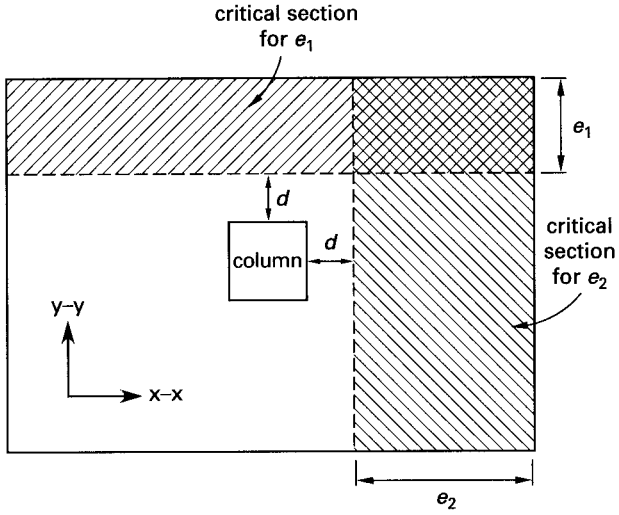

Figure 55.3 *Critical Section for One-Way Shear*

In addition to the footing failing in shear as a wide beam, failure can also occur in *two-way shear* (also known as *double-action shear* and *punching shear*). In this failure mode, the column and an attached concrete piece punch through the footing. Although the failure plane is actually inclined outward, the failure surface is assumed for simplicity to consist of vertical planes located a distance $d/2$ from the column sides.

The area in punching is given by Eq. 55.12. b_1 is the length of the critical area normal to the applied column moment. Similarly, b_2 is the length of the critical area parallel to the applied column moment.

$$A_p = 2(b_1 + b_2)d \qquad 55.12$$

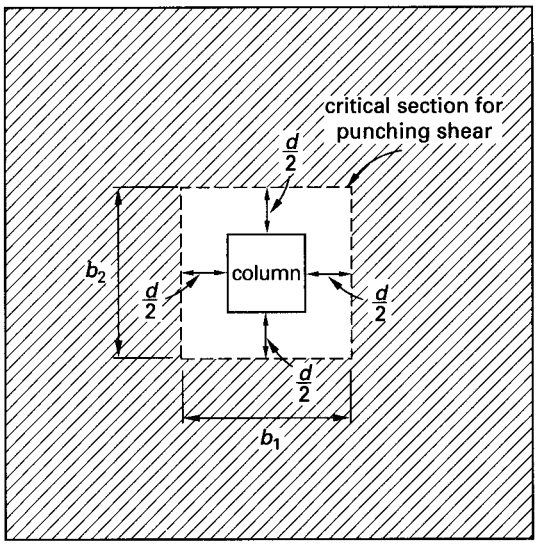

Figure 55.4 *Critical Section for Two-Way Shear*

Assume for generality that the column supports a moment. The maximum shear stress on the critical shear plane is computed as the sum of the shear stresses resulting from the axial load and the moment. The punching shear stress is given by Eq. 55.13.

$$v_u = \frac{P_u - R}{A_p} + \frac{\gamma_v M_u (0.5 b_1)}{J} \qquad 55.13$$

In Eq. 55.13, R is the resultant of the soil pressure acting over the area $b_1 b_2$. The stresses from the moment cancel over this area, so R is

$$R = \frac{P_u b_1 b_2}{A_f} \qquad 55.14$$

γ_v is the fraction of the moment M_u that is assumed to contribute to shear stress (ACI 318 11.12.6.1 and ACI 318 13.5.3.2).

$$\gamma_v = 1 - \frac{1}{1 + \frac{2}{3}\sqrt{\frac{b_1}{b_2}}} \qquad 55.15$$

When the column is located at the center of the footing, the constant J is given by Eq. 55.16. (Refer to ACI 318 11.12.6 for edge-located columns.)

$$J = \left(\frac{d b_1^3}{6}\right)\left(1 + \left(\frac{d}{b_1}\right)^2 + 3\left(\frac{b_2}{b_1}\right)\right) \qquad 55.16$$

The allowable shear stress for punching shear is given by Eq. 55.17.

$$v_c = (2 + y)\sqrt{f'_c} \qquad 55.17$$

$$y = \min\{2,\ 4/\beta_c,\ 40d/b_o\} \qquad 55.18$$

$$\beta_c = \frac{\text{column long side}}{\text{column short side}} \qquad 55.19$$

$$b_o = \frac{A_p}{d} \qquad 55.20$$

Determining the footing thickness is accomplished through trial and error. First, obtain the required depth for punching shear using the following procedure.

step 1: Assume a value of d.

step 2: Compute b_1 and b_2.

step 3: Evaluate A_p, J, and γ_v.

step 4: Compute R.

step 5: Compute v_u.

step 6: Calculate v_c.

step 7: If $v_u \geq \phi v_c$, increase d and repeat from step 2.

If $v_u < \phi v_c$, the punching strength is adequate. If the excess in capacity is substantial, reduce d and repeat from step (2). Second, check the adequacy of the footing depth for one-way shear.

Structural

The effective depth for shear is typically assumed to be the distance from the top of the footing to the average depth of the two perpendicular steel reinforcement layers. (The two steel layers may use different bar diameters, so the average depth may not correspond to the contact point.) The total thickness of a column footing is

$$h = d + \left(\tfrac{1}{2}\right)(\text{diameter of x-x bars} + \text{diameter of y-y bars}) + \text{cover} \qquad 55.21$$

As with wall footings, the minimum cover (below the bars) for cast-in-place concrete against and permanently exposed to earth is 3 in (ACI 318 7.7.1). The minimum depth above the bottom reinforcement is 6 in (ACI 318 15.7). Therefore, the minimum total thickness of a footing is

$$h \geq 6 \text{ in} + \text{diameter of x-x bars} + \text{diameter of y-y bars} + 3 \text{ in} \qquad 55.22$$

4. SELECTION OF FLEXURAL REINFORCEMENT

For the purpose of designing flexural reinforcement, footings are treated as cantilever beams carrying an upward-acting, nonuniform distributed load. The critical section for flexure is located at the face of the column or wall. (Masonry walls are exceptions. The critical section is halfway between the center and the edge of the wall (ACI 318 15.4.2).) The moment acting at the critical section from a uniformly distributed soil pressure distribution (i.e., as when there is no column moment) is

$$M_u = \frac{q_u L l^2}{2} \quad \text{[no column moment]} \qquad 55.23$$

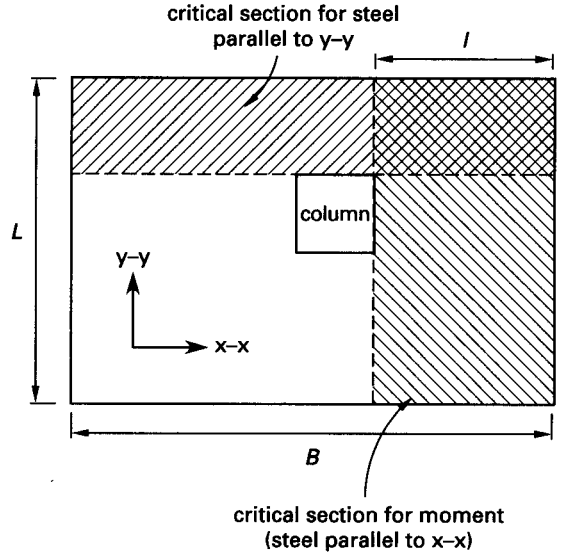

Figure 55.5 *Critical Section for Moment*

The required steel area is given by Eq. 55.24. As with beams, a good starting point is $\lambda = 0.1d$.

$$A_s = \frac{M_u}{\phi f_y (d - \lambda)} \qquad 55.24$$

The effective depth of the flexural reinforcement will differ in each perpendicular direction. However, it is customary to design both layers using a single effective depth. While the conservative approach is to use the smaller effective depth for both layers, it is not unusual in practice to design the steel in the x-x and y-y directions based on the average effective depth.

The following provisions apply.

- The minimum steel ratio (based on the gross cross-sectional area) in any direction is 0.002 for f_y = 40 kips/in^2 steel and 0.0018 for f_y = 60 kips/in^2 steel (ACI 7.12.2.1). The minimum reinforcement ratio of $200/f_y$ for flexural members (i.e., beams) does not apply to footings (ACI 10.5.4).
- In one-way wall footings and square two-way footings, the steel is distributed uniformly (ACI 318 15.4.3).
- In rectangular two-way footings, the steel parallel to the long dimension is distributed uniformly. However, the total steel, A_{sd}, parallel to the short dimension is divided into two parts (ACI 318 15.4.4.2).

$$A_1 = A_{sd}\left(\frac{2}{\beta + 1}\right) \qquad 55.25$$

$$A_2 = A_{sd} - A_1 \qquad 55.26$$

β is the ratio of the long footing side to the short footing side. The steel area A_1 is distributed uniformly in a band centered on the column and having a width equal to the short dimension of the footing. The area A_2 is distributed uniformly in the remaining part of the footing.

- The maximum spacing center-to-center of bars cannot exceed the lesser of $3h$ (three times the overall footing thickness) or 18 in (ACI 318 10.5.4). (The 18 in maximum spacing usually controls in footings.)
- The steel bars must be properly anchored.

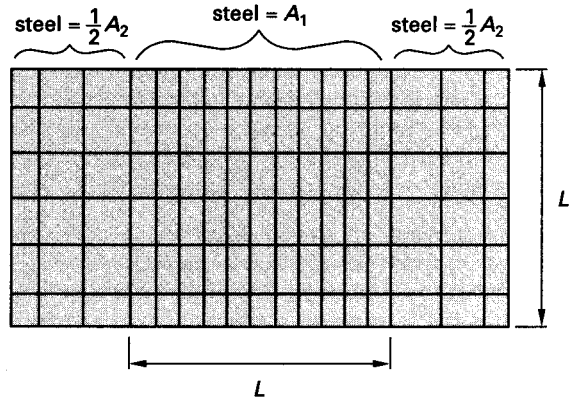

Figure 55.6 *Distribution of Steel (parallel to the short dimension)*

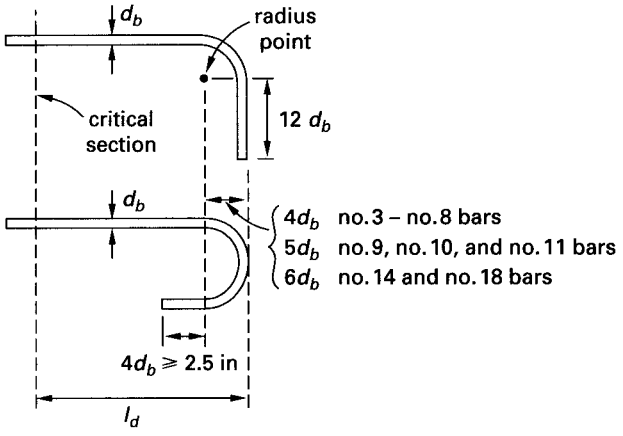
5. DEVELOPMENT LENGTH OF FLEXURAL REINFORCEMENT

Either ACI 318 12.2.2 or ACI 318 12.2.3 can be used to calculate the development length for straight bars of diameter d_b in tension. However, both sections offer a number of complex alternatives. Using the simpler section (ACI 318 12.2.2), the development length for straight bars in tension can be conservatively estimated as



$$l_d = \frac{3d_b f_y \beta\gamma}{50\sqrt{f'_c}} \geq 12 \text{ in} \qquad 55.27$$

The *epoxy coating factor*, β, and *size factor*, γ, are both given in ACI 318 12.2.4.

$\beta = 1.5$	epoxy-coated, clear spacing $\leq 6d_b$
$\beta = 1.2$	for all other epoxy-coated bars
$\beta = 1.0$	uncoated bars
$\gamma = 0.8$	no. 6 and smaller
$\gamma = 1.0$	no. 7 bars and larger

Equation 55.28 can be used for bars in tension with standard hooks (ACI 318 12.5). However, β can only take on the values of 1.0 and 1.2.

$$l_d = \frac{0.02\beta d_b f_y}{\sqrt{f'_c}} \geq 8d_b \geq 6 \text{ in} \qquad 55.28$$

Adapted from ACI 318 Fig. R12.5.1

Figure 55.7 *Standard Hooks*

6. TRANSFER OF FORCE AT COLUMN BASE

Column and wall forces are transferred to footings by direct bearing and by forces in steel bars. The steel bars used to transfer forces from one member to the other are known as *dowels* or *dowel bars*. Dowel bars are left to extend above the footing after the footing concrete has hardened, and they are spliced into the column or wall reinforcement prior to pouring the column or wall concrete.

It is common practice to use at least four dowel bars. Where a significant moment must be transferred from a column to a footing, the dowel steel provided is typically chosen to match the column steel. Generally, the number of dowels and longitudinal bars are equal. The minimum dowel area is (ACI 318 15.8.2.1)

$$A_{db,\min} = 0.005A_c \qquad 55.29$$

The dowels must extend into the footing no less than the compressive *development length*, l_d, of the dowels (ACI 318 15.8.2.3). For straight bars in compression,

$$l_d = 0.02d_b\left(\frac{f_y}{\sqrt{f'_c}}\right) \geq 0.0003d_b f_y \geq 8 \text{ in} \qquad 55.30$$

If the dowel bar is bent in an L-shape, the development length must be achieved over the vertical portion. (While hooks and bends can be used to decrease the required development length for dowels acting in tension, hooks and bends are ineffective for compressive forces.) Since lap splices are considered to be class-B splices (ACI 12.15.2), the dowel bar must extend into the column or wall 1.3 times the development length of the dowel or 1.3 times the development length of the bar in the column or wall, whichever is larger (ACI 318 12.15.1).

The footing thickness sets a limit on the length of dowel that is effective. If the footing depth is less than the development length, smaller bars must be used. The maximum effective dowel length is

$$l_d \leq h - \text{cover} - \text{diameter of x-x steel} - \text{diameter of y-y steel} \qquad 55.31$$

The maximum bearing strength of concrete is (ACI 318 10.17.1)

$$f_{\text{bearing}} = 0.85f'_c \qquad 55.32$$

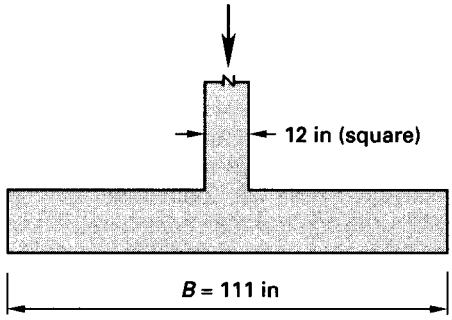
However, the effective bearing capacity of the column-footing connection is actually greater than $f_{\text{bearing}}A_c$, since a redistribution of stressed area over the larger footing area will increase the effective allowable bearing load. The ultimate load carried by bearing is given by Eq. 55.33 (ACI 318 10.17.1). For bearing on concrete, as in Eq. 55.33, $\phi = 0.70$ (ACI 318 9.3.2.4).

$$P_{\text{bearing}} = 0.85\alpha\phi f'_c A_c \qquad 55.33$$

α accounts for the enhancement in the capacity of the concrete that results because the loaded area is only a fraction of the total area of the footing.

$$\alpha = \sqrt{\frac{A_{ff}}{A_c}} \leq 2 \qquad 55.34$$

Structural



A_{ff} is the largest footing area that is geometrically similar to the column and that does not exceed any of the edges of the footing (ACI 318 10.17.1). For a square column and square footing, this is the same as the footing area.

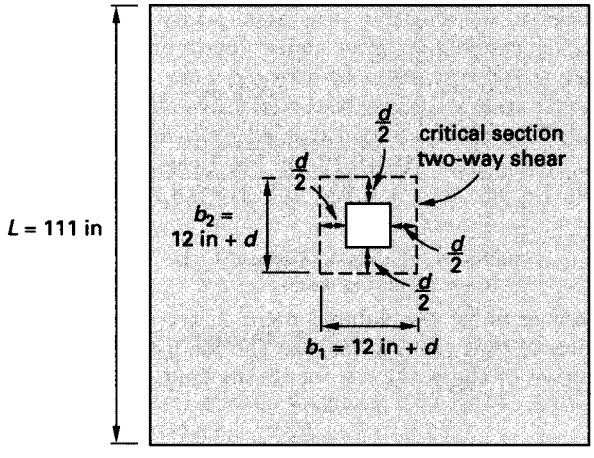
For the case of pure axial loading (no moment), the required area of the dowel bars is

$$A_{db} = \frac{P_u - 0.85\alpha\phi f'_c A_c}{\phi f_y} \qquad 55.35$$

Example 55.1

A 111 in square footing supports a 12 in square column. The service loads are 82.55 kips dead load and 75.4 kips live load. Material properties are $f'_c = 4000$ lbf/in^2, and f_y =60,000 lbf/in^2. Design the footing depth and reinforcement.

(a)



Solution

step 1: Assume punching shear controls the depth.

$$b_1 = b_2 = 12 \text{ in} + (2)\left(\frac{d}{2}\right) = 12 \text{ in} + d$$

The area resisting the punching shear is given by Eq. 55.12.

$$A_p = 2(b_1 + b_2)d$$
$$= 2(12 + d + 12 + d)d = 48d + 4d^2$$

(b)

The factored load is

$$P_u = 1.4P_d + 1.7P_l$$
$$= (1.4)(82.56 \text{ kips}) + (1.7)(75.4 \text{ kips})$$
$$= 243.76 \text{ kips}$$

The upward force from the soil pressure that acts to reduce the total punching shear force is given by Eq. 55.14.

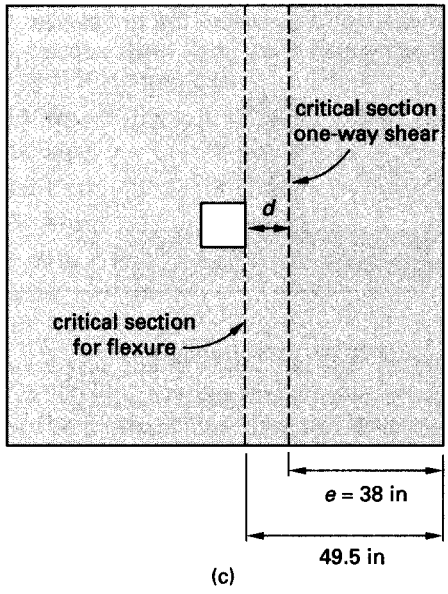
$$R = P_u\left(\frac{b_1 b_2}{A_f}\right)$$
$$= \frac{(243.76 \text{ kips})(12 + d)(12 + d)}{(111 \text{ in})^2}$$
$$= \left(0.0198 \frac{\text{kip}}{\text{in}^2}\right)(12 + d)^2$$

There is no moment. The punching shear stress is given by Eq. 55.13.

$$v_u = \frac{P_u - R}{A_p}$$
$$= \frac{243.76 \text{ kips} - (0.0198)(12 + d)^2}{48d + 4d^2}$$

Using $y = 2$, the allowable stress for punching shear is given by Eq. 55.17.

$$v_c = (2 + y)\sqrt{f'_c}$$
$$= (2 + 2)\sqrt{4000 \frac{\text{lbf}}{\text{in}^2}} = 252.98 \text{ lbf/in}^2$$



Equate the capacity to the shear stress. From Eq. 55.5,

$$\phi v_c = v_u$$
$$\frac{(0.85)\left(252.98 \frac{\text{lbf}}{\text{in}^2}\right)}{1000 \frac{\text{lbf}}{\text{kip}}} = \frac{243.76 \text{ kips} - (0.0198)(12 + d)^2}{48d + 4d^2}$$
$$d = 11.5 \text{ in}$$

step 2: Check the capacity of the footing in one-way shear.

The critical section for one-way shear is at a distance d from the face of the column.

$$e = (0.5)(111 \text{ in} - 12 \text{ in}) - d$$
$$= (0.5)(111 \text{ in} - 12 \text{ in}) - 11.5 \text{ in}$$
$$= 38 \text{ in}$$

(c)

The contact pressure is

$$q_u = \frac{P_u}{A_f} = \frac{243.76 \text{ kips}}{(111 \text{ in})^2}$$
$$= 0.0198 \text{ kip/in}^2$$

The shear stress at the critical section is given by Eq. 55.11.

$$v_u = \frac{q_u e}{d}$$
$$= \frac{\left(0.0198 \frac{\text{kip}}{\text{in}^2}\right)(38 \text{ in})\left(1000 \frac{\text{lbf}}{\text{kip}}\right)}{11.5 \text{ in}}$$
$$= 65.43 \text{ lbf/in}^2$$

The nominal shear stress capacity for one-way shear is given by Eq. 55.6.

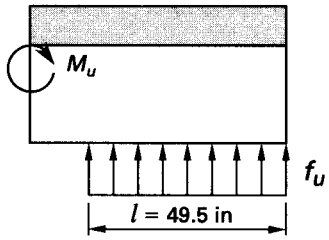
$$v_c = 2\sqrt{f'_c} = 2\sqrt{4000 \frac{\text{lbf}}{\text{in}^2}}$$
$$= 126.49 \text{ lbf/in}^2$$

Compare v_u and ϕv_c to determine if the value of d is adequate.

$$65.43 \frac{\text{lbf}}{\text{in}^2} < (0.85)\left(126.49 \frac{\text{lbf}}{\text{in}^2}\right) \quad \text{[OK]}$$

step 3: Design the flexural reinforcement.

Assuming no. 6 bars and taking the average for both layers, the overall depth of the footing is



$$h = 11.5 \text{ in} + 0.75 \text{ in} + 3.0 \text{ in} = 15.25 \text{ in}$$

It is customary to use a footing depth that is rounded to the nearest inch. Use $h = 16$ in. Using no. 6 bars, the actual (average) effective depth is

$$d = 16 \text{ in} - 3 \text{ in} - 0.75 \text{ in} = 12.25 \text{ in}$$

The critical section for moment is at the face of the column. From the free-body diagram,

$$M_u = \frac{q_u L l^2}{2}$$
$$= \frac{\left(0.0198 \frac{\text{kip}}{\text{in}^2}\right)(111 \text{ in}) \times (49.5 \text{ in})(49.5 \text{ in})}{2}$$
$$= 2692.6 \text{ in-kips}$$

(d)

As with beams, start by assuming λ.

$$\lambda = 0.1d = (0.1)(12.25 \text{ in}) = 1.22 \text{ in}$$

The steel area is given by Eq. 55.24.

$$A_s = \frac{M_u}{\phi f_y (d - \lambda)}$$
$$= \frac{2692.6 \text{ in-kips}}{(0.9)\left(60 \frac{\text{kips}}{\text{in}^2}\right)(12.25 \text{ in} - 1.22 \text{ in})}$$
$$= 4.52 \text{ in}^2$$

Check the assumed value of λ. Use Eq. 55.17.

$$A_c = \frac{f_y A_s}{0.85 f'_c}$$
$$= \frac{\left(60 \frac{\text{kips}}{\text{in}^2}\right)(4.52 \text{ in}^2)}{(0.85)\left(4 \frac{\text{kips}}{\text{in}^2}\right)}$$
$$= 79.76 \text{ in}^2$$

Since the compressed zone is rectangular with a width of 111 in, the value of λ is given by Eq. 50.20.

$$\lambda = \frac{A_c}{2b} = \frac{79.76 \text{ in}^2}{(2)(111 \text{ in})} = 0.36 \text{ in}$$

Structural

Using $\lambda = 0.36$, the revised steel area is given by 55.24.

$$A_s = \frac{M_u}{\phi f_y (d - \lambda)}$$

$$= \frac{2692.6 \text{ in-kips}}{(0.9)\left(60 \frac{\text{kips}}{\text{in}^2}\right)(12.25 \text{ in} - 0.36 \text{ in})}$$

$$= 4.19 \text{ in}^2$$

The minimum steel is

$$A_{s,\min} = (0.0018)(111 \text{ in})(16 \text{ in})$$

$$= 3.20 \text{ in}^2 \quad \text{[does not control]}$$

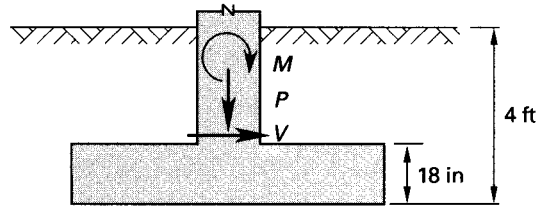
step 4: Check the development length of the flexural reinforcement. For no. 6 bars, using Eq. 55.27,

$$l_d = \frac{3 d_b f_y \gamma}{50\sqrt{f'_c}}$$

$$= \frac{(3)(0.75 \text{ in})\left(60{,}000 \frac{\text{lbf}}{\text{in}^2}\right)(1)(0.8)}{50\sqrt{4000 \frac{\text{lbf}}{\text{in}^2}}}$$

$$= 34.15 \text{ in}$$

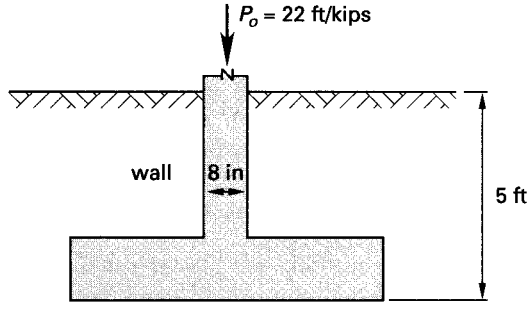
The available distance for development (with a 2 in cover at the tip of the bar) is 49.5 in − 2 in = 47.5 in. Since the available distance exceeds l_d, the anchorage is adequate. Use 10 no. 6 bars spaced evenly in each direction.



PRACTICE PROBLEMS

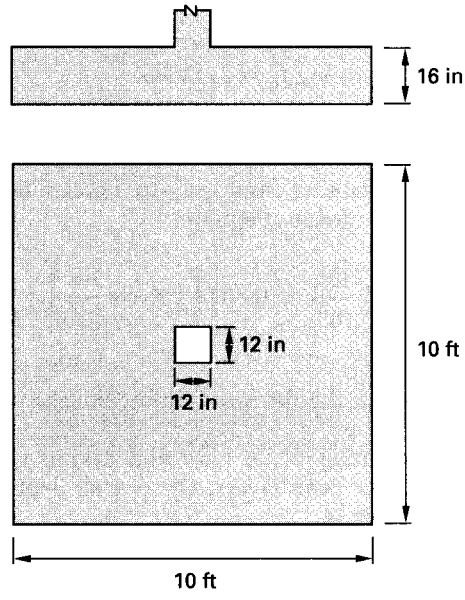
(In the following problems, none of the loads is the result of wind or earthquake action. Unless specified in the problem, assume concrete has a specific weight of 150 lbf/ft^3. All bars are uncoated.)

1. A reinforced concrete column is supported at the center of a square footing. The footing is in contact with the bare ground 4 ft below grade. The allowable gross soil pressure is 2000 lbf/ft^2. The specific weight of the soil is 110 lbf/ft^3. The footing thickness is 18 in. The axial loads, moments, and shears (directed along the top of the footing surface) acting on the footing through the column are



$P_d = 100$ kips
$P_l = 58$ kips
$M_d = 20$ ft-kips
$M_l = 40$ ft-kips
$V_d = 2$ kips [to the right]
$V_l = 4$ kips [to the right]

Determine the footing size. (Do not design the reinforcement.)



Answer: 11.3 ft by 11.3 ft square

2. An 8 in thick concrete wall carries a service load of 22 kips/ft. As shown, the footing for the wall sits on the ground 5 ft below grade. At this depth, the allowable gross soil pressure is 5000 lbf/ft^2. The soil has a unit weight of 120 lbf/ft^3. No. 4 bars are to be used for reinforcement. Size the footing and determine the steel requirements.

Answers: 5 ft by 5 ft; depth to reinforcement, d = 8.25 in; thickness, h = 12 in; eight no. 4 bars

3. (*Time limit: one hour*) A 16 in thick, 10 ft square footing supports a 12 in square column as shown. The net allowable soil pressure is 3000 lbf/ft^2.

(a) If the column is not subjected to a moment, the maximum service load that the footing can transmit safely to the soil is most nearly

(A) 200 kips
(B) 250 kips
(C) 300 kips
(D) 350 kips

The answer is (C).

(b) If the column has a total axial service load (dead plus live) of 200 kips, the maximum moment about the centroid of the footing print that the footing can support is most nearly

(A) 140 ft-kips
(B) 170 ft-kips
(C) 190 ft-kips
(D) 220 ft-kips

The answer is (B).

(c) The area of the critical section resisting punching shear is most nearly

(A) 680 in^2
(B) 960 in^2
(C) 1200 in^2
(D) 1400 in^2

The answer is (C).

For parts (d) through (f), assume the column is subjected to a factored axial force of 340 kips and no moment.

(d) The punching shear stress at the critical section is most nearly

(A) 200 lbf/in^2
(B) 250 lbf/in^2
(C) 280 lbf/in^2
(D) 320 lbf/in^2

The answer is (C).

(e) The one-way shear stress at the critical section is most nearly

(A) 60 lbf/in^2
(B) 80 lbf/in^2
(C) 100 lbf/in^2
(D) 120 lbf/in^2

The answer is (B).

(f) The design moment at the critical section is most nearly

(A) 280 ft-kips
(B) 300 ft-kips
(C) 340 ft-kips
(D) 440 ft-kips

The answer is (C).

In parts (g) through (j), assume the loading on the footing consists of a factored load of 340 kips plus a moment of 150 ft-kips.

(g) The maximum punching shear stress at the critical section is most nearly

(A) 220 lbf/in^2
(B) 250 lbf/in^2
(C) 360 lbf/in^2
(D) 410 lbf/in^2

The answer is (C).

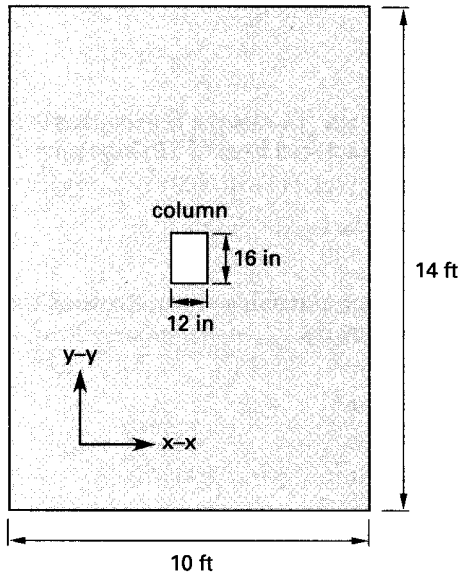
(h) The maximum one-way shear stress at the critical section is most nearly

(A) 86 lbf/in^2
(B) 97 lbf/in^2
(C) 100 lbf/in^2
(D) 120 lbf/in^2

The answer is (B).

(i) The design moment at the critical section is most nearly

(A) 350 ft-kips
(B) 380 ft-kips
(C) 410 ft-kips
(D) 510 ft-kips



The answer is (C).

(j) The number of no. 6 bars needed as reinforcement for the moment of part (i) is most nearly

(A) 12
(B) 14
(C) 19
(D) 24

The answer is (C).

4. (*Time limit: one hour*) A 10 ft by 14 ft rectangular footing supports a 12 in by 16 in reinforced concrete column placed at its center. The strength of the concrete for the column and the footing are 5000 lbf/in^2 and 3000 lbf/in^2, respectively. All steel is f_y = 60,000 lbf/in^2. The relative orientation of the column with respect to the footing is shown.

(a) Assume the column is subjected to a factored axial load of 650 kips. The minimum area of dowels needed to transfer the axial force from the column to the footing is most nearly

(A) 0
(B) 0.6 in^2
(C) 2.0 in^2
(D) 3.8 in^2

The answer is (A).

(b) Assume the column is subjected to axial compression only. If the dowels are no. 6 bars with 90° standard hooks, the minimum depth of the footing for which they will be fully anchored is most nearly

(A) 16 in
(B) 18 in
(C) 25 in
(D) 35 in

The answer is (C).

In parts (c) through (e), assume the footing is 24 in thick with an effective depth of 20 in.

(c) The minimum permitted amount of steel oriented parallel to the 10 ft side is most nearly

(A) 5.2 in^2
(B) 7.3 in^2
(C) 11 in^2
(D) 12 in^2

The answer is (B).

(d) As controlled by punching shear, the maximum factored axial load that can be resisted is most nearly

(A) 270 kips
(B) 480 kips
(C) 540 kips
(D) 610 kips

The answer is (C).

(e) As controlled by one-way shear, the maximum axial load that can be transferred by the footing is most nearly

(A) 300 kips
(B) 450 kips
(C) 670 kips
(D) 1200 kips

The answer is (C).

In parts (f) through (h), assume the column is subjected to a factored axial force of 400 kips and a factored moment of 600 ft-kips acting about the y-y axis.

(f) The punching shear stress at the critical section is most nearly

(A) 140 lbf/in^2
(B) 220 lbf/in^2
(C) 300 lbf/in^2
(D) 350 lbf/in^2

The answer is (B).

(g) The one-way shear stress at the critical section is most nearly

(A) 21 lbf/in^2
(B) 32 lbf/in^2
(C) 49 lbf/in^2
(D) 55 lbf/in^2

The answer is (C).

(h) The design moment for bars parallel to the x-x direction is most nearly

(A) 470 ft-kips
(B) 530 ft-kips
(C) 660 ft-kips
(D) 1100 ft-kips

The answer is (C).

(i) If the required steel area for bars parallel to the y-y direction is 12 in^2 for some applied load, the spacing of no. 6 bars in the region near the column is most nearly

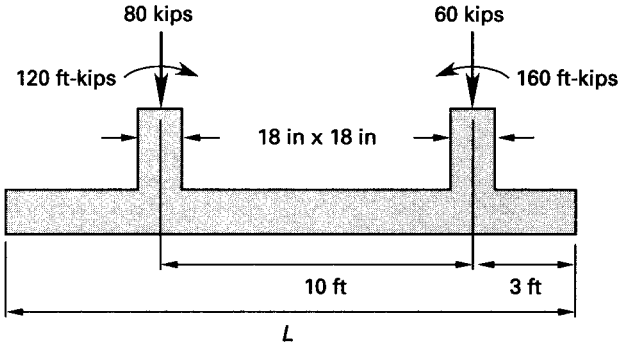
(A) 4.0 in
(B) 4.5 in
(C) 5.2 in
(D) 6.0 in

The answer is (C).

(j) The available anchorage length for bars in the y-y direction is most nearly

(A) 69 in
(B) 74 in
(C) 78 in
(D) 84 in

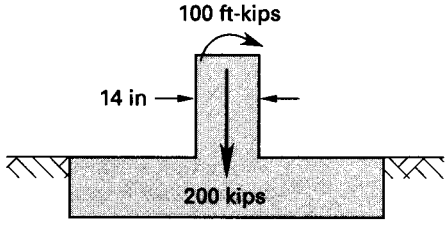
The answer is (B).



5. A square footing is to carry a live load of 240,000 lbf that is transmitted through a 16 in square column. (The column dead load can be disregarded, although the footing dead loading cannot.) The allowable soil pressure is 4000 lbf/ft^2, and the top of the footing is level with the surrounding soil surface. Material properties are $f'_c = 3000$ lbf/in^2 and $f_y = 40{,}000$ lbf/in^2. The footing thickness is 20 in. Design the footing.

Answers: 8 ft by 8 ft; $d = 16$ in; eleven no. 7 bars

6. An 18 in square column supports 200,000 lbf dead load and 145,000 lbf live load. The allowable soil pressure is 4000 lbf/ft^2. Material properties are $f'_c = 3000$ lbf/in^2 and $f_y = 40{,}000$ lbf/in^2. The column steel consists of ten no. 9 bars. Design the footing.



Answers: 10 ft by 10 ft; 25 in thickness; $d = 21$ in; ten no. 8 bars

7. A 10 ft wide combined footing carries the service loads and moments shown. Loads and moments are transmitted through 18 in square columns. The footing weight can be disregarded. (a) What dimension L will result in a uniform soil pressure? (b) Draw the shear and moment diagrams. (c) Does the footing need a layer of top steel?

Answers: (a) 18 ft; (c) no

8. A 14 in square column carries a live load of 200 kips and a live moment of 100 ft-kips, as shown. The footing and column self-weights can be disregarded. The allowable soil pressure is 6000 lbf/ft^2. The concrete's compressive strength is 3000 lbf/in^2. The soil specific weight is 110 lbf/ft^3. The top of the footing is even with the soil surface. (a) Size the footing. (Do not design the steel reinforcement.) (b) What are the maximum and minimum pressures along the footing base? (c) What thickness of footing would be required if shear reinforcement were to be completely eliminated? (d) What is the maximum moment the footing must resist?

Answers: (a) 6 ft by 8.25 ft; (b) 3004 lbf/in^2 and 5943 lbf/ft^2; (c) 18 in; (d) 58.9 ft-kips

1. INTRODUCTION

Concrete is strong under compressive stresses but weak under tensile stresses. The tensile strength of concrete varies from 8 to 14% of its compressive strength. Because of the low tensile capacity of concrete, flexural cracks develop at early stages of loading.

In traditional reinforced concrete structures, steel provides the tensile strength that the concrete is incapable of developing. However, it is also possible to impose an initial state of stress such that, when the stresses from the applied loads are added, no tensile stresses occur. The initial state of stress is provided by high-strength tendons compressing the concrete. The prestressing force keeps all or most of the member's cross section in compression.

2. PRETENSIONING AND POST-TENSIONING

Prestressing procedures can be achieved by two different methods: pretensioning and post-tensioning. In *pretensioned construction*, the tendons are pulled to the

specified tensile force before placing the concrete. Then, concrete is poured around the tendons. After the concrete reaches the specified strength, f'_{ci}, the tendons are cut at the anchorages. The compressive stress caused by the shortening of the wires transfers to the concrete through a steel-concrete bond.

In *post-tensioned construction*, the tendons are free to slide within the member inside tubes, sheaths, or conduits. (Early tendons were paper-wrapped bundles of greased wires.) After the concrete hardens, the tendons are tensioned by anchoring them to one end and pulling ("jacking") from the other. Tubes may or may not be subsequently grouted ("bonded") to prevent corrosion. The tubes can also be filled with corrosion-resistant grease.

3. BONDED AND UNBONDED TENDONS

Unbonded tendons can be used in relatively shallow construction. They provide good crack control for longer spans. Unbonded construction has made practical and economical post-tensioning of longer-span flat plates, shallow beams, and slabs.

Grouting bonds tendons directly to the concrete. If a bonded tendon breaks at any point, it is still capable of providing local prestress for part of the structure. A failed unbonded tendon, on the other hand, stops contributing when it fails. Unbonded failure is sudden; bonded failure is gradual. Because of this, bonded tendons may be required in areas subject to seismic loading. (However, unbonded tendons were originally used in nuclear power plants where they could be replaced as needed.)

The ultimate strength of a simple beam with unbonded tendons is about 30% less than the same beam with bonded tendons. The ultimate strength of a continuous beam or slab is about 20% less. Unbonded tendons do not help in controlling crack sizes and growth.

4. BENEFITS AND DISADVANTAGES

Prestressed members are shallower in depth than conventional reinforced concrete members for the same spans and loading conditions. In general, the depth of a prestressed concrete member is usually about 65 to 80% of the depth of the equivalent conventionally reinforced concrete member. This can lead to savings due to reductions in concrete and steel. However, the materials needed for prestressed construction are of higher quality and are therefore more expensive, so the material savings are minimal.

Prestressing significantly reduces the amount of cracking in a beam at service load levels. Since uncracked sections have a larger moment of inertia than cracked sections, the deflection of a prestressed beam for a given applied load is less than that of a conventionally reinforced beam. The increased stiffness of prestressed construction permits smaller, lighter sections to be used, thereby reducing dead weight and some components of the total cost. Other benefits are increased protection of the steel from the environment and the fact that the prestressing can be used to induce camber.

The dead weight of nonprestressed concrete members in excess of 70 to 90 ft (21 to 27 m) long can become excessive, resulting in greater long-term deflection and cracking. Therefore, the best construction technique for long-span concrete members is prestressed concrete. In fact, very long concrete spans, such as those found in cable-stayed bridges, can only be constructed with prestressing.

Prestressed concrete members have high toughness (i.e., the ability to absorb energy under impact loads). The fatigue resistance of prestressed concrete members is also high due to the low steel stress variation.

The disadvantages of prestressed construction are the costs associated with the prestressing itself and the increased costs that derive from higher quality materials, inspection, testing, and quality control.

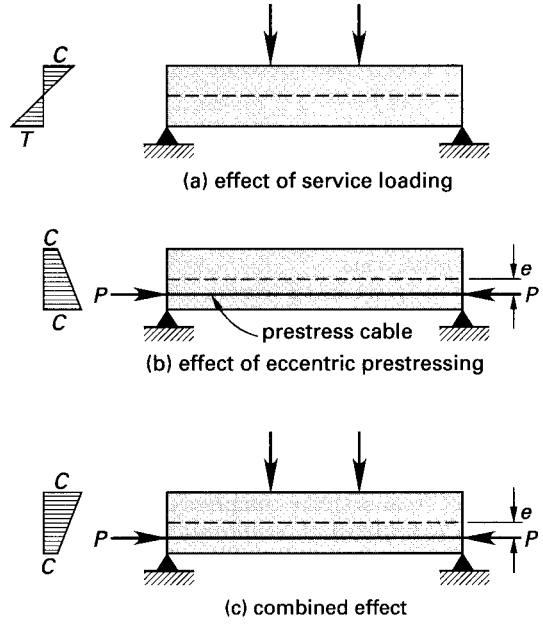

Figure 56.1 *Prestressing Effect on a Simple Beam*

5. PRESTRESSING LIMITATIONS

When a live load acting on a beam is a large fraction of the total load but acts intermittently, it may not be possible to design the beam so that it has no tensile stresses under full live load and still behaves appropriately when the live load is not present. High prestressing required for a full live load may be such that, when the live load is not present, the beam deforms upward excessively. This upward camber can be exacerbated by long-term effects from creep and shrinkage. Very large prestressing forces may also produce enough axial shortening in the beam to damage other framing members.

In such cases, it is better to allow some tensile stresses to develop when the beam is fully loaded. Members in which tensile stresses are allowed under service loads are termed *partially prestressed members*. When no tensile stresses are permitted, the term *fully prestressed members* is utilized.

6. CONSTRUCTION METHODS AND MATERIALS

The performance of prestressed concrete structures is related directly to the quality of the materials used. Strict production methods and quality assurance are needed at the various stages of production, construction, and maintenance.

High-quality concrete and steel tendons are used. The two major qualities of concrete are strength and long-term endurance. Concrete strengths of 5000 and 6000 psi (34.5 and 41.3 MPa) are common. The specified concrete strength must be achieved by the time of prestressing.

Accelerating agents containing chlorides are excluded because they contribute to strand corrosion.

7. CREEP AND SHRINKAGE

Long-term deflections (deformations) related to creep and shrinkage can reduce the prestressing forces and can lead to unexpected failure. Both creep and shrinkage are time-dependent phenomena. *Creep* is the deformation that occurs under a constant load over a period of time. Creep depends primarily on loading and time, but is also influenced by the composition of concrete, the environmental conditions, and the size of the member.

Shrinkage is a volume change that is unrelated to load application. Shrinkage is closely related to creep. As a general rule, concrete that has a low volume change also has a low creep tendency.

Creep and shrinkage contribute to a loss of prestressing force as well as increased deflection. For prestressed members without compression reinforcement, the long-term deflection can be estimated from the immediate deflection by use of a *coefficient of creep*, C_c. For members without compression reinforcement, C_c has values of 1.0 for three months, 1.2 for six months, 1.4 for twelve months, and 2.0 for five years [ACI 318 9.5.2.5.].

$$\Delta_{\text{long term}} = C_c \Delta_{\text{immediate}} \qquad 56.1$$

8. PRESTRESS LOSSES

Several effects tend to reduce the prestress, including creep and shrinkage in the concrete, elastic shortening of the member from the applied compressive stress, movements at the anchorage sitting, relaxation of the steel tendons, and friction between the tendons and the tubes (in the case of ungrouted post-tensioned construction). The strains associated with these losses are close to the strain associated with yielding of conventional 40,000 psi (270 MPa) reinforcement, so regular-grade steel cannot be used for prestressing. The tendons used for prestressing are manufactured from steel with an approximate ultimate strength (f_{pu}) of 250 ksi (1.70 GPa), and the typical losses average 25 to 35 ksi (170 to 240 MPa).

High early strength concrete, such as type III, with a compressive strength, f'_c, of 4000 to 10,000 psi (27.6 to 69.0 MPa) is commonly used. This concrete sets up quickly and suffers smaller elastic compression losses. Due to the higher quality of concrete, the *modular ratio*, n, is typically lower than in conventional construction.

$$n = \frac{E_s}{E_c} \qquad 56.2$$

Losses of prestressing forces occur in the prestressing steel due to relaxation of steel and creep and shrinkage of the concrete. This type of loss is known as *time-dependent loss*. On the other hand, there are immediate elastic losses due to fabrication or construction techniques. Those include elastic shortening of concrete, anchorage losses, and frictional losses. The exact amounts of these losses are difficult to estimate analytically, though methods exist. There are also several empirical methods for estimating prestress losses. Table 56.1 shows the lump-sum losses permitted by AASHTO. (A *lump-sum loss* is a rule-of-thumb loss that is applied to the design without more analytical methods of determination.)

Table 56.1 *AASHTO Lump-Sum Losses*[a,b] *in psi (MPa)*

total of prestressing steel	total loss	
	4000 psi concrete (27.6 MPa concrete)	5000 psi concrete (34.5 MPa concrete)
pretensioning strand		45,000 (310)
post-tensioning wire or strand	32,000 (221)	33,000 (228)
bars	22,000 (152)	23,000 (159)

(Multiply psi by 0.00689 to obtain MPa.)

[a] For normal-weight concrete, normal prestress levels, and average exposure conditions. Use exact methods for exceptionally long spans and unusual designs.

[b] Losses due to friction are excluded. Such losses should be calculated according to AASHTO specifications.

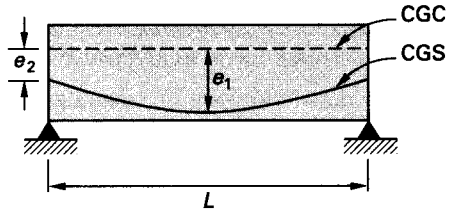
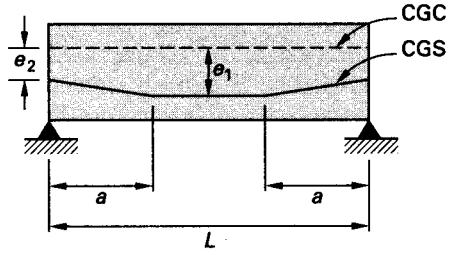
Structural

9. DEFLECTIONS



Prestressed concrete members are generally thinner than conventional reinforced concrete members. This makes them subject to increased deflection. Deflection consists of the short-term (instantaneous) and long-term effects.

Several assumptions are made when calculating deflection. (a) The modulus of elasticity of concrete is given by the ACI empirical equation $E_c = 33w^{1.5}\sqrt{f'_c}$. (b) The moment of inertia is calculated from the concrete cross-sectional area. (c) Superposition can be used to calculate the combined deflection due to applied loads and the opposing *camber*. (d) All of the strands act as a single tendon with a combined steel area. (e) Deflection computations can be based on the center of gravity of the prestressing strands (CGS). (f) Deflections resulting from shear deformations can be ignored.



$$\Delta = -\frac{Fe_1L^2}{8EI}$$

(a) straight tendons

$$\Delta = -\left(\frac{FL^2}{8EI}\right)\left(e_2 + \left(\frac{5}{6}\right)(e_1 - e_2)\right)$$

(b) parabolically draped tendons

$$\Delta = -\left(\frac{FL^2}{8EI}\right)\left(e_1 + (e_2 - e_1)\left(\frac{4}{3}\right)\left(\frac{a^2}{L^2}\right)\right)$$

(c) shaped tendons

[a]CGC—centroid of concrete; CGS—centroid of prestressing tendons

Figure 56.2 *Midspan Deflections from Prestressing*[a]

10. STRANDS

Prestressing tendons can be single wires, strands composed of several wires twisted together, and high-strength bars. Seven-wire strands, manufactured by twisting six wires around a larger, straight central wire, are the most widely used. Strands come in two grades, 250 ksi and 270 ksi (1.72 GPa and 1.896 GPa), representing the ultimate tensile strength. Different diameters are available.

The high-strength steel strands are stress-relieved to reduce residual stresses caused by cold-working during winding. Stress-relieving consists of heating the steel to about 930°F (500°C). The stress-relieving process improves the ductility of steel and reduces the stress relaxation. *Stress relaxation* is the loss of prestress when wires or strands are subject to constant strain. It is similar to creep in concrete, except that creep is a change in strain whereas relaxation in steel is a loss in steel stress.

Aramid tendons are manufactured from aramid fibers. Aramid tendons are the focus of ongoing research and experimental use. Tensile rigidities are approximately one-fifth of those from prestressing steel, so uses are limited to special applications.

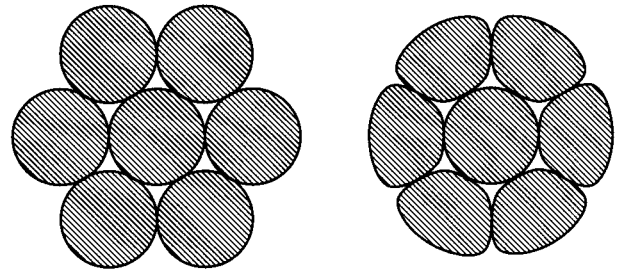


Figure 56.3 *Typical Cross Sections for Seven-Wire Prestressing Tendons*

11. CORROSION PROTECTION

Any reduction in the cross-sectional area of prestressing tendons reduces the nominal moment strength of the prestressed section. Therefore, prestressing tendons should be protected against corrosion. In pretensioned members protection against corrosion is provided by the concrete surrounding the tendon, while in post-tensioned members grouting is commonly used to prevent moisture from entering the ducts. However, concrete with grouted tendons is susceptible to freeze-induced cracking if grouting occurs during the winter. Therefore, other options, including heat-sealed and extruded coatings, can be specified.

Table 56.2 *ASTM Standard Prestressing Tendons*

type[a]	nominal diameter (in)		nominal area (in^2)	nominal weight (lbf/ft)
grade 250[b]	$\frac{1}{4}$	(0.250)	0.036	0.122
seven-wire	$\frac{5}{16}$	(0.313)	0.058	0.197

(Multiply in^2 by 645 to obtain mm^2.)
(Multiply lbf/ft by 1.51 to obtain kg/m.)
[a]All sizes in all types may not be readily available.
[b]Strand grade is f_{pu} in kips/in^2.

12. MAXIMUM STRESSES

The maximum stresses in concrete and reinforcement permitted by ACI are presented in Table 56.3. The maximum permissible stresses permitted by AASHTO are presented in Table 56.4.

AASHTO also specifies the following strength reduction factors (load factors) for prestressed concrete construction: for post-tensioned anchorage zones exposed to maximum tendon jacking force, 1.2; for factory-produced precast prestressed members, $\phi = 1$; for post-tensioned cast-in-place members, $\phi = 0.95$; for shear, $\phi = 0.90$; for anchorage zones with normal-weight concrete, $\phi = 0.85$; and for anchorage zones with lightweight concrete, $\phi = 0.70$ [AASHTO *Bridges*, Div. 1, Sec. 9.14].

13. ACI CODE PROVISIONS FOR STRENGTH

The ACI code contains the following strength-related provisions. (AASHTO specifications are similar but not identical.)

(1) The moment due to factored loads, M_u, cannot exceed the reliable moment capacity, ϕM_n [ACI 318 18.7.1].

(2) The reliable moment capacity, ϕM_n, must be at least 1.2 times the cracking moment, M_{cr}, calculated from the modulus of rupture [ACI 318 18.8.3].

(3) The area of prestressed and non-prestressed reinforcement used to compute the flexural strength, ϕM_n, is limited to ensure that failure is initiated by yielding of the steel and not by crushing of the concrete in compression. (Exact values are specified in ACI 318 18.8.1.)

The moment capacity, ϕM_n, is calculated in the same manner as for a conventional reinforced section. The only method that is specific to prestressed construction is the fact that the tension in the steel at failure is computed from formulas that apply for specific circumstances. For example, in the common case of members with bonded tendons, the ultimate stress in the tendons, f_{ps}, is

$$f_{ps} = f_{pu}\left(1 - \left(\frac{\gamma_p}{\beta_1}\right)\left(\rho_p\left(\frac{f_{pu}}{f'_c}\right) + \left(\frac{d}{d_p}\right)(\omega - \omega')\right)\right) \quad \text{[bonded tendons]} \quad 56.3$$

γ_p is the tendon prestressing factor, equal to 0.55 when $0.80 \leq f_{py}/f_{pu} < 0.85$; 0.40 when $0.85 \leq f_{py}/f_{pu} < 0.90$; and 0.28 when $f_{py}/f_{pu} \geq 0.80$.

ρ_p is the *prestressing steel ratio*.

$$\rho_p = \frac{A_{sp}}{b_d} \quad 56.4$$

If any compression reinforcement is taken into account, the negative part of Eq. 56.3 cannot be less than 0.17, and the distance from the extreme compression fiber to the centroid of the compression reinforcement, d', cannot be greater than $0.15d_p$, where d_p is the distance from the extreme compression fiber to the centroid of the prestressed reinforcement.

$$\left(\frac{\gamma_p}{\beta_1}\right)\left(\rho_p\left(\frac{f_{pu}}{f'_c}\right) + \left(\frac{d}{d_p}\right)(\omega - \omega')\right) \geq 0.17 \quad 56.5$$

For Eq. 56.5 to apply, the stress in the tendons after all losses have been subtracted shall not be less than $0.5f_{pu}$ [ACI 318 18.7.2]. Other formulas for f_{ps} can be found in ACI 318 18.7.2.

The *cracking moment*, M_{cr}, is computed as the moment required to induce a tensile stress equal to the modulus or rupture. In this calculation, the force in the tendons after all losses must be used. Long-term losses are frequently assumed to be 35,000 psi (240 MPa) for prestressed construction and 25,000 psi (170 MPa) for post-tensioned construction.

Structural

Table 56.3 ACI Maximum Prestressing Stresses

Concrete Stresses in Flexure			
Stresses in concrete immediately after prestress transfer (before time-dependent prestress losses) shall not exceed the following:			
(1)	extreme fiber stress in compression		$0.60f'_{ci}$
(2)	extreme fiber stress in tension except as permitted in (3)	[U.S.]	$3\sqrt{f'_{ci}}$
		[SI]	$\frac{1}{4}\sqrt{f'_{ci}}$
(3)	extreme fiber stress in tension at ends of simply supported members	[U.S.]	$6\sqrt{f'_{ci}}$
		[SI]	$\frac{1}{2}\sqrt{f'_{ci}}$
Stresses in concrete at service loads (after all prestress losses) shall not exceed the following:			
(1)	extreme fiber stress in compression		$0.45f'_c$
(2)	extreme fiber stress in tension in precompressed tensile zone	[U.S.]	$6\sqrt{f'_c}$
		[SI]	$\frac{1}{2}\sqrt{f'_{ci}}$
Prestressing Steel Stresses			
(1)	due to tendon jacking force (but not greater than the lesser of $0.80f_{pu}$ or the maximum value recommended by the manufacturer of prestressing tendons or anchorages)		$0.94f_{py}$
(2)	immediately after prestress transfer but not more than $0.74f_{pu}$		$0.82f_{py}$
(3)	post-tensioning tendons at anchorages and couplers, immediately after tendon anchorage		$0.70f_{pu}$

14. ANALYSIS OF PRESTRESSED BEAMS

If a beam's cable layout is known, the flexural capacity to support a particular load distribution can be determined.

Service Load Review

step 1: Compute the transformed moment of inertia for the cross section. If the beam is post-tensioned and the tendons are not grouted, the area of steel of the tendons should not be considered.

step 2: Calculate the eccentricity, e, of the tendons as the distance from the centroid of the tendons to the neutral axis of the transformed section.

step 3: Compute the stress distribution in the concrete at transfer from Eq. 56.6. P is the net prestress force acting on the beam before losses, M_s is the moment due to the loads on the beam at transfer (typically the self-weight only), and y is the distance from the neutral axis to the fiber in question. y is positive upward. Negative stresses indicate compression.

$$f_c = \frac{-P}{A} + \frac{Pey}{I} - \frac{M_s y}{I} \qquad 56.6$$

step 4: Compute the stresses in the concrete when the full service load is acting. These stresses are also computed with Eq. 56.6 with the following changes: P is the force in the tendons after all losses, and M_s is the moment due to the full service load.

Strength Review

step 5: Compute the ultimate stress in the tendons from Eq. 56.3. (Use the appropriate ACI 318 code equation if the tendon is not bonded.)

step 6: Use the stress from step 5 to calculate the moment capacity, ϕM_n. Compare this capacity to the maximum moment due to factored loads, M_u.

step 7: Use Eq. 56.6 to compute the cracking moment. The cracking moment is the value of M_s required to induce a tension stress equal to the modulus of rupture. Check to see if the requirement $\phi M_n \geq 1.2M_{cr}$ is satisfied.

Table 56.4 *AASHTO Maximum Prestressing Stresses*

Concrete Stresses in Flexure

Stresses in concrete immediately after prestress transfer (before time-dependent prestress losses) shall not exceed the following:

(1)	extreme fiber stress in compression		
	• pretensioned members		$0.60f'_{ci}$
	• post-tensioned members		$0.55f'_{ci}$
(2)	extreme fiber stress in tension		
	• precompressed tensile zone[a]		–
	• other areas without bonded reinforcement, lesser of	[U.S.]	200 psi and $3\sqrt{f'_c}$
		[SI]	1.38 MPa and $\frac{1}{4}\sqrt{f'_c}$
	• other areas with bonded reinforcement	[U.S.]	$7.5\sqrt{f'_c}$
		[SI]	$\frac{5}{8}\sqrt{f'_c}$

Stresses in concrete at service loads (after all prestress losses) shall not exceed the following:

(1)	extreme fiber stress in compression		$0.40f'_c$
(2)	extreme fiber stress in tension in precompressed tensile zone		
	• with bonded reinforcement, normal exposure	[U.S.]	$6\sqrt{f'_c}$
		[SI]	$\frac{1}{2}\sqrt{f'_c}$
	• with bonded reinforcement, in coastal areas and other severe corrosive exposures	[U.S.]	$3\sqrt{f'_c}$
		[SI]	$\frac{1}{2}\sqrt{f'_c}$
	• without bonded reinforcement		0

Cracking stress

(1)	normal-weight concrete	[U.S.]	$7.5\sqrt{f'_c}$
		[SI]	$\frac{5}{8}\sqrt{f'_c}$
(2)	sand-lightweight concrete	[U.S.]	$6.3\sqrt{f'_c}$
		[SI]	$0.525\sqrt{f'_c}$
(3)	all other lightweight concrete	[U.S.]	$5.5\sqrt{f'_c}$
		[SI]	$0.458\sqrt{f'_c}$
Anchorage bearing stress (post-tensioned anchored at service loads), lesser of		[U.S.]	$0.9f'_{ci}$ and 3000 psi
		[SI]	$0.9f'_{ci}$ and 20.7 MPa

Prestressing Steel Stresses

(1)	after seating	
	• pretensioned members[b]	
	stress-relieved strands	$0.70f_{pu}$
	low-relaxation strands	$0.75f_{pu}$
	• post-tensioned members[c]	$0.70f_{pu}$
(2)	at service load after losses[d]	$0.80f_{py}$

[a] AASHTO does not specify tension limits for the precompressed tensile zone. Other specifications may apply.
[b] Slight overstressing up to $0.80f_{pu}$ is permitted to offset seating losses and temperature drops as long as the final stress after seating does not exceed specified f_{py} values.
[c] Overstressing up to $0.90f_{py}$ for short periods of time to offset seating and friction losses as long as the final anchorage stress does not exceed specified values. Includes bonded prestressed strands. Other limitations apply.
[d] Includes bonded prestressed strands.

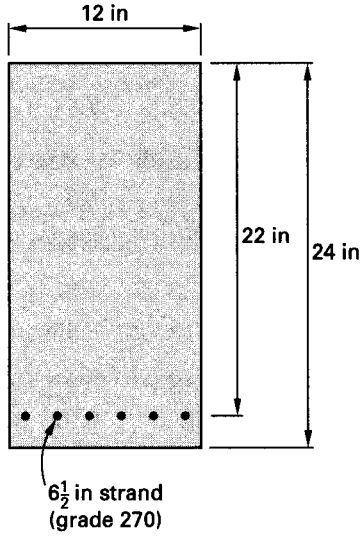
15. SHEAR IN PRESTRESSED SECTIONS

The shear design requirement for prestressed concrete members is the same as for the conventionally reinforced concrete members.

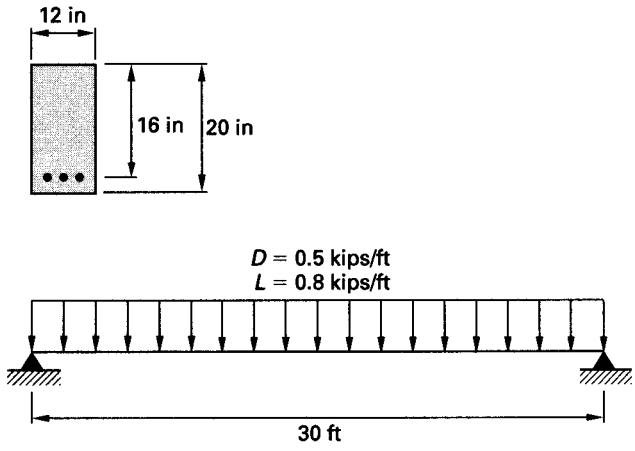
$$V_u < \phi V_n \qquad 56.7$$



For prestressed and reinforced concrete members, the nominal shear strength, V_n, is the sum of the shear strength provided by concrete and steel.

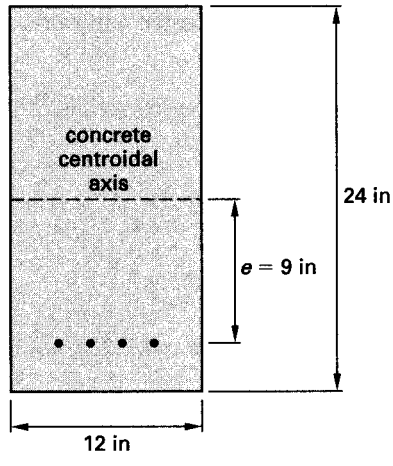
$$V_n = V_c + V_s \qquad 56.8$$

For prestressed concrete members, ACI 318 11.1.3.2 states that the critical section for computing the maximum factored shear V_u is located at a distance of $h/2$ from the face of the support. This is different from the provisions for the conventional reinforced concrete members where the critical section is located at a distance d from the face of the support.



PRACTICE PROBLEMS

1. Calculate the nominal moment strength of the cross section of the prestressed beam shown. $f'_c = 5000$ psi, f_{pu} =270,000 psi (stress-relieved strands), and $f_{py} = 0.85f_{pu}$.



Answer: 370 ft-kips

2. The cross section of the simply supported pretensioned concrete beam is shown. The live and dead loads are given as indicated. The beam has straight cables with initial stresses of 180 ksi and final stresses after losses of 140 ksi. The concrete is uncracked. The creep coefficient is 2.0, and the modulus of elasticity is 4×10^6 psi. (a) Calculate the centerline deflection of the beam immediately after the cables are cut. (b) Calculate the centerline deflection of the beam five years after the cables are cut.

Answers: (a) −0.51 in [upward]; (b) 0.29 in [downward]

3. *(Time limit: one hour)* The 12 in×24 in prestressed beam shown carries a dead load of 3 kips/ft (which includes the beam's self-weight). The beam length is 20 ft. The tensile force in the prestressing steel is 250 kips.

(a) The moment of inertia of the section of the beam shown is most nearly

(A) 13,000 in^4
(B) 14,000 in^4
(C) 15,000 in^4
(D) 16,000 in^4

The answer is (B).

(b) The area of the cross section of the beam is most nearly

(A) 250 in^2
(B) 290 in^2
(C) 300 in^2
(D) 320 in^2

The answer is (B).

(c) The maximum bending moment is most nearly
(A) 100 ft-kips
(B) 130 ft-kips
(C) 150 ft-kips
(D) 180 ft-kips

The answer is (C).

(d) The axial compression stress at the top fibers at the centerline of the beam is most nearly
(A) 0.470 ksi
(B) 0.570 ksi
(C) 0.770 ksi
(D) 0.870 ksi

The answer is (D).

(e) The axial compression stress at the bottom fibers at the centerline of the beam is most nearly
(A) 0.470 ksi
(B) 0.570 ksi
(C) 0.770 ksi
(D) 0.870 ksi

The answer is (D).

(f) The axial compression stress at the top fibers at the ends of the beam is most nearly
(A) 0.470 ksi
(B) 0.570 ksi
(C) 0.770 ksi
(D) 0.870 ksi

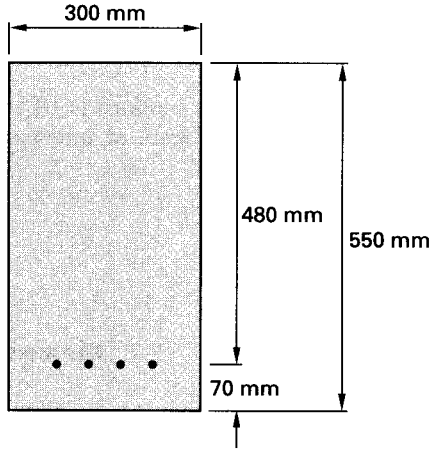
The answer is (D).

(g) The total stress at the top fibers at the centerline of the beam is most nearly
(A) 0.48 ksi
(B) 0.87 ksi
(C) 1.6 ksi
(D) 2.0 ksi

The answer is (A).

(h) The total stress at the bottom fibers at the centerline of the beam is most nearly
(A) 0.87 ksi
(B) 1.3 ksi
(C) 2.0 ksi
(D) 2.3 ksi

The answer is (B).



(i) The total stress at the top fibers at the ends of the beam is most nearly
(A) 0.48 ksi
(B) 0.87 ksi
(C) 1.1 ksi
(D) 1.6 ksi

The answer is (C).

(j) The total stress at the bottom fibers at the ends of the beam is most nearly
(A) 0.87 ksi
(B) 2.0 ksi
(C) 2.8 ksi
(D) 3.8 ksi

The answer is (C).

4. *(Time limit: one hour)* The cross section for a 12 m simply supported beam is shown. The initial tendon prestress is 1.10 GPa. $f'_c = 34.5$ MPa, and $f_{pu} = 1.725$ GPa. The total area of prestressing steel is 774 mm^2.

(a) The eccentricity for this section of the beam is most nearly
(A) 70 mm
(B) 210 mm
(C) 480 mm
(D) 550 mm

The answer is (B).

(b) The maximum bending moment due to the beam dead load is most nearly
(A) 60 kN·m
(B) 63 kN·m
(C) 70 kN·m
(D) 73 kN·m

The answer is (C).

(c) The initial force used for the initial prestressing is most nearly
(A) 800 kN
(B) 810 kN
(C) 840 kN
(D) 850 kN

The answer is (D).

(d) The concrete stress in the top of the beam at midspan after the tendons are cut is most nearly

(A) 1.8 MPa
(B) 4.6 MPa
(C) 5.2 MPa
(D) 12 MPa

The answer is (A).

(e) The concrete stress in the bottom of the beam at midspan after the tendons are cut is most nearly

(A) 4.6 MPa
(B) 5.2 MPa
(C) 10 MPa
(D) 12 MPa

The answer is (D).

(f) Assuming the losses in the tendons is 18%, the concrete stress at the top of the beam at midspan is most nearly

(A) 0.62 MPa
(B) 1.8 MPa
(C) 4.6 MPa
(D) 5.2 MPa

The answer is (A).

(g) Assuming the losses in the tendons is 18%, the concrete stress in the bottom of the beam at midspan is most nearly

(A) 5.2 MPa
(B) 4.6 MPa
(C) 9.1 MPa
(D) 9.8 MPa

The answer is (C).

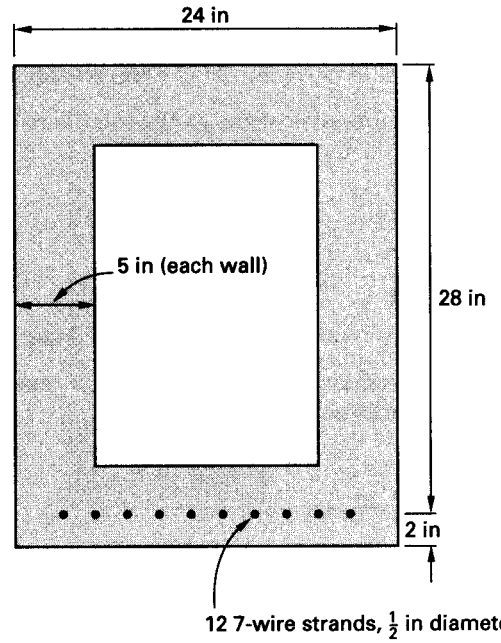
(h) Assuming the allowable stress is $0.45f'_c$ in compression, the maximum allowable bending moment at midspan is most nearly

(A) 250 kN·m
(B) 290 kN·m
(C) 310 kN·m
(D) 340 kN·m

The answer is (C).

(i) Assuming the allowable stress is $0.5\sqrt{f'_c}$ in tension, the maximum allowable bending moment at midspan is most nearly

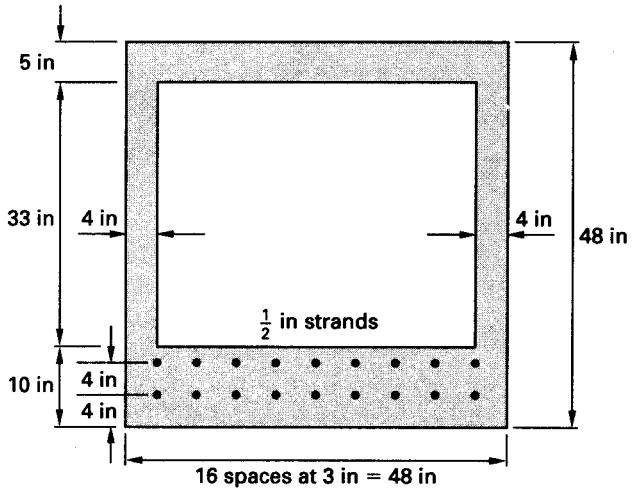
(A) 250 kN·m
(B) 270 kN·m
(C) 300 kN·m
(D) 330 kN·m



The answer is (A).

(j) Using the answers from parts (h) and (i), the maximum allowable uniform live load that the beam can support in addition to its own weight is most nearly

(A) 8.1 kN/m
(B) 8.6 kN/m
(C) 9.1 kN/m
(D) 10 kN/m



The answer is (D).

5. A prestressed hollow box cross section is shown. The prestressing is applied through twelve ½ in diameter grade 270 seven-wire strand tendons. For these strands, $f_{py} = 0.95f_{pu}$, and the effective prestress after losses is $f_{se} = 148$ ksi. The specified strength of the concrete is 5000 psi. (a) Determine the flexural strength of the section. (b) Determine the cracking moment. (c) Does the relationship between the cracking moment and the flexural capacity satisfy the requirements of the ACI Code?

Answers: (a) 905 ft-kips; (b) 586 ft-kips; (c) yes

6. *(Time limit: one hour)* A pretensioned girder is constructed with 30 bonded strands. The girder spans 100 ft and is supported on simple supports. It carries a uniform live load of 540 lbf/ft as well as its own weight of 150 lbf/ft. The modular ratio is 7, $f'_c = 5000$ psi, $f'_{ci} = 3800$ psi, $f_{pu} = 250$ ksi, $f_y/f_{pu} = 0.85$, and $A_p = 0.144$ in^2/strand. It is not necessary to check the tendon stress. (a) If the effective prestress before losses is 80% of f_{pu}, is the stress in the concrete acceptable immediately after transfer, before any live load is added? (b) If the effective prestress after losses is 60% of f_{pu}, is the concrete stress acceptable under service loading?

Answers: (a) yes; (b) yes

Figure 57.1 *Composite Members*

1. INTRODUCTION

Any conventionally reinforced concrete structure could be considered a composite structure since it contains two dissimilar materials. However, the term "composite member" normally refers to the combinations of concrete with structural steel member as shown in Fig. 57.1.

The composite construction shown in Fig. 57.1(a) is widely used for highway bridges. A cast-in-place reinforced concrete slab is bonded to a steel beam, producing a stronger and stiffer structure. Fig. 57.2 shows a typical highway bridge utilizing composite construction.

There are three authoritative "codes" governing composite design: (a) ACI 318, (b) the *AISC Manual*, and (c) AASHTO's *Standard Specifications for Highway Bridges* ("*Bridges*"). The requirements imposed by these three codes are similar, though not always exactly the same.

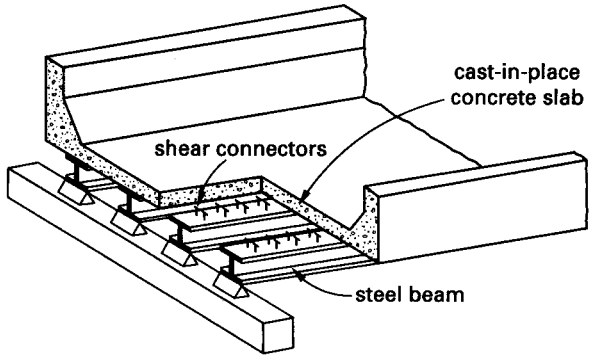

Figure 57.2 *Highway Bridge Deck*

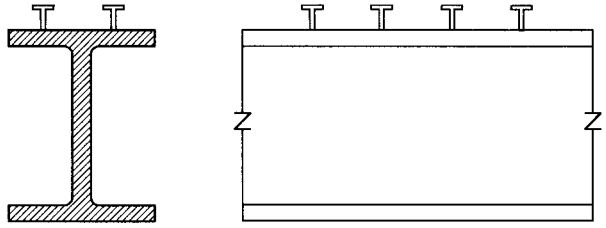
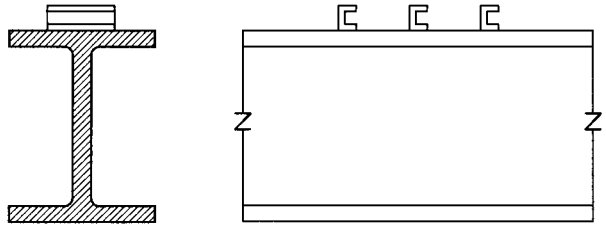
2. COMPOSITE ACTION



Composite construction depends on *composite action* between the two materials. Composite action means that the steel and concrete components act together to

resist loading. There is a tendency for slip to occur at the interface between the concrete slab and the steel beam. Slippage nullifies composite action. The tendency to slip is maximum near the supports, where the vertical shear (and horizontal) forces are the greatest. Tendency to slip is zero at the point of maximum bending moment.



To prevent slippage from occurring, *shear connectors* (straight studs, L-connectors, or steel channels) are welded to the top flange of the steel beam as shown in Fig. 57.3. When the concrete is poured, the encased studs bond the beam to the slab.

According to the AASHTO specifications, the following criteria for shear connectors should be met. (a) The clear depth of concrete cover over the tops of all shear connectors must be not less than 2 in. (b) The connectors must penetrate at least 2 in above the bottom of the slab. (c) The clear distance between the edge of the beam flange and the edge of the connector must be not less than 1 in. (d) The welds must be at least $^3/_{16}$ in fillets [*Bridges*, Div. 1, Sec. 10.38.2].

AASHTO specifications also contain details of requirements that the shear connectors be designed for fatigue and checked for strength [*Bridges*, Div. 1, Sec. 10.38.5].

(a) stud connectors

(b) channel connectors

Figure 57.3 *Types of Shear Connectors*

3. ADVANTAGES

The primary advantages of composite construction are as follows. (a) The load-carrying capacity of composite systems is greater than the noncomposite construction. (b) A composite system is stronger and more rigid than a noncomposite system. (c) Smaller and shallower steel beams can be used. This will provide economic savings in the steel to be used for a given project. The savings in weight can reach about 20 to 30%. (d) Spans can be longer without exceeding the allowable deflection.

4. DISADVANTAGES

The disadvantages of composite construction are as follows. (a) There are additional materials and labor costs related to the shear connectors. However, the savings from using smaller sections generally offset the additional costs of the connectors. (b) The construction of composite members requires additional supervision and quality control.

Despite these disadvantages of composite construction, a large number of medium-span highway bridges in the United States are constructed using the slab-beam composite system.

5. EFFECTIVE SLAB WIDTH

In the slab-beam composite system used for bridge decking, the steel beams (girders) are placed parallel to each other in the direction parallel to the traffic. The steel beams can be standard W shapes with cover plates to increase the resistance of the beam in the regions of high moment, or they can be built-up plate girders.

The concrete slab is designed for bending in the transverse direction (i.e., is designed as a one-way slab). However, all of the slab may not be considered effective in resisting compressive stresses. The portion of the slab that resists the compressive stresses is the *effective width*, b_e. The *AISC Manual* [Sec. I1] states that the effective width of an interior beam with slab extending on both sides is the smaller of the following.

$$b_e = \text{smaller of } \{L/4;\ b_o\} \qquad 57.1$$

According to the AASHTO specifications [*Bridges*, Div. 1, Sec. 10.38.3.1], the effective width of the compression flange for an interior girder may not exceed the following.

$$b_e = \text{smallest of } \{L/4;\ 12t;\ b_o\} \qquad 57.2$$

For an exterior girder, the AASHTO specifications [*Bridges*, Div. 1, Sec. 10.38.3.2] state that the effective width may not exceed the following.

$$b_e = \text{smallest of } \{L/12;\ 6t;\ \tfrac{1}{2}b_o\} \qquad 57.3$$

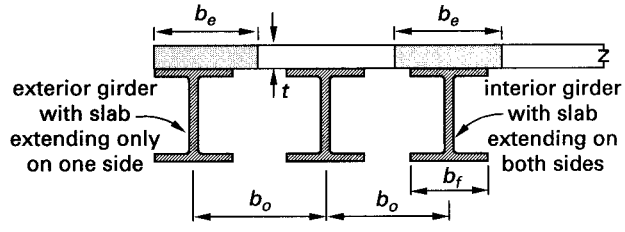


Figure 57.4 *Effective Width*

6. SECTION PROPERTIES

In order to compute the stresses for a nonhomogeneous cross section, the section properties (e.g., centroidal axis location, moment of inertia, and section modulus) are computed using the concept of transformed cross section.

The concrete modulus of elasticity may be calculated from the ACI formula. The minimum *modular ratio*, n, permitted by ACI and AASHTO is 6 [ACI 318 A.5.4 and *Bridges*, Div. 1, Sec. 10.38.1.3]. The ACI code states that the modular ratio may be taken as the nearest whole number.

$$n = \frac{E_s}{E_c} \qquad 57.4$$

The transformed slab width is calculated by dividing b_e by n. This "transforms" the concrete slab to steel. The neutral axis and moment of inertia are calculated for the transformed section.

Table 57.1 *Modular Ratio*[a]

compressive strength, f'_c (psi)	compressive strength, f'_c (MPa)	modular ratio[b] n
3000	21	9
3500	24	8.5
4000	28	8
4500	31	7.5
5000	35	7
6000	42	6.5
AASHTO recommendations[c]		
2000–2300	14–16	11
2400–2800	17–19	10
2900–3500	20–24	9
3600–4500	25–31	8
4600–5900	32–41	7
> 6000	> 41	6

(Multiply psi by 0.00689 to obtain MPa.)
[a]Based on a concrete specific weight of 145 lbf/ft^3 and a steel modulus of elasticity of 29,000,000 psi
[b]The modular ratio may be rounded to the nearest whole number [ACI 318 A.5.4].
[c]*Bridges*, Div. 1, Sec. 10.38.1.3

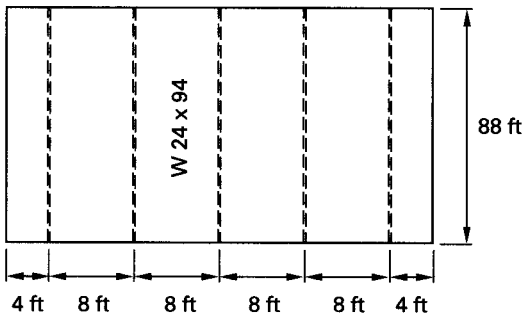
7. STRENGTH OF COMPOSITE SECTIONS

The ultimate strength of the composite section depends on the (a) section properties of the steel beam (girder), (b) yield strength of the steel beam, (c) compressive strength of concrete used for the slab, and (d) capacity of the shear connectors.

In analyzing a composite section, it is assumed that the shear connectors transfer the total shear at the steel-concrete interface. It is also assumed that concrete carries only compressive stress, and the small tensile stress capacity of concrete is ignored.

When analyzing or designing a composite section, the effects of noncomposite and composite loads should be considered. Also, the method of construction of composite members (with or without shoring) will have an effect on the actual stresses resulting from loads.

Noncomposite loads are those loads acting on the steel beam before the concrete slab hardens and can contribute to the strength. These loads include the weight of the steel beam, the weight of the fresh concrete slab, and the weight of formwork and bracing members. In unshored construction, the flexure stresses caused by these loads are resisted by the steel beam alone. *Composite loads* are those loads that act on the section after concrete has hardened. Composite loads include live loads from traffic, snow, and ice, and any additional dead load such as future roadway surfacing, sidewalks, railing, and permanent utilities fixtures.



Erection of composite members can be done either without shoring (unshored) or with shoring (shored). *Unshored construction* is the simplest construction method. The steel beams are placed first and used to support the formwork, fresh concrete, and live loads of construction crew and equipment. The steel beam acts noncompositely. It supports all noncomposite loads by itself.

With *shored construction*, the steel beams are supported by temporary falsework until the concrete cures. All noncomposite loads, including the steel beam itself, are supported by the falsework. After the concrete cures, the falsework is removed and the section acts compositely to resist all noncomposite and composite loads. Shored construction results in a reduction in the service load stresses.

The ultimate moment capacity of the composite section depends on the location of the neutral axis of the composite section. There are two possible locations of the neutral axis. (a) If the neutral axis is within the concrete slab, the slab is capable of resisting the total compressive force. In this case, the slab is "adequate." (b) If the neutral axis is within the steel beam below the concrete slab, the slab resists only a portion of the compressive force. The remainder is carried by the steel beam. The slab is said to be "inadequate." The calculation of the ultimate moment capacities of both cases is similar to the calculations for T-beam sections.

PRACTICE PROBLEMS

1. *(Time limit: one hour)* A simple bridge span is shown. The deck of the bridge consists of a 7 in thick concrete slab supported by 88 ft W 24×94 steel beams. Normal-weight concrete is used. The concrete strength is 3000 psi. Use AASHTO specifications.

(a) The effective width for an interior girder is most nearly
(A) 42 in
(B) 84 in
(C) 96 in
(D) 260 in

The answer is (B).

(b) The effective width for an exterior girder is most nearly
(A) 42 in
(B) 48 in
(C) 88 in
(D) 98 in

The answer is (A).

(c) The modular ratio is most nearly
(A) 6
(B) 7
(C) 8
(D) 9

The answer is (D).

(d) The equivalent width (steel) of the effective width for an interior girder is most nearly
(A) 8.3 in
(B) 9.3 in
(C) 10 in
(D) 11 in

The answer is (B).

(e) The centroidal distance of the transformed section measured from the bottom of the steel beam is most nearly
(A) 21 in
(B) 22 in
(C) 23 in
(D) 24 in

The answer is (C).

(f) The moment of inertia of the transformed section about the centroidal axis is most nearly
(A) 7700 in^4
(B) 8100 in^4
(C) 8300 in^4
(D) 8500 in^4

The answer is (A).

(g) The section modulus with respect to the top fiber is most nearly
(A) 910 in^3
(B) 930 in^3
(C) 950 in^3
(D) 990 in^3

The answer is (C).

(h) The section modulus with respect to the bottom fiber is most nearly
(A) 290 in^3
(B) 330 in^3
(C) 380 in^3
(D) 420 in^3

The answer is (B).

(i) If a 1 in by 8 in plate is welded to the bottom flange of the steel beam, the centroid of the transformed section will
(A) move up.
(B) move down.
(C) not move.
(D) move only after the concrete has failed (i.e., is 100% cracked).

The answer is (B).

(j) The addition of the 1 in by 8 in steel plate to the bottom flange will
(A) increase the moment of inertia about the x-axis.
(B) decrease the moment of inertia about the x-axis.
(C) have no effect on the moment of inertia about the y-axis.
(D) decrease the moment of inertia about the y-axis.

The answer is (A).

2. *(Time limit: one hour)* The steel support beams described in Prob. 1 are reinforced with a 1 in by 8 in steel plate welded to the bottom flange. After curing, the dead and live load moment is 620 ft-kips. Use AASHTO specifications to evaluate an interior girder with a span length of 39.3 ft.

(a) The moment of inertia of the transformed section of the composite section about the centroidal axis is most nearly
(A) 11,000 in^4
(B) 12,000 in^4
(C) 13,000 in^4
(D) 14,000 in^4

The answer is (B).

(b) The centroidal distance of the noncomposite section measured from the bottom of the steel beam is most nearly
(A) 8.3 in
(B) 10 in
(C) 11 in
(D) 12 in

The answer is (B).

(c) The moment of inertia of the noncomposite section about the centroidal axis is most nearly

(A) 3700 in^4
(B) 3800 in^4
(C) 3900 in^4
(D) 4000 in^4

The answer is (A).

(d) The bending stress at the top fibers due to noncomposite dead load in the case of unshored construction is most nearly

(A) 4.3 ksi
(B) 6.9 ksi
(C) 7.7 ksi
(D) 8.5 ksi

The answer is (C).

(e) The bending stress at the bottom fibers due to noncomposite dead load in the case of unshored construction is most nearly

(A) 5.3 ksi
(B) 6.2 ksi
(C) 7.4 ksi
(D) 8.9 ksi

The answer is (A).

(f) The additional bending stress at the top fibers of the concrete slab due to composite dead and live moment in the case of unshored construction is most nearly

(A) 0.5 ksi
(B) 0.6 ksi
(C) 0.7 ksi
(D) 0.8 ksi

The answer is (C).

(g) The additional bending stress at the top fibers of the steel beam due to composite dead and live moment in the case of unshored construction is most nearly

(A) 1.1 ksi
(B) 1.9 ksi
(C) 2.4 ksi
(D) 3.8 ksi

The answer is (B).

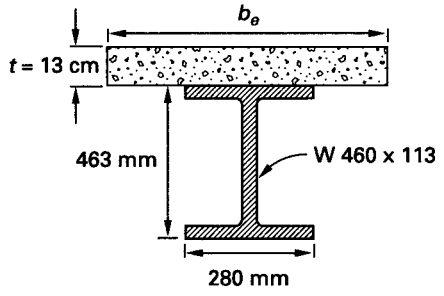
(h) The additional bending stress at the bottom fibers of the steel plate due to composite dead and live moment in the case of unshored construction is most nearly

(A) 14 ksi
(B) 15 ksi
(C) 20 ksi
(D) 22 ksi

The answer is (A).

(i) The bending stress at the top fibers of the concrete slab due to all loads in the case of shored construction is most nearly

(A) 0.7 ksi
(B) 0.9 ksi
(C) 1.3 ksi
(D) 2.3 ksi



The answer is (B).

(j) The bending stress at the bottom fibers of the steel plate due to all loads in the case of shored construction is most nearly

(A) 11 ksi
(B) 14 ksi
(C) 16 ksi
(D) 18 ksi

The answer is (D).

3. Calculate the ultimate moment capacity of the composite section shown. All pieces are A36 steel. The beam is W460×113 (metric). The concrete compressive strength is 20.7 MPa. The modular ratio is 9.

Answer: 1.07 MN·m

4. The beam described in Prob. 3 is changed such that the equivalent width of the concrete slab is 130 cm. The material properties are unchanged. Determine the ultimate moment capacity.

Answer: 1.02 MN·m

α	coefficient of thermal expansion	$1/^\circ\text{F}$
ν	Poisson's ratio	–
ρ	density	lbm/ft^3

Subscripts

b	bending
f	flange
t	tensile
u	ultimate (maximum) tensile
y	yield
v	shear

1. TYPES OF STRUCTURAL STEEL

The term *structural steel* refers to a number of steels that, because of their economy and desirable mechanical properties, are suitable for load-carrying members in structures. In the United States, the customary way to specify a structural steel is to use an ASTM (American Society for Testing and Materials) designation. For ferrous metals, the designation has the prefix letter "A" followed by two or three numerical digits (e.g., ASTM A36, ASTM A514). The general requirements for such steels are covered under ASTM A6 specifications. Basically, three groups of hot-rolled structural steels are available for use in buildings: carbon steels, high-strength low-alloy steels, and quenched and tempered alloy steels.

Carbon steels use carbon as the chief strengthening element. These are divided into four categories based on the percentages of carbon: *low-carbon* (less than 0.15%), *mild-carbon* (0.15 to 0.29%), *medium-carbon* (0.30 to 0.59%), and *high-carbon* (0.60 to 1.70%). The most widely used all-purpose structural steel, ASTM A36, belongs to the mild-carbon category, and it has a maximum carbon content varying from 0.25% to 0.29%, depending on thickness. Carbon steels used in structures have minimum yield stresses ranging from 32 to 42 ksi (kilopounds per square inch). An increase in carbon content raises the yield stress but reduces ductility, making welding more difficult. The maximum percentages of other elements of carbon steels are: 1.65% manganese, 0.60% silicon, and 0.60% copper.

High-strength low-alloy steels (HSLA) having yield stresses from 40 to 70 ksi are available under several ASTM designations. In addition to carbon and manganese, these steels contain one or more alloying elements (e.g., columbium, vanadium, chromium, silicon, copper, and nickel) that improve strength and other mechanical properties. The term "low-alloy" is arbitrarily used to indicate that the total of all alloying elements is limited to 5%. No heat treatment is used in the manufacture of HSLA steels. These steels generally have greater atmospheric corrosion resistance than the carbon steels. ASTM designations A242, A441, A572, and A588, among others, belong to this group.

Quenched and tempered alloy steels have yield stresses of 70 to 100 ksi. These steels of higher strengths are obtained by heat-treating low-alloy steels. The heat treatment consists of quenching (rapid cooling) and tempering (reheating). ASTM designations A514, A852, and A709 belong to this category.

2. STEEL NOMENCLATURE

In contrast to concrete nomenclature, it is traditional in steel design to use the uppercase letter F to indicate strength or allowable stress. Furthermore, such strengths or maximum stresses are specified in ksi. For example, $F_y = 36$ ksi is a steel with a yield stress of 36 ksi. Similarly, F_v is the allowable shear stress and F_b is the allowable bending stress, both in ksi. Actual or computed stresses are given the symbol of lowercase f.

Computed stresses are also specified in ksi. For example, f_t is a computed tensile stress in ksi.

In the United States, steel design is carried out exclusively in customary U.S. (inch-pound) units.

3. STEEL PROPERTIES

Each structural steel is produced to specified minimum mechanical properties as required by the specific ASTM designation by which it is identified. Some properties of steel (such as the modulus of elasticity and density) are essentially independent of the type of steel. Other properties (such as the tensile strength and the yield stress) depend not only on the type of steel but also on the size or thickness of the piece. The mechanical properties of structural steel are generally determined from tension tests on small specimens in accordance with standard ASTM procedures. The results of a tension test are displayed on a stress-strain diagram. Figure 58.1 shows typical diagrams of three different types of steels.

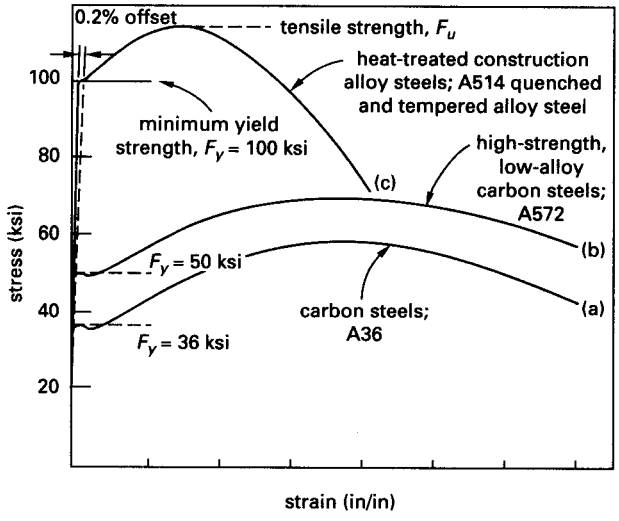

Figure 58.1 *Typical Stress-Strain Curves for Structural Steels*

Yield stress, F_y, is that unit tensile stress at which the stress-strain curve exhibits a well-defined increase in strain without an increase in stress. For carbon and HSLA steels that show sharply defined yield points, F_y represents the stress at the obvious yield point. For the heat-treated steels that do not show a definite *yield point*, F_y represents the yield strength. The *yield strength* is defined as the stress corresponding to a specified deviation (usually 0.2%) from perfectly elastic behavior. The elastic behavior is characterized by the initial, nearly vertical straight-line portion of the stress-strain diagram. The yield stress property is extremely important in structural design because it serves as a limiting value of a member's usefulness.

Tensile strength, F_u, is the largest unit stress that the material achieves in a tension test. The *modulus of elasticity*, E, is the slope of the initial straight-line portion of the stress-strain diagram. For all structural steels, it is usually taken as 29,000 ksi for design calculations. *Ductility* is the ability of the material to undergo large inelastic deformations without fracture. In a tension test, it is generally measured by percent elongation for a specified gage length (usually 2 or 8 in). This property allows redistribution of stresses in continuous members and at points of high local stresses, such as those at holes or other discontinuities.

Toughness is the ability of a specimen to absorb energy and is characterized by the area under a stress-strain curve. *Weldability* is the ability of steel to be welded without changing its basic mechanical properties. Generally, weldability decreases with increases in carbon and manganese. *Poisson's ratio* is the ratio of transverse strain to longitudinal strain. Poisson's ratio is essentially the same for all structural steels and has a value of 0.3 in the elastic range. *Shear modulus* is the ratio of shearing stress to shearing strain during the initial elastic behavior.

Table 58.1 *Typical Properties of A36 Steel*

modulus of elasticity, E	29,000 ksi
yield strength, F_y	36 ksi (up to 8 in thickness)
	32 ksi (over 8 in thickness)
tensile strength, F_u	58 ksi (minimum)
endurance strength	30 ksi (approximately)
density, ρ	490 lbm/ft^3
Poisson's ratio, ν	0.3
shear modulus, G	11,200 ksi
coefficient of thermal expansion, α	6.5×10^{-6} °F^{-1}

(Multiply ksi by 6.9 to obtain MPa.)
(Multiply in by 25.4 to obtain mm.)
(Multiply lbm/ft^3 by 16 to obtain kg/m^3.)
(Multiply °F^{-1} by 9/5 to obtain °C^{-1}.)

Appendix 58.A lists common structural steels along with their minimum yield stresses, tensile strengths, and uses. Under normal conditions, characterized by a fairly narrow temperature range (usually taken as −30°F to 120°F), the yield stress, tensile strength, and modulus of elasticity of a structural steel remain virtually constant. But when steel members are subjected to the elevated temperatures of a fire, a significant reduction in strength and rigidity occurs over time (see App. 58.B). For that reason, structural steels are given a spray-applied fire-resistant coating.

4. STRUCTURAL SHAPES

Many different structural shapes are available. The dimension and weight must be added to the designation to uniquely identify the shape. For example, W 30 × 132 refers to a W-shape with an overall depth of approximately 30 in that weighs 132 lbf/ft. The term *hollow structural sections* (HSS) is used to describe round

and rectangular tubular members, which are often used as struts in trusses and space frames. Table 58.2 lists structural shape designations, and Figure 58.2 shows common structural shapes.

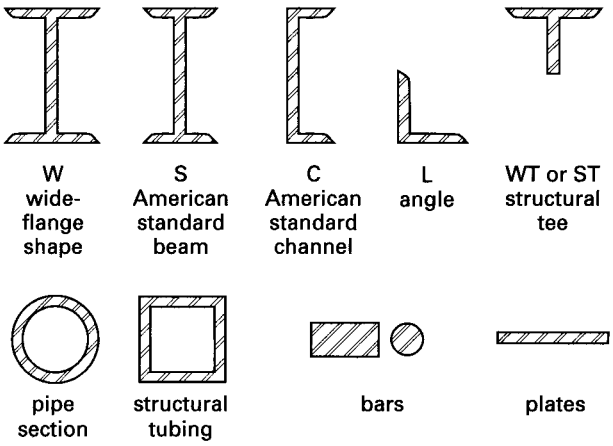

Figure 58.2 *Structural Shapes*

Table 58.2 *Structural Shape Designations*

shape	designation
wide flange beam	W
American standard beam	S
bearing piles	HP
miscellaneous (those that cannot be classified as W, S or HP)	M
American standard channel	C
miscellaneous channel	MC
angle	L
structural tee (cut from W or S or M)	WT or ST
structural tubing	TS
pipe	pipe
plate	PL
bar	bar

Figure 58.3 illustrates several combinations of shapes that are used in construction. The double-angle combination is particularly useful for carrying axial loads. Combinations of W-shapes and channels, channels with channels, or channels with angles are used for a variety of special applications, including struts and light crane rails. Properties for certain combinations have been tabulated in the *AISC Manual*.

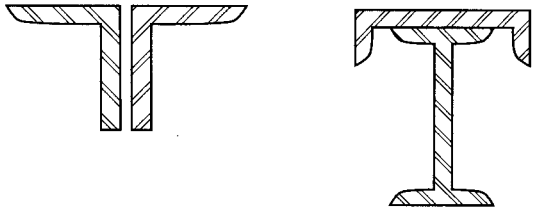

Figure 58.3 *Typical Combined Sections*

Occasionally, it will be desirable to provide additional bending or compressive strength to a shape by adding plates. It is generally easy to calculate the properties of the built-up section from the properties of the shape and plate. The following characteristics can be used when it is necessary to specify plate reinforcement.

- Plate widths should not be the same as the flange width (b_f), due to difficulty in welding. Widths should be somewhat larger or smaller. It is better to keep the plate width as close to b_f as possible, as width-thickness ratios specified in the *AISC Manual* may govern.
- Width and length tolerances smaller than $1/8$ in are not practical. Table 58.3 (from the *AISC Manual*, Part 1, Standard Mill Practice) should be used when specifying the nominal plate width.
- Not every plate exists in the larger thicknesses. Unless special plates are called for, the following thickness guidelines should be used.

  $1/32$ in increments up to $1/2$ in

  $1/16$ in increments from $9/16$ in to 1 in

  $1/8$ in increments from $1\,1/8$ in to 3 in

  $1/4$ in increments for $3\,1/4$ in and above

Table 58.3 *Width Tolerance for Universal Mill Plates*

	width (in)		
thickness (in)	8 to 20 exclusive	20 to 36 exclusive	36 and above
0 to $\frac{3}{8}$, exclusive	$\frac{1}{8}$	$\frac{3}{16}$	$\frac{5}{16}$
$\frac{3}{8}$ to $\frac{5}{8}$, exclusive	$\frac{1}{8}$	$\frac{1}{4}$	$\frac{3}{8}$
$\frac{5}{8}$ to 1, exclusive	$\frac{3}{16}$	$\frac{5}{16}$	$\frac{7}{16}$
1 to 2, inclusive	$\frac{1}{4}$	$\frac{3}{8}$	$\frac{1}{2}$
over 2 to 10, inclusive	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{9}{16}$
over 10 to 15, inclusive	$\frac{1}{2}$	$\frac{9}{16}$	$\frac{5}{8}$

(Multiply in by 25.4 to obtain mm.)

Example 58.1

A W 30 × 124 shape must be reinforced to achieve the strong-axis bending strength of a W 30 × 173 shape by welding plates to both flanges. All steel is A36. The plates are welded continuously to the flanges. What size plate is required if all plate sizes are available?

Structural

Solution

The moments of inertia for the W 30 × 124 and W 30 × 173 beams are 8200 in^4 and 5360 in^4, respectively. The difference in bending resistance to be provided by the supplemental plates is

$$I_{\text{plates}} = 8200\ \text{in}^4 - 5360\ \text{in}^4 = 2840\ \text{in}^4$$

For ease of welding, assume the plate thickness, t, will be approximately the same as the flange thickness. For the W 30 × 124 beam, the flange thickness is 0.930 in, so choose a plate thickness of 1.0 in. If w is the required plate width, the centroidal moment of inertia of the two plates acting together is

$$I_{c,\text{plates}} = \frac{(\text{number of plates})wh^3}{12}$$

$$= \frac{2w(1\ \text{in})^3}{12} = w/6$$

The depth of the W 30×124 beam is 30.17 in. Therefore, the distance from the neutral axis to the plate centroid is

$$C = \frac{d}{2} + \frac{t}{2}$$

$$= \frac{30.17\ \text{in}}{2} + \frac{1\ \text{in}}{2} = 15.585\ \text{in}$$

From the parallel axis theorem, the moment of inertia of the two plates about the neutral axis is

$$I_{\text{plates}} = \frac{w}{6} + 2w(1)(15.585)^2 = 486.0w$$

The required moment of inertia is 2840 in^4.

$$w = \frac{2840\ \text{in}^4}{486\ \text{in}^3} = 5.84\ \text{in} \quad \text{[use 6 in]}$$

5. SPECIFICATIONS AND BUILDING CODES

Although the terms "specification" and "building code" are often used interchangeably in the context of steel design, there is a difference between the two. A *specification* is a set of guidelines or recommendations put forth by a group of experts in the field of steel research and design with the intent of ensuring safety. A specification is not legally enforceable unless it is a part of a building code.

The design of steel buildings in the United States is principally based on the specifications of the American Institute of Steel Construction (AISC), a nonprofit trade association representing and serving the fabricated structural steel industry in the United States. There are two AISC specifications in use: (a) "AISC Specification for Structural Steel Buildings—Allowable Stress Design" (referred to as ASDS in this book) and (b) "AISC Load and Resistance Factor Design Specification for Structural Steel Buildings." These two specifications are contained, respectively, in the two primary publications of the AISC: *Allowable Stress Design Manual of Steel Construction* (referred to as ASDM) and the *Load and Resistance Factor Design Manual of Steel Construction* (referred to as LRFD). In addition to the ASD and LRFD specifications, both of these manuals contain a wealth of information on products available, design aids, examples, erection guidelines, and other applicable specifications.

A *building code* is a broad-based document covering all facets of safety, such as design loadings, occupancy limits, plumbing, electrical requirements, and fire protection. Building codes are adopted by states, cities, or other government bodies as a legally enforceable means of protecting public safety and welfare. There are three common model codes that are integrated, fully or partially, into many state or local building codes. These are: Building Officials and Codes Administrators International Incorporated (BOCA), National Building Code; International Conference of Building Officials (ICBO), Uniform Building Code (UBC); and Southern Building Code Congress International (SBCCI), Standard Building Code. Progress is being made toward developing a single national building code that can be adopted by all states.

6. PHILOSOPHIES OF DESIGN

There are two philosophies of design in current use in the United States: allowable stress design (ASD) and *load and resistance factor design* (LRFD). For steel design, the *allowable stress design* (also called *working stress design*) philosophy has been the primary one used for over 100 years.

ASD is based on the premise that all components of a structure remain elastic during their lifetimes. According to this philosophy, a structural element is designed such that the computed stresses under service or working loads do not exceed the allowable values. The allowable stresses are prescribed by the building codes or specifications to provide a factor of safety against attaining some limiting stress such as the minimum specified yield stress or the stress at which buckling occurs.

The other design philosophy, LRFD, also referred to as *limit states design*, has been in use since 1986. "Limit state" is a general term meaning a condition at which a

structure or some part of it ceases to fulfill its intended function. There are two categories of limit states: strength and serviceability. The strength limit states that are the primary concerns of designers include plastic strength, fracture, buckling, fatigue, and so on. These affect the safety or load-carrying capacity of a structure. The serviceability limit states refer to the performance under normal service loads and pertain to uses and/or occupancy of structures, including excessive deflection, drift, vibration, and cracking.

7. LOADS

Structures are designed to resist many types of loads including dead loads, live loads, snow loads, wind loads, and earthquake loads. The complete design must take into account all effects of these loads, including all applicable load combinations. Building codes (state, municipal, or other) usually provide minimum loads for a designer's use in a particular area. In the absence of such provisions, *ASCE Standard 7-95*, "Minimum Design Loads for Buildings and Other Structures," may be referred to.

8. FATIGUE LOADING

The effects of fatigue loading are generally not considered except in the cases of bridge and connection design. If a load is to be applied and removed less than 20,000 times (roughly equivalent to twice daily for 25 years), as would be the case in a conventional building, no provision for repeated loading is necessary. However, some designs, such as for crane runway girders and supports, must consider the effects of fatigue. Design for fatigue loading is covered in App. K4 of the *AISC Specifications*.

9. ALLOWABLE STRESSES

The allowable stresses for all structural members, connections, and connectors are specified in the AISC *ASD Specifications*, Chs. D through K. However, these values do not apply to peak stresses in regions of connections (areas of stress concentration). Most allowable stresses, including those for connectors, columns, and beams, may be increased by one third for transitory wind and earthquake loading. This increase is applied to all stresses in a structural member, not just the wind or earthquake-induced stresses. The one third increase cannot be applied in fatigue loading problems. Also, the calculated section area cannot be less than the area required to carry the dead and live loads alone (without the one third increase). The effects of impact are included by increasing the actual live load (but not the dead load) by the percentages contained in Table 58.4.

10. MOST ECONOMICAL SHAPE

Since a major part of the cost of using a rolled shape in construction is the cost of raw materials, the lightest shape possible that will satisfy the structural requirements should always be used. Thus, generally speaking, the most *economical shape* is the structural shape that has the lightest weight per foot and that has the required strength. (ASTM A572 grade-50 steel is approximately 35% stronger than ASTM A36 steel, but it costs only approximately 14% more than A36 steel. For beams whose designs are not driven by deflection criteria, as is usually the case in composite construction, ASTM A572 grade-50 steel will generally provide the economical section.) The beam selection table and chart are designed to make choosing economical shapes possible.

Table 58.4 *Impact Loading Factors*

supports for	live load increase
elevators	100%
cab-operated travel cranes	25%
pendant-operated travel cranes	10%
shaft- or motor-driven machinery	20%
reciprocating machinery	50%
floors and balconies (hangers)	33%

Source: AISC Specification A4.2

11. DESIGNING WITH WEATHERING STEEL

Weathering steel is a term used to describe A588 steel when it is used unpainted, particularly as part of bridge substructures. The natural layer of oxidation (rust) that forms provides all the protection needed for most applications. The higher cost of the material is offset by eliminating the need to paint and repaint the structure. (A588 steel usually costs somewhat less than painted A572 grade-50 steel, which also has a 50 ksi yield strength.)

If used without a careful evaluation of environmental location and detailing, however, weathering steel can experience significant corrosion and cracking. Successful use depends on considering several factors in the design. (a) The use of A588 steel in locations that interfere with the development of the protective oxide coating should be avoided. For example, contact between the steel and vegetation, masonry, wood, or other materials should be avoided so that weathering can be maintained on a natural basis. (b) Retention of water and debris on steel surfaces should be avoided. In bridge decks, rely on camber rather than deck drains that can be easily clogged by roadside debris. (c) "Jointless," continuous construction should be used, or the steel beneath joints should be protected and sealed by galvanizing. (d) Surface runoff from the deck to the steel below should be prevented. Similarly, the "tunnel effect," whereby road salts are sucked onto the substructure due to limited space between it and surrounding terrain or features, should be eliminated. (e) Areas where debris has collected should be flushed and cleaned regularly to prevent the buildup of corrosive salts.

To prevent unsightly staining of concrete abutments and piers in urban areas, the first 5 to 6 ft (1.5 to 1.8 m) of the steel structure can be painted.

12. DESIGNING WITH HIGH-STRENGTH STEEL

100 ksi high-strength structural steel is readily available, and rods and prestressing steel can have strengths near or over 200 ksi. These steels are frequently used in structural steel connectors (A514 quenched and tempered steel with a 100 ksi yield, for example). However, high-strength steels have particular characteristics that must be considered.

Higher strengths are obtained at the expense of decreased ductility and increased brittleness. Very high-strength steels have very little or almost no margin of strength above the yield strength. The design stress that controls is often half of the tensile strength, and it may be lower than the fraction of yield used in lower-strength steels. In the same vein, the transition temperature, below which the steel loses its ductility, must be considered.

High-strength steels used in structural shapes are sensitive to welding-induced hydrogen cracking. Welding may change the grain structure significantly, introducing discontinuities (flaws) in the steel structure that can serve as sites for fractures. Also, welding may introduce residual stresses, particularly with thick plates and complex joints, unless preheating and postheating are used. Some complex joints may need to be fabricated offsite, heated in an annealing furnace, and allowed to cool slowly in order to reduce the high levels of residual stresses introduced by welding.

High-strength steels are sensitive to fatigue (dynamic loading) and the rate of stress application. Bridges, for example, are subjected to thousands or millions of vehicle loads over their lifetimes. The design stress in such cases is limited to the endurance strength, which might be only a fraction of the design stress in the absence of fatigue.

High-strength steels are also more sensitive to corrosion, leading to *stress-corrosion cracking*. Even environments where the strongest corrosive is rainwater may cause high-strength bolts to fail.

For applications where the use of high-strength steel is problematic, several options exist. (a) Use a lower-strength steel or a steel with a higher fracture toughness. Some state highway departments limit the strength of connectors used in thick members for this reason. (b) Closely monitor pretensioning of bolts. (c) Use accepted procedures for welding and weld inspection. (d) Design for redundancy. For example, in bridge design, a larger number of smaller stringers is preferred over ever-larger rolled sections or large sections built up by welding. (e) Predict fatigue-crack rates in order to determine realistic service lives of structures subjected to repeated loadings, such as bridges and offshore structures. (f) Design for inspection. (g) Use proper inspection techniques. For example, bolt tension cannot be adequately field-checked by using a torque wrench.

13. HIGH-PERFORMANCE STEEL

The term *high-performance steel* (HPS), as used in bridge design, generally refers to HPS 70W grade steel plate. This 70 ksi (485 MPa) steel meets ASTM A709 specifications and is tougher than traditional grades. Available primarily in plate form, it is finding increasing use in bridge steel plate girders where the cost savings can range from 10 to 20% since less material is needed.

Most HPS 70W plate is quenched and tempered (manufacturing operations that involve additional heating and cooling steps and that limit plate lengths to approximately 50 ft (15 m) and thicknesses to approximately 2 in). Advanced compositions may allow HPS plate to be manufactured in longer and thicker sections without quenching and tempering. True structural sections may also then be possible.

As with all high-strength steel, welding protocol must be strictly controlled to avoid hydrogen cracking. Specific techniques and different consumables (e.g., rod, flux, and shield gas) are required for each combination of steels to be joined.

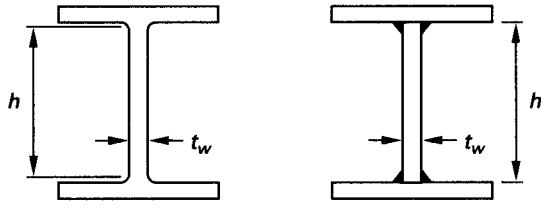
v	shear
w	web
x	strong axis
y	yield or weak axis

1. TYPES OF BEAMS

Beams primarily support transverse loads (i.e., loads that are applied at right angles to the longitudinal axis of the member). They are subjected primarily to flexure (bending). Although some axial loading is practically unavoidable in any structural member, the effect of axial loads is generally negligible, and the member can be treated strictly as a beam. If an axial compressive load of substantial magnitude is also present with transverse loads, the member is called a *beam-column.*

Beams are often designated by names that are representative of some specialized functions: A *girder* is a major (deep) beam that often provides supports for other



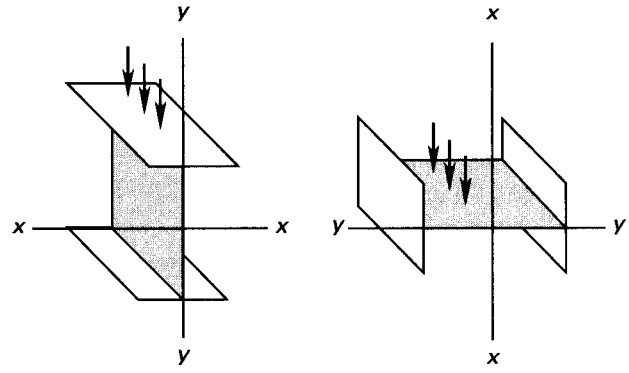
beams. A *stringer* is a main longitudinal beam, usually supporting bridge decks. A *floor beam* is a transverse beam in bridge decks. A *joist* is a light beam that supports a floor. A *lintel* is a beam spanning an opening (a door or window), usually in masonry construction. A *spandrel* is a beam on the outside perimeter of a building that supports, among other loads, the exterior wall. A *purlin* is a beam that supports a roof and frames between or over supports, such as roof trusses or rigid frames. A *girt* is a light beam that supports only the lightweight exterior sides of a building, as is typical in pre-engineered metal buildings.

Commonly used beam cross sections are standard hot-rolled shapes including the W, S, M, C, T, and L shapes. Doubly symmetrical shapes, such as W, S, and M sections, are the most efficient. They have excellent flexural strength and relatively good lateral strength for their weight. Channels have reasonably good flexural strength but poor lateral strength, and they require horizontal bracing or some other lateral support. Tees and angles are suitable only for light loads.

The flexural strength of a rolled section can be improved by adding flange plates. But if the loadings are too heavy or the spans are too long for a standard rolled section, a plate girder may be necessary. *Plate girders* are built up from plates in I (most common), H, or box shapes of any depth. A *box shape* is used if depth is restricted or if lateral stability is a problem.

Shapes that are built up from plate elements are usually considered plate girders, but the *AISC Manual* distinguishes beams from plate girders on the basis of the width-thickness ratio of the web. Figure 59.1 shows two cross sections—a hot-rolled shape and a built-up shape—along with the dimensions to be used for the width-thickness ratios. If Eq. 59.1 is valid, the member is to be treated as a beam, regardless of whether it is a rolled shape or built up. Otherwise, the member is considered to be a plate girder. Allowable bending stresses for beams are given in Chap. F of the *AISC Manual*.

$$\frac{h}{t_w} \le \frac{760}{\sqrt{F_y}} \qquad 59.1$$



(a) hot-rolled shape (b) built-up shape

Figure 59.1 *Steel Beam Cross Sections*

2. BEAM BENDING PLANES

The property tables for W shapes contain two moments of inertia, I_x and I_y, for each beam. There are several ways of referring to the *plane of bending*. Figure 59.2(a) shows a W-shape beam as it is used typically. The value of I_x should be used to calculate bending stress. This bending mode is referred to as "bending about the major (or strong) axis." However, it is also referred to as "loading in the plane of the web." Figure 59.2(b) shows a W shape "bending about the minor (or weak) axis" This mode is also referred to as "loading perpendicular to the plane of the web."

(a) bending about major axis (b) bending about minor axis

Figure 59.2 *Beam Bending Planes*

3. BENDING STRESS IN STEEL BEAMS

Elastic design and analysis of one-span beams is carried out with simple bending theory equations. Unless the beam is very short, it should be sized and analyzed with the flexure formula and subsequently checked for shear. The maximum stress due to flexure (bending) at any cross section in a beam is determined from the standard bending stress formula.

$$f_b = \frac{Mc}{I} = \frac{M}{S} \qquad 59.2$$

Since both c and I are constant for any specific prismatic beam, the *section modulus*, S, can be used from the *AISC Manual* tables. Generally, only the absolute maximum bending stress is of interest. Therefore, unless otherwise stated, f_b represents the maximum stress that occurs at the extreme fiber of a cross section carrying the maximum moment.

4. COMPACT SECTIONS

Compact sections have thicker webs and flanges than noncompact sections. Therefore, compact sections are permitted to achieve higher stresses in many instances. To be compact, the flanges of a beam must be continuously connected to the web. Therefore, a built-up section or plate girder constructed with intermittent welds does not qualify. In addition, Eqs. 59.3 and 59.4 must be satisfied by standard rolled shapes without flange stiffeners. (Equation 59.4 applies only to webs in flexural compression.) [AISC Table B5.1 with $b = b_f/2$]

$$\frac{b_f}{2t_f} \leq \frac{65.0}{\sqrt{F_y}} \qquad 59.3$$

$$\frac{d}{t_w} \leq \frac{640}{\sqrt{F_y}} \quad \text{[webs]} \qquad 59.4$$

Compactness, as Eqs. 59.3 and 59.4 show, depends on the steel strength. Most rolled W shapes are compact at lower values of F_y. However, a 36 ksi beam may be compact, while the same beam in 50 ksi steel may not be. The shape tables in the *AISC Manual* contain columns (F_y' and F_y''') that indicate the yield strengths at which the beams become noncompact due to the two conditions.

5. LATERAL BRACING

To prevent *lateral buckling* (illustrated in Fig. 59.3), a beam's compression flange must be supported at frequent intervals. Complete support is achieved when a beam is fully encased in concrete or has its flange welded or bolted along its full length (see Fig. 59.4). In many designs, however, lateral support is provided only at regularly spaced intervals. The actual spacing between points of lateral bracing is designated as L_b. For the purpose of determining allowable bending stress, two limits are placed on spacing: $F_b = 0.66F_y$ if $L_b \leq L_c$ and $F_b = 0.60F_y$ if $L_c < L_b \leq L_u$ (see Fig. 59.12).

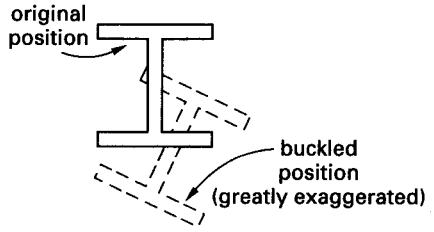


Figure 59.3 *Lateral Buckling in a Beam*

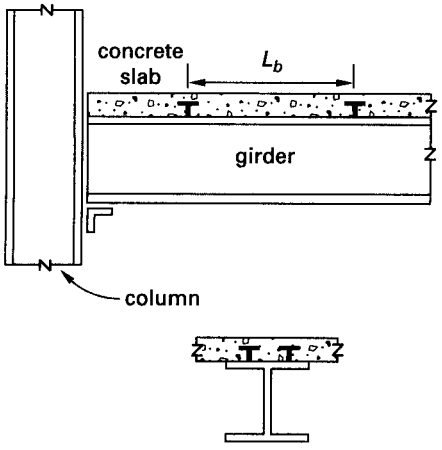

Figure 59.4 *Compression Flange Bracing Using Headed Studs*

For most shapes, L_c is calculated from Eq. 59.5 and L_u is calculated from Eq. 59.6. The quantity b_f and the ratio d/A_f are both tabulated for regular shapes, although L_c and L_u are themselves tabulated for rolled shapes with standard values of F_y in the *AISC Manual*, Part 2, based on the equations in Sec. F1.

$$L_c = \text{smaller of} \left\{ \begin{array}{c} \dfrac{76b_f}{\sqrt{F_y}} \\ \dfrac{20{,}000}{\left(\dfrac{d}{A_f}\right)F_y} \end{array} \right\} \quad \text{[F1-2]} \qquad 59.5$$

$$L_u = \text{larger of} \left\{ \begin{array}{c} \dfrac{20{,}000C_b}{\left(\dfrac{d}{A_f}\right)F_y} \\ r_T\sqrt{\dfrac{102{,}000C_b}{F_y}} \end{array} \right\} \quad \text{[F1-6]} \qquad 59.6$$

The *moment gradient multiplier*, C_b, can be used to increase L_u, but C_b is never used with L_c (i.e., C_b is used only when $L_c < L_b \leq L_u$). The conservative case of $C_b = 1$ is almost always taken. The moment gradient multiplier is described in more detail in App. 59.A. r_T is the radius of gyration of a section comprised of the compression flange plus one third of the compression web area, taken about an axis in the plane of the web [Sec. F1]. r_T is tabulated in the *AISC Manual* for each beam, but is approximately $1.2r_y$.

6. ALLOWABLE BENDING STRESS: W SHAPES BENDING ABOUT MAJOR AXIS

For W shapes loaded in the plane of their webs and bending about the major axis, the allowable bending stress will be $0.66F_y$ or less. If $L_b \leq L_c$, or if the bracing is continuous and the beam is compact, the allowable stress is $0.66F_y$. If $L_u \geq L_b > L_c$, then the basic bending allowance of $0.60F_y$ applies. If $L_b > L_u$, or if there is no bracing at all between support points, then the allowable bending stress is less than $0.60F_y$. Equations 59.7 through 59.9, corresponding to AISC ASD equations [F1-6], [F1-7], and [F1-8], respectively, must be used to determine the actual value of F_b for compression. (The allowable tensile bending stress remains at $0.60F_y$. However, for symmetrical shapes, the compressive and tensile stresses are the same.) The largest value calculated from Eqs. 59.7 through 59.9 is used.

$$F_b = \left(\frac{2}{3} - \frac{F_y\left(\dfrac{l}{r_T}\right)^2}{1530 \times 10^3 C_b} \right) F_y \qquad 59.7$$

$$F_b = \frac{170 \times 10^3 C_b}{\left(\dfrac{l}{r_T}\right)^2} \leq 0.60F_y \qquad 59.8$$

$$F_b = \frac{12 \times 10^3 C_b}{\dfrac{ld}{A_f}} \leq 0.60F_y \qquad 59.9$$

7. ALLOWABLE BENDING STRESS: WEAK-AXIS BENDING

If a doubly symmetrical rolled shape is placed such that bending will occur about its weak axis, the allowable bending stress is $0.75F_y$. The shape must be compact, and other conditions may also apply. However, this is not an efficient use of the beam, so this configuration is seldom used. Nevertheless, weak-axis bending may occur, particularly in beam-columns.

$0.75F_y$ is also the allowable bending stress for solid square, solid round, and solid rectangular shapes (including flat bearing plates).

F_b is larger for bending about the weak axis than for bending about the strong axis because the failure modes are different. About the strong axis, the beams fails by compression flange buckling and twisting about the minor axis. About the weak axis, the beam fails by yielding, which is more controlled and predictable.

8. ALLOWABLE BENDING STRESS: INTERMEDIATE CASES

For both strong-axis and weak-axis bending, special cases exist for non-compact beams with $L_b < L_c$. In such instances, the so-called *blending formulas* [F1-3] and [F1-4] are used to produce intermediate values of F_b. (The name "blending" is used because the allowable stress for strong-axis bending will be between $0.60F_y$ and $0.66F_y$.)

9. SHEAR STRESS IN STEEL BEAMS

It is assumed that only the web thickness carries shear in W shapes. The statical moment concept is almost never used in steel design, and the average shear stress is compared against the shear stress limitations. The maximum allowable shear stress F_v in the web of a beam is $0.40F_y$. (Different limitations apply to shear stresses in bolts, rivets, and plate girders.) The average shear stress in the web is

$$f_v = \frac{V}{A_w} = \frac{V}{dt_w} \qquad 59.10$$

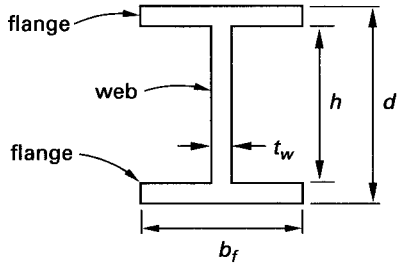

Figure 59.5 *Nomenclature and Terminology for Steel W-Shape Beam*

10. LOCAL BUCKLING

Local buckling is a factor in the vicinity of large concentrated loads. Such loads may occur at a reaction point or where a column frames into a supporting girder. *Web yielding* and *web crippling*, two types of local buckling shown in Fig. 59.6, can be reduced or eliminated by use of *stiffeners*. If the load is applied uniformly over a large enough area (say, along N inches of beam flange or more), no stiffeners will be required.

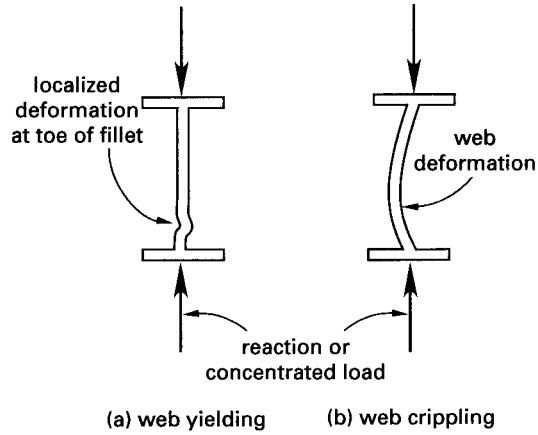

Figure 59.6 *Local Buckling*

Regarding web yielding, if the maximum stress at the toe of the beam fillet is to be kept below $0.66F_y$, the minimum length, N, is specified by Eq. 59.11 ([K1-2]) for interior loads and Eq. 59.12 ([K1-3]) for loads at beam ends (see Fig. 59.7). R_1 and R_2 are tabulated in the beam tables in Part 2 of the *AISC Manual*. (In Eqs. 59.11 and 59.12, R is the reaction or load.)

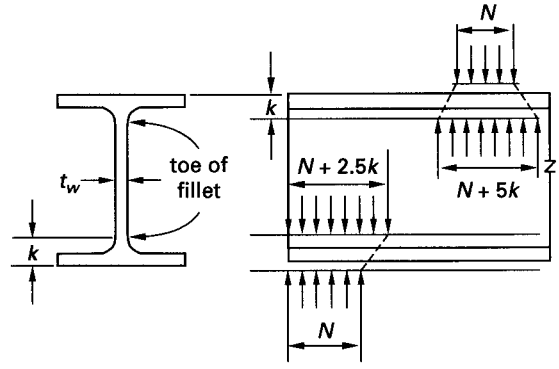

Figure 59.7 *Nomenclature for Web Yielding Calculations*

$$N_{\min} = \frac{R - 2R_1}{R_2} \quad \text{[interior]} \qquad 59.11$$

$$N_{\min} = \frac{R - R_1}{R_2} \quad \text{[ends]} \qquad 59.12$$

$$R_1 = 0.66F_{yw}t_w(2.5k) \quad [F_{yw} \text{ in kips/in}^2] \qquad 59.13$$

$$R_2 = 0.66F_{yw}t_w \quad [F_{yw} \text{ in kips/in}^2] \qquad 59.14$$

Regarding web crippling, the minimum length, N, is specified by Eq. 59.15 ([K1-4]) for interior loads and by Eq. 59.16 ([K1-5]) for reactions at beam ends. R_3 and R_4 are tabulated in the beam tables in Part 2 of the *AISC Manual*. In Eqs. 59.15 and 59.16, R is the reaction or load.

$$N_{\min} = \frac{R - 2R_3}{R_4} \quad \text{[interior]} \qquad 59.15$$

$$N_{\min} = \frac{R - R_3}{R_4} \quad \text{[ends]} \qquad 59.16$$

$$R_3 = 34t_w^2\sqrt{\frac{F_{yw}t_f}{t_w}} \quad [F_{yw} \text{ in kips/in}^2] \qquad 59.17$$

$$R_4 = 34t_w^2\left(\frac{3}{d}\right)\left(\frac{t_w}{t_f}\right)^{1.5}\sqrt{\frac{F_{yw}t_f}{t_w}} \quad [F_{yw} \text{ in kips/in}^2] \qquad 59.18$$

Intermediate stiffeners (i.e., web stiffeners spaced throughout a stock rolled shape) are never needed with rolled shapes but are typically used in plate girders. (For built-up beams, diagonal buckling requirements should also be checked.) *Bearing stiffeners* (see Fig. 59.8) are typically web stiffeners connected as plates welded to the webs and flanges of rolled sections.

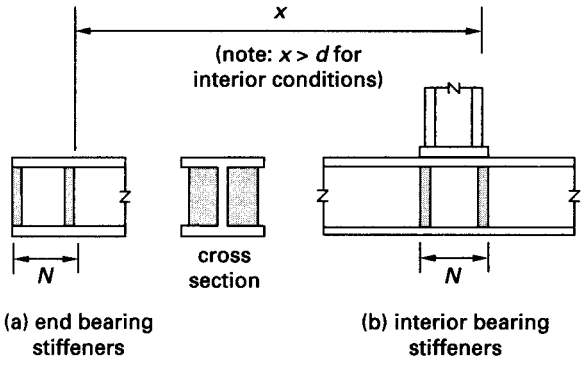

Figure 59.8 *Bearing Stiffeners*

Flange stiffeners (see Fig. 59.9) are typically angles placed at the web-flange corner used to keep the flange perpendicular to the web. Flange stiffeners cannot be used in place of bearing stiffeners.

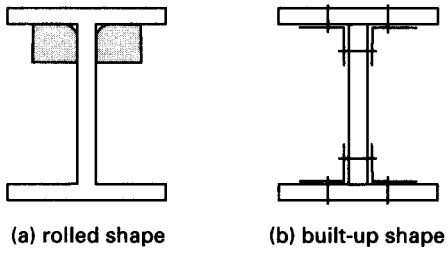

Figure 59.9 *Flange Stiffeners*

11. SERVICEABILITY AND BEAM DEFLECTIONS

In addition to being safe, a structure with all its components must be serviceable. While stresses in a beam due to moment and shear must be within allowable limits to ensure safety, the beam cannot be too flexible. This usually limits the deflection of the beam. Among the many reasons for avoiding excessive deflections are the effects on nonstructural elements (e.g., doors, windows, and partitions), undesirable vibrations, and the proper functioning of the roof drainage systems.

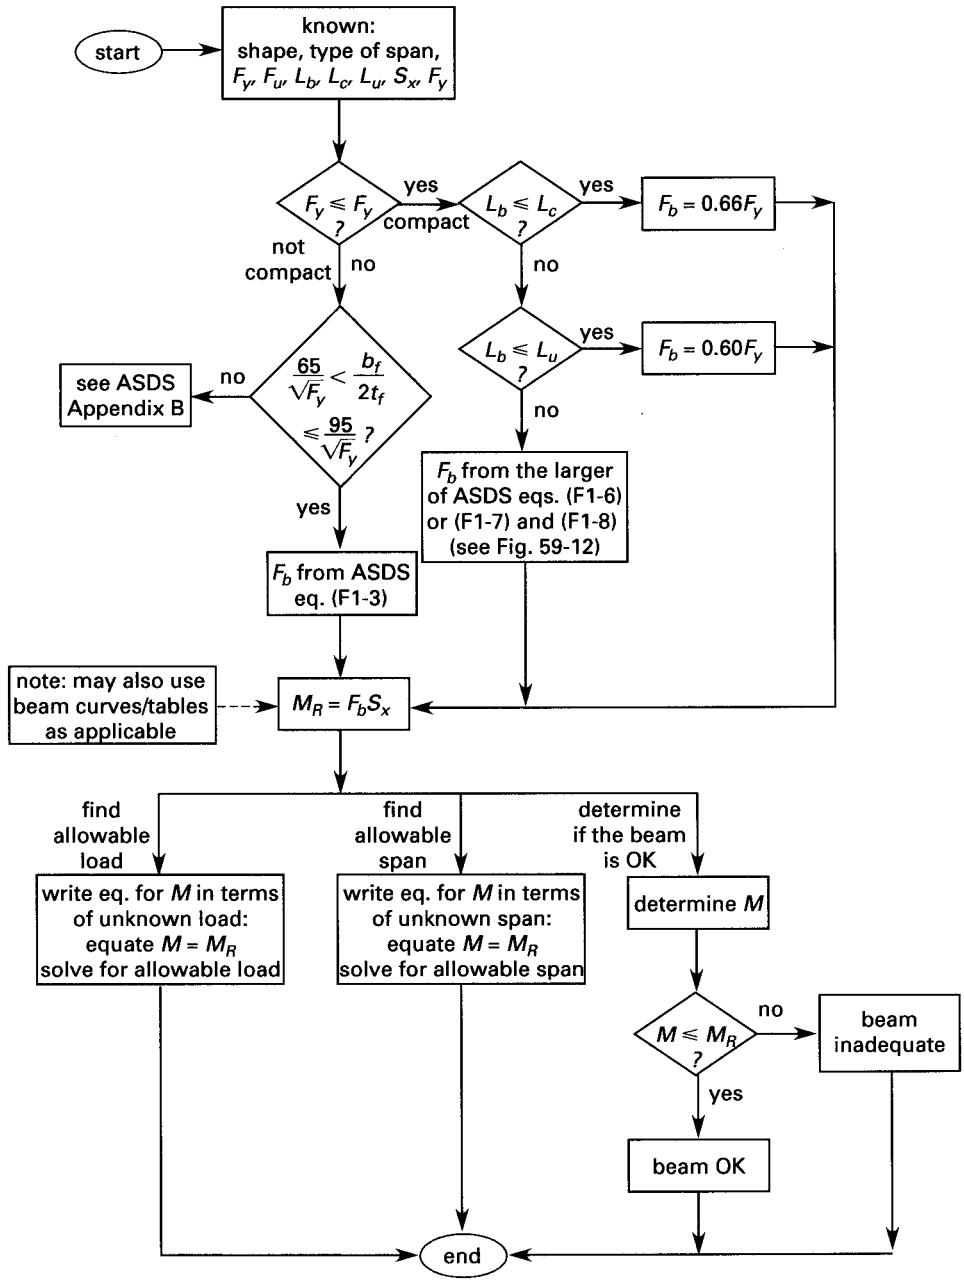
Steel beam deflections are calculated using traditional beam equations based on the principles of strength of materials. For common beams and loadings the *AISC Manual*, Part 2, Beam Diagrams and Formulas, contains deflection formulas. Deflection limitations are typically unique to each design situation and are generally expressed in terms of some fraction of the span length. The *AISC Manual* suggests, but does not require, general guidelines to maintain appearance and occupant confidence in a structure. Chapter L of the *AISC Commentary* suggests the following guidelines. (Special provisions in the *AISC Commentary* K2 are used to check for ponding on flat roofs.)

- The depths of fully stressed floor beams and girders should not be less than $F_y/800$ times their spans.
- The depths of fully stressed roof purlins should not be less than $F_y/1000$ times their spans, except in the case of flat roofs.
- To attenuate floor vibrations where human comfort is the criterion for limiting motion, the depths of steel beams should not be less than $1/20$ of their spans.

12. ANALYSIS OF STEEL BEAMS

Although bending stress is the primary criterion for beams, a complete analysis of a steel beam of known cross section also includes checking for shear stress and deflection. A flowchart for beam analysis is shown in Fig. 59.10.

- The ratio is 1:360 for live-load deflections of beams and girders supporting plastered ceilings.



Example 59.1

Based on moments only, determine the maximum allowable superimposed uniformly distributed load that a W 18×55 beam of A36 steel can carry on a simple span of 36 ft. Consider the compression flange to be braced at (a) 6 ft intervals, (b) 12 ft intervals, and (c) 18 ft intervals.

Solution

For A36 steel, $F_y = 36$ ksi. Obtain the properties of a W 18×55 beam from the *AISC Manual*, Shape Table.

Structural

Source: *Applied Structural Steel Design*, 3rd ed., by Spiegel/Limbrunner, copyright © 1997. Reprinted by permission of Prentice-Hall, Inc., Upper Saddle River, NJ.

Figure 59.10 *Flowchart for Analysis of Beams (W shape, strong-axis bending, moment criteria only)*

Check for compactness.

$$S_x = 98.3 \text{ in}^3$$

$$r_T = 1.95 \text{ in}$$

$$\frac{b_f}{2t_f} = 6.0 < \frac{65}{\sqrt{F_y}} = 10.83 \quad \text{[Eq. 59.3]}$$

$$\frac{d}{t_w} = 46.4 < \frac{640}{\sqrt{F_y}} = 106.67 \quad \text{[Eq. 59.4]}$$

The shape is compact.

From the *AISC Manual*, Part 2, Allowable Stress Design Selection Table for W 18 × 55, $L_c = 7.9$ ft and $L_u = 12.1$ ft.

(a) The unbraced length is $L_b = 6$ ft.

Since $L_b < L_c$, the allowable bending stress is

$$F_b = 0.66F_y = (0.66)(36 \text{ ksi}) = 23.8 \text{ ksi}$$

Let w be the allowable superimposed load plus the beam weight in kips/ft. The bending moment is

$$M = \frac{wL^2}{8} = \frac{w(36 \text{ ft})^2}{8} = 162w \text{ ft-kips}$$

Then, the bending stress is

$$f_b = \frac{M}{S_x} = \frac{(162w)\left(12 \frac{\text{in}}{\text{ft}}\right)}{98.3 \text{ in}^3} = 19.78w$$

Equate the allowable bending stress to the actual bending stress.

$$23.8 \text{ ksi} = 19.78w$$
$$w = 1.203 \text{ kips/ft}$$

Subtract the beam's own weight.

$$\text{superimposed load} = 1.203 \frac{\text{kips}}{\text{ft}} - 0.055 \frac{\text{kip}}{\text{ft}}$$
$$= 1.148 \text{ kips/ft}$$

(b) The unbraced length is $L_b = 12$ ft.

Since $L_c < L_b < L_u$, the allowable bending stress is

$$F_b = 0.60F_y = (0.60)(36 \text{ ksi}) = 21.6 \text{ ksi}$$
$$21.6 \text{ ksi} = 19.78w$$
$$w = 1.092 \text{ kips/ft}$$

The superimposed load is

$$1.092 \frac{\text{kips}}{\text{ft}} - 0.055 \frac{\text{kip}}{\text{ft}} = 1.037 \text{ kips/ft}$$

(c) The unbraced length is $L_b = 18$ ft.

$L_b > L_u$, so the allowable bending stress is less than $0.60F_y$. Compute F_b.

$$\frac{l}{r_T} = \frac{(18 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{1.95 \text{ in}} = 110.8$$
$$C_b = 1.0$$

Use Eqs. 59.7 through 59.9.

$$F_b = \left(\frac{2}{3} - \frac{F_y\left(\frac{l}{r_T}\right)^2}{1530 \times 10^3 C_b}\right) F_y$$
$$= \left(\frac{2}{3} - \frac{(36 \text{ ksi})(110.8)^2}{(1530 \times 10^3)(1.0)}\right)(36 \text{ ksi})$$
$$= 13.60 \text{ ksi}$$

$$F_b = \frac{170 \times 10^3 C_b}{\left(\frac{l}{r_T}\right)^2}$$
$$= \frac{(170 \times 10^3)(1.0)}{(110.8)^2} = 13.85 \text{ ksi}$$

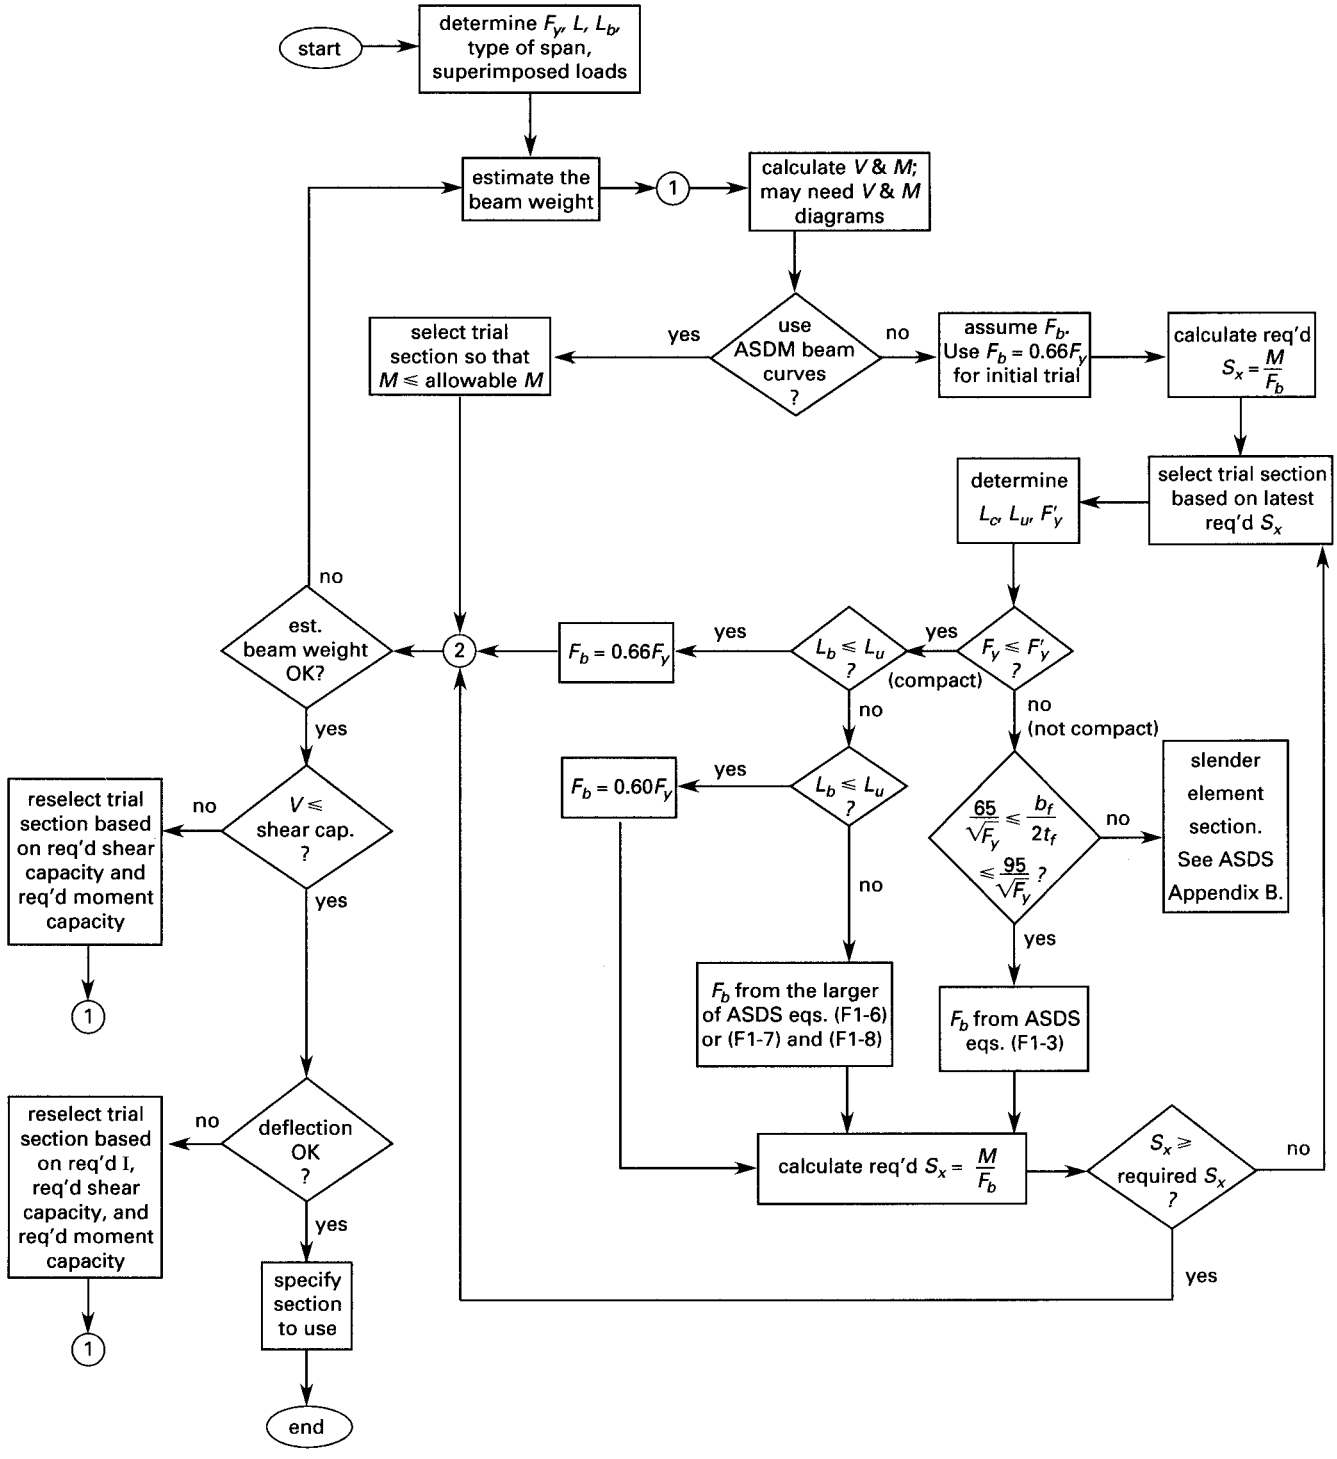
$$F_b = \frac{12 \times 10^3 C_b}{l\left(\frac{d}{A_f}\right)}$$
$$= \frac{(12 \times 10^3)(1.0)}{(18 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)(3.85 \text{ in}^{-1})} = 14.43 \text{ ksi}$$

F_b is the largest value, 14.43 ksi.

$$14.43 \text{ ksi} = 19.78w$$
$$w = 0.729 \text{ kip/ft}$$

The superimposed load is

$$0.729 \frac{\text{kip}}{\text{ft}} - 0.055 \frac{\text{kip}}{\text{ft}} = 0.674 \text{ kip/ft}$$



13. DESIGN OF STEEL BEAMS

Steel beams can be designed with either the *allowable stress method* (also known as the *working stress method* and the *elastic design method*) or the *plastic design method* (also known as the *load factor method* and the *ultimate strength design method*). Simple one-span beams are usually designed by the allowable stress method since there is no advantage to using plastic design. The *AISC Manual* provides three design aids for choosing beams: the Allowable Stress Design Selection Table, the Allowable Loads on Beams Table, and the Allowable Moments in Beams Chart. A flowchart for design of steel beams is given in Fig. 59.11.

Design Selection Table

The AISC Allowable Stress Design Selection Table is easy to use, and it provides a method for quickly selecting economical beams. Its use assumes that either the required section modulus, S, or the required resisting moment, M_R, is known, and one of these two criteria is used to select the beam. It is not used to check shear stress or deflection, and the designer must ensure that $L_b \leq L_c$.

Beams are grouped in the beam selection table. Within a group, the most economical shape is listed at the top in bold print. This is the beam that should generally be used, even if the moment-resisting capacity and section modulus are greater than necessary. The weight of the most economical beam will be less than the beam in the group that most closely meets the structural requirements. Care must be taken not to confuse the 50 ksi columns with the 36 ksi columns, and both steel strengths are listed in the table.

Figure 59.11 *Flowchart for Beam Design (W and M shapes—moment, shear, and deflection criteria)*

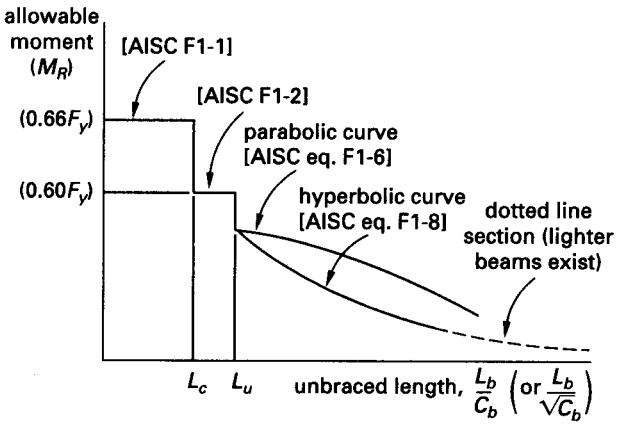
Allowable Loads Table

In the Allowable Loads on Beams Table, loads are tabulated for both $F_y = 36$ ksi and $F_y = 50$ ksi steels using $F_b = 0.66F_y$ for compact shapes and F_b (calculated from AISC ASD Eq. [F1-3]) $< 0.66F_y$ for noncompact shapes. Loads can be read directly from the table when $L_b \leq L_c$ for compact and noncompact W, M, and S shapes. When $L_u \geq L_b > L_c$, the tabulated loads must be reduced as follows. (a) For compact shapes, multiply the load by $0.60F_y/0.66F_y$. (b) For noncompact shapes, multiply the load by $0.60F_y/F_b$. If $L_b > L_u$, the table is not applicable.

The table is convenient for selecting laterally supported simple beams with equal concentrated loads spaced as shown in the *AISC Manual*, Part 2, Table of Concentrated Load Equivalents. Except for short spans where shear controls the design, the beam load table may be entered with an equivalent uniform load. Also listed in the table, among others, are values of maximum web shear V and the four constants R_1, R_2, R_3, and R_4, used to check local web yielding and web crippling.

Allowable Moments Chart

When the unbraced length L_b is greater than L_c, the Allowable Moments in Beams Chart should be used. The chart for 36 ksi steel can be used with unbraced lengths up to 108 ft. Each beam that is plotted on the chart is shown with a profile similar to that in Fig. 59.12.



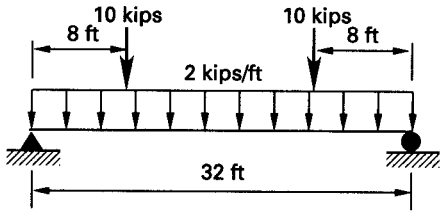


Figure 59.12 *Allowable Beam Moments*

The chart is entered knowing L_b and M_R. (An allowance for self-weight should be included when calculating M_R. When the unbraced length varies along the beam span, use the longest unbraced length.) The nearest solid line above the intersection of the L_b and M_R values is the most economical beam. Dotted line sections mean that a lighter beam exists that has the same capacity. As with the beam selection table, shear stress and deflection must still be checked.

The Allowable Moments Chart implicitly assumes $C_b = 1$, and this remains a conservative assumption. However, to achieve additional economy, the chart can be used with other values of C_b if either L_b/C_b or $L_b/\sqrt{C_b}$ is used instead of L_b. The proper replacement for L_b depends on the beam. Most beams are controlled by torsional strength, and Eq. 59.9 is applicable. In this case, the curved portion of the allowable moments chart will be hyperbolic (as shown in Fig. 59.12), and L_b is replaced by L_b/C_b. In other cases, the curved line in the Allowable Moments Chart will be parabolic, indicating that Eq. 59.7 is applicable. In this case, L_b is replaced with $L_b/\sqrt{C_b}$.

Example 59.2

Select the lightest W shape of A36 steel for the beam and loading shown. The load does not include the weight of the beam. Assume the compression flange is braced at the ends and at intervals of 8 ft. Consider moment, shear, and deflection. The maximum allowable deflection for the total load is $L/360$.

Solution

Design for moment.

$$M = \frac{wL^2}{8} + Pa$$

$$= \frac{\left(2\ \frac{\text{kips}}{\text{ft}}\right)(32\ \text{ft})^2}{8} + (10\ \text{kips})(8\ \text{ft})$$

$$= 336\ \text{ft-kips}$$

Assume the maximum bending stress applies.

$$F_b = 0.66F_y = (0.66)(36\ \text{ksi}) = 24\ \text{ksi}$$

The required section modulus is

$$S_x = \frac{M}{F_b} = \frac{(336\ \text{ft-kips})\left(12\ \frac{\text{in}}{\text{ft}}\right)}{24\ \text{ksi}} = 168\ \text{in}^3$$

From the Allowable Stress Design Selection Table, try W 24×76 (in boldface type).

$$S_x = 176\ \text{in}^3$$

$$M_R = 348\ \text{ft-kips}$$

$$L_c = 9.5\ \text{ft}$$

Structural

Check the additional moment due to the self-weight of the beam.

$$M = \frac{wL^2}{8} = \frac{\left(0.076\ \frac{\text{kip}}{\text{ft}}\right)(32\ \text{ft})^2}{8}$$
$$= 9.73\ \text{ft-kips}$$

The total moment is

$$M = 336\ \text{ft-kips} + 9.73\ \text{ft-kips}$$
$$= 346\ \text{ft-kips} < M_R = 348\ \text{ft-kips} \quad \text{[OK]}$$

Since $L_b = 8\ \text{ft} < L_c = 9.5\ \text{ft}$, the bracing is adequate and the assumed allowable stress of $0.66F_y$ is correct.

A check of the F_y' column shows a dash, indicating F_y' is greater than 65 ksi. Therefore, the shape is compact.

Check the shear.

For this beam, the maximum shear occurs at the support and is equal to the reaction.

$$V = \frac{wL + 2P}{2} = \frac{\left(2.076\ \frac{\text{kips}}{\text{ft}}\right)(32\ \text{ft}) + (2)(10\ \text{kips})}{2}$$
$$= 43.2\ \text{kips}$$

From the Allowable Uniform Load Table, the maximum permissible web shear for the W 24×76 is 152 kips.

$$43.2\ \text{kips} < 152\ \text{kips} \quad \text{[OK]}$$

Check the deflection.

From the shape tables of the *AISC Manual*, I_x for W 24×76 is 2100 in^4. The maximum allowable deflection is

$$\Delta = \frac{L}{360} = \frac{(32\ \text{ft})\left(12\ \frac{\text{in}}{\text{ft}}\right)}{360} = 1.07\ \text{in}$$

From the *AISC Manual*, Part 2, Beam Diagrams and Formulas, or from App. 44.A, the actual deflection is

$$\Delta = \frac{5wL^4}{384EI} + \frac{Pa(3L^2 - 4a^2)}{24EI}$$
$$= \frac{(5)\left(2.076\ \frac{\text{kips}}{\text{ft}}\right)(32\ \text{ft})^4\left(12\ \frac{\text{in}}{\text{ft}}\right)^3}{(384)\left(29{,}000\ \frac{\text{kips}}{\text{in}^2}\right)(2100\ \text{in}^4)}$$
$$+ \frac{(10\ \text{kips})(8\ \text{ft})\left(12\ \frac{\text{in}}{\text{ft}}\right)^3\left((3)(32\ \text{ft})^2 - (4)(8\ \text{ft})^2\right)}{(24)\left(29{,}000\ \frac{\text{kips}}{\text{in}^2}\right)(2100\ \text{in}^4)}$$
$$= 0.804\ \text{in} + 0.266\ \text{in}$$
$$= 1.07\ \text{in} \quad \text{[OK]}$$

14. PLASTIC DESIGN OF CONTINUOUS BEAMS

Plastic design, also known as *ultimate strength design*, is based on comparing a factored moment to the ultimate capacity of the beam. This design procedure should be used when the design must be in accordance with Chap. N of the *AISC Manual*. The design is accomplished without stress calculations. Plastic design is ideally suited to continuous beams and frames and is not normally used with single-span beams. It must not be used with noncompact shapes, crane runway rails, A514 steel, or steels with yield strengths in excess of 65 ksi. The basic procedure consists of the following steps.

step 1: Obtain the factored loading. (Additional terms are needed when wind and earthquake loads are present.)

$$\text{factored load} = 1.7 \times \text{dead load} + 1.7 \times \text{live load} \qquad 59.19$$

step 2: Based on the factored loading, calculate the maximum (plastic) moment, M_p. (This moment cannot be calculated from elastic moment diagrams.) See Fig. 59.13.

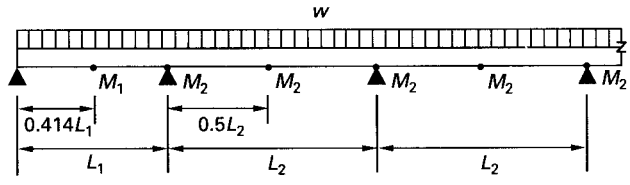

Figure 59.13 *Ultimate Moments on a Uniformly Loaded Continuous Beam (plastic hinges shown as •)*

step 3: If beam selection is to be made according to the required *plastic section modulus*, calculate Z_x.

$$Z_x = \frac{M_p}{F_y} \qquad 59.20$$

step 4: Use the Plastic Design Selection Table in the *AISC Manual* to select an economical beam. Use of this table is similar to that of the Allowable Stress Design Selection Table.

step 5: Check that the maximum factored shear based on plastic failure does not exceed the allowable shear (calculated from AISC ASD Eq. [N5-1]).

$$V_{\text{factored,max}} \le 0.55F_y t_w d \qquad 59.21$$

step 6: Specify web (intermediate) stiffeners at loading points where plastic hinges are expected.

step 7: Determine lateral bracing requirements. Compression flange support (lateral bracing)

is required at points where plastic hinges will form. In addition, the distance between points of lateral support must be less than or equal to laterally unsupported distances given by Eq. 59.22 ([N9-1]) and 59.23 ([N9-2]). (l_{cr} and r_y are both in inches for these two equations.)

$$\frac{l_{cr}}{r_y} = \frac{1375}{F_y} + 25 \quad \left[+1.0 > \frac{M}{M_p} > -0.5\right] \qquad 59.22$$

$$\frac{l_{cr}}{r_y} = \frac{1375}{F_y} \quad \left[-0.5 \geq \frac{M}{M_p} > -1.0\right] \qquad 59.23$$

r_y is the radius of gyration of the member about its weak axis as determined from the shape table. M is the smaller (absolute value) moment at the two ends of the unbraced segment. M_p is the maximum plastic moment on the span. M/M_p is positive when the segment is bent in reverse curvature (i.e., the moment diagram goes through zero) and negative when the segment is bent in single curvature.

Some easing of the l_{cr} distance is allowed for the last hinge to form in the failure mechanism, since having other hinges form is tantamount to having the beam in failure. However, normal bracing lengths for elastic design must still be met. The term *mechanism* (i.e., a mechanical device with its own joints and elbows) is used to describe each of the different ways that the beam can fail plastically. Each of the spans may experience hinges at different locations and/or loadings and thus represents a distinctly unique mechanism.

This procedure assumes that the Plastic Design Selection Table will be used and, therefore, compactness is assured. The procedure also omits thickness checks that must be performed when the beam carries axial loads in addition to transverse loads.

15. ULTIMATE PLASTIC MOMENTS

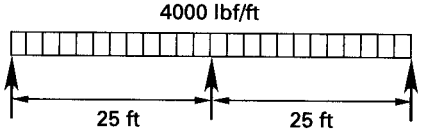
Step 2 requires calculating the maximum moment based on plastic theory. This moment is not the same as the moment determined from elastic theory. Table 59.1 can be used in a simple case to determine the ultimate moment, M_p. Locations of plastic hinges are also indicated in the table.

A uniformly loaded, continuous beam is a case that occurs frequently. The ultimate moments can be derived from the cases in Fig. 59.13. Both ultimate moments should be checked, since the interior hinges will form first if the span lengths are short. (The end span hinges will form first if all spans are the same length.)

$$M_1 = \left(\tfrac{3}{2} - \sqrt{2}\right) wL_1^2 \approx 0.0858wL_1^2 \qquad 59.24$$

$$M_2 = \frac{wL^2}{16} \qquad 59.25$$

16. ULTIMATE SHEARS



The ultimate shear in step 5 may or may not be the factored shear on the beam. The shear, by definition, is the slope of the moment diagram. In the case of a uniformly loaded beam with built-in ends, the effect of plastic failure is merely to move the baseline without changing the overall shape of the moment diagram. Since there is no change in the slope, the ultimate shear is merely the factored shear.

In the case of continuous beams, however, the effect of plastic failure will change the slope of the lines in the moment diagram. Graphical or analytical means can be used to obtain the maximum slope. For a uniformly loaded continuous beam as shown in Fig. 59.13, the maximum shear induced will be

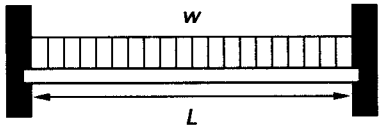
$$V_{max} = \frac{wL}{2} + \frac{M_{max}}{L} = 0.5858wL \qquad 59.26$$

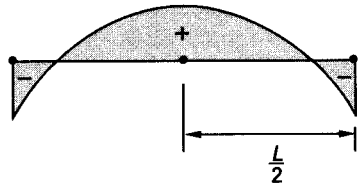
Example 59.3

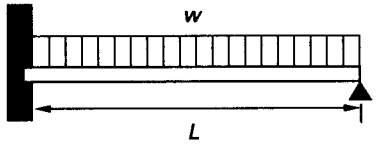
Use plastic design to select a W-shape beam (A36 steel) to support dead and live loads totaling 4000 lbf/ft over the beam shown. The beam is simply supported at all three points.

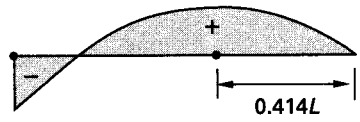
Solution

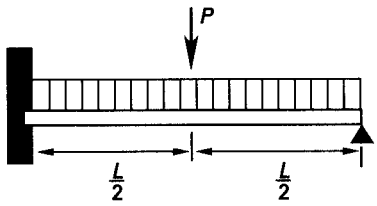
step 1: The factored load is

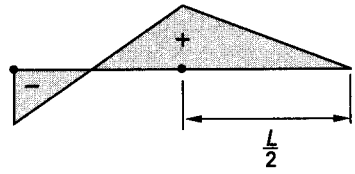


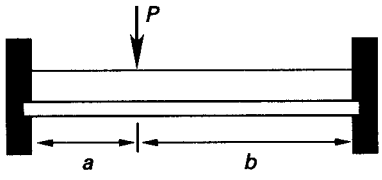


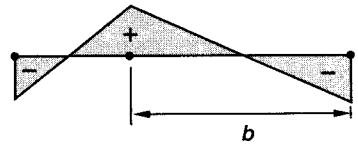


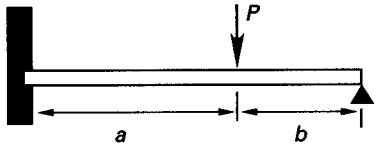


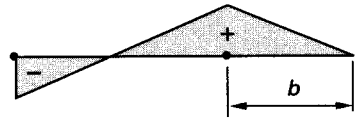












$$w = (1.7)\left(4000\ \frac{\text{lbf}}{\text{ft}}\right) = 6800\ \text{lbf/ft}$$

step 2: The maximum moment on an end-span of a uniformly loaded continuous beam is given in Table 59.1.

$$M_{max} = 0.0858wL^2 = (0.0858)\left(6800\ \frac{\text{lbf}}{\text{ft}}\right)(25\ \text{ft})^2 = 364{,}650\ \text{ft-lbf}$$

step 3: The selection can be made on the basis of required plastic moment. This step is skipped.

Table 59.1 *Maximum Plastic Moments (plastic hinges shown as •)*

loading	moment diagram and locations of plastic hinges	governing equations
		$M_{max} = \frac{wL^2}{16}$
		$M_{max} = 0.0858wL^2$
		$M_{max} = \frac{PL}{6}$
		$a + b = L$ $M_{max} = \frac{abP}{2L}$
		$a + b = L$ $M_{max} = \frac{abP}{L + b}$

step 4: Entering the Plastic Design Selection Table, a W 24×55 beam is chosen. The capacity is 402 ft-kips, which is more than required. However, this is the economical beam with a capacity exceeding the requirements.

step 5: The maximum shear on an end span of a uniformly loaded, continuous beam is given by Eq. 59.26.

$$\begin{aligned} V_{max} &= 0.5858wL \\ &= (0.5858)\left(6800\ \frac{\text{lbf}}{\text{ft}}\right)(25\ \text{ft}) \\ &= 99{,}586\ \text{lbf} \end{aligned}$$

From the AISC shape tables, $d = 23.57$ in and $t_w = 0.395$ in. The allowable shear is

$$\begin{aligned} V_{allowable} &= F_v A \\ &= (0.55)(36{,}000\ \text{psi})(0.395\ \text{in})(23.57\ \text{in}) \\ &= 184{,}341\ \text{lbf} \end{aligned}$$

Since $V_{max} < V_{allowable}$, shear is not a problem.

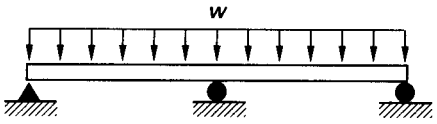
17. CONSTRUCTING PLASTIC MOMENT DIAGRAMS

There are several methods of determining the shape of the plastic moment diagram. Most of these methods are based on theory. The method presented here is

a semigraphical approach that can be used to quickly draw moment diagrams and locate points where plastic hinges will form.

step 1: Consider the beam as a series of simply supported spans.

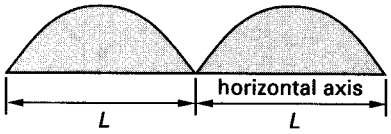
step 2: Draw the elastic bending moment on each span.



step 3: Construct the modified baseline. This is a jointed set of straight lines that meets the following conditions: (a) The baseline meets the horizontal axis at simply supported exterior ends. This is consistent with the requirement that the moment be zero at free and simply supported ends. (It is not necessary for the baseline to reach the horizontal axis at built-in ends. In fact, the moment is usually nonzero at such points.) (b) The slope of the baseline changes only at points of support. (c) The baselines for all spans connect at points of support. The baseline is located to minimize the maximum ordinate along the entire length of the beam (along all spans). Therefore, one span will control. (Do not consider the distance between the baseline and the horizontal axis when minimizing the maximum ordinate.)

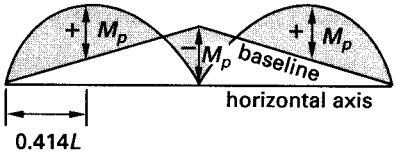
step 4: The maximum ordinate determines M_p.

step 5: Hinges form at points of maximum ordinates and wherever else required to support full rotation. The moments at hinges that form simultaneously are identical.



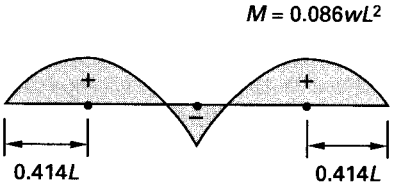
Example 59.4

Draw the plastic moment diagram for the uniformly loaded, two-span beam shown.



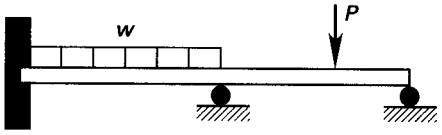
Solution

steps 1 and 2: The moment diagram of a simply supported, uniformly loaded single span is drawn twice.



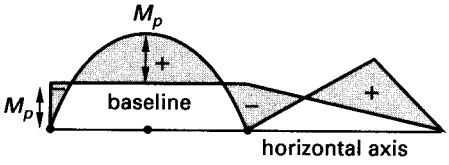
step 3: The modified baseline is chosen to minimize the distance between the curved line and the baseline.

step 4: The maximum ordinate is determined visually to be near the middle of the end spans.



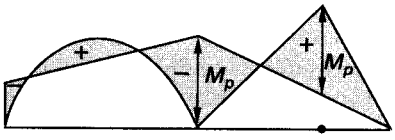
step 5: If hinges form near the middle of the end spans, a hinge must also form over the center support. Otherwise, the beam could not rotate in failure.

The final moment diagram is drawn by "straightening out" the modified baseline.



Example 59.5

Draw the plastic moment diagram for the beam shown.



Solution

Since the actual numerical loads are unknown, it is not possible to determine which of the two spans controls. If the left span controls, then three hinges must form simultaneously. This forces the baseline to be horizontal along the left span. The baseline along the right span is fixed by its end points.

If the right span controls, then two hinges must form simultaneously. The moments at these two hinge points are equal. The baseline along the left span is chosen to minimize the positive and negative ordinates.

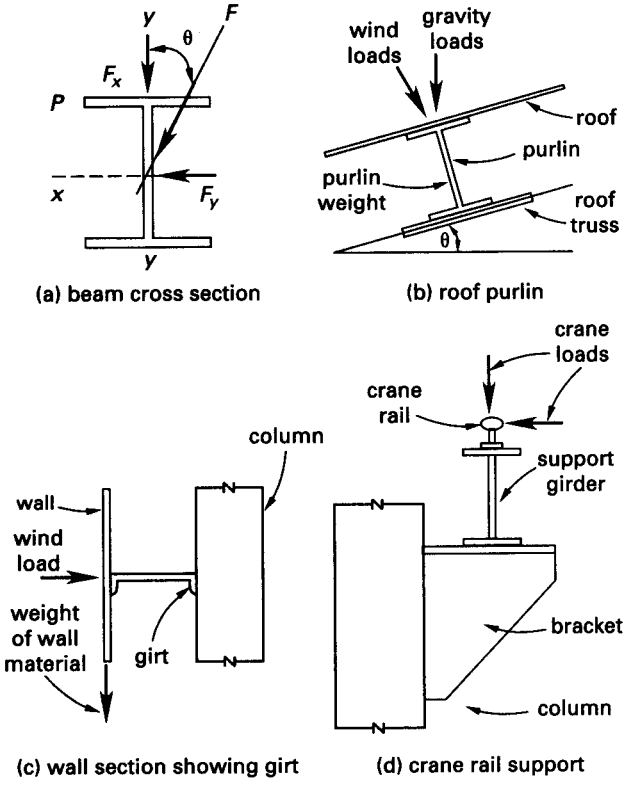
Structural

18. UNSYMMETRICAL BENDING

Typically, a wide-flange beam is oriented with its web in the plane of the loading (i.e., the plane of the weak axis), and the bending is said to occur about the strong axis or the x-x axis of beam cross section. The x-x and y-y axes of a beam cross section are known as the *principal axes* for which the product of inertia is zero. A beam is said to be subjected to *unsymmetrical bending* when bending occurs about an axis other than one of the principal axes. When the applied loads are not in a plane with either of the principal axes or when loads are simultaneously applied from more than one direction, unsymmetrical bending (also called *biaxial bending*) is the result.

There are two categories of unsymmetrical bending: (a) loads applied through the shear center and (b) loads not applied through the shear center. The *shear center* of a cross section is that point through which the loads must act if there is to be no twisting (torsion) of the beam. The location of the shear center is determined from principles of mechanics of materials by equating the internal resisting torsional moment to the external torque. For a wide-flange section, however, the shear center and the centroid are the same point. In either case, an appropriate interaction equation is used for design or analysis purpose.

In category 1, the load applied through the shear center may be resolved into two mutually perpendicular components along the principal (x-x and y-y) axes. Thus, referring to Fig. 59.14(a) where θ is the angle between the applied load F and the y-y axis, the components of F are $F_x = F\cos\theta$ and $F_y = F\sin\theta$. The moments M_x and M_y about the principal axes are computed from F_x and F_y, respectively. (Note: The force F_x creates a moment about the x-x axis and F_y creates a moment about the y-y axis.) The stresses due to moments M_x and M_y are computed separately for bending about each axis as: $f_{bx} = M_x/S_x$ and $f_{by} = M_y/S_y$.



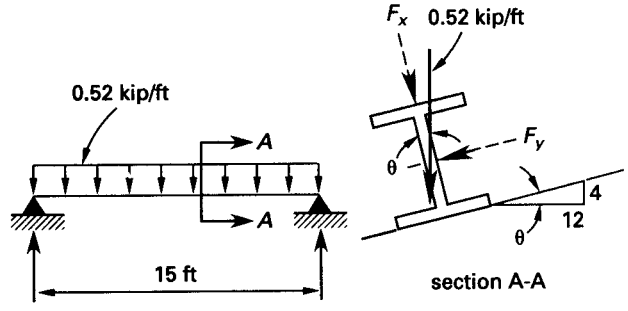
Finally, to check the adequacy of a section, Eq. 59.27 (corresponding to the interaction equation [H1-3]), which serves as the design criterion since the allowable bending stresses with respect to the x-x and y-y axes are different, is used.

$$\frac{f_a}{F_a} + \frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \leq 1.0 \qquad 59.27$$

Since the axial stress for a beam in pure bending is zero, the first term of the equation drops out and the equation becomes

$$\frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \leq 1.0 \qquad 59.28$$

Since loads are frequently applied from different directions on the top flange, category 2 (where load does not pass through the shear center) is a common occurrence. The top flange alone is assumed to resist the lateral force component. For a typical wide-flange shape, the section modulus of the top flange is approximately equal to $S_y/2$, and the stress due to bending about the y-y axis becomes $f_{by} = 2M_y/S_y$.



Source: *Applied Structural Steel Design*, 3rd ed., by Spiegel/Limbrunner, copyright © 1997. Reprinted by permission of Prentice-Hall, Inc., Upper Saddle River, NJ.

Figure 59.14 *Cases of Unsymmetrical Bending*

Example 59.6

A W 8×21 beam of A36 steel is used as a roof purlin on a simple span of 15 ft. The roof slope is 4:12. The beam carries a uniformly distributed gravity load of 0.50 kip/ft that passes through the centroid of the section. Assuming that the beam has full lateral support provided by the roofing above, check the adequacy of the section.

Solution

Properties of W 8×21 are $S_x = 18.2 \text{ in}^3$ and $S_y = 3.71 \text{ in}^3$. With a weight per foot of 21 lbf, the uniform gravity load is $w = 0.52$ kip/ft.

Resolve the load into its components.

$$\theta = \tan^{-1}\left(\frac{4}{12}\right) = 18.4^\circ$$

$$w_x = w\cos\theta = \left(0.52\ \frac{\text{kip}}{\text{ft}}\right)\cos 18.4^\circ = 0.49 \text{ kip/ft}$$

$$w_y = w\sin\theta = \left(0.52\ \frac{\text{kip}}{\text{ft}}\right)\sin 18.4^\circ = 0.16 \text{ kip/ft}$$

Compute the moments.

$$M_x = \frac{w_x l^2}{8} = \frac{\left(0.49\ \frac{\text{kip}}{\text{ft}}\right)(15 \text{ ft})^2}{8}$$
$$= 13.8 \text{ ft-kips}$$

$$M_y = \frac{w_y l^2}{8} = \frac{\left(0.16\ \frac{\text{kip}}{\text{ft}}\right)(15 \text{ ft})^2}{8}$$
$$= 4.5 \text{ ft-kips}$$

Compute the actual bending stresses.

$$f_{bx} = \frac{M_x}{S_x} = \frac{(13.8 \text{ ft-kips})\left(12\ \frac{\text{in}}{\text{ft}}\right)}{18.2 \text{ in}^3}$$
$$= 9.1 \text{ ksi}$$

$$f_{by} = \frac{M_y}{S_y} = \frac{(4.5 \text{ ft-kips})\left(12\ \frac{\text{in}}{\text{ft}}\right)}{3.71 \text{ in}^3}$$
$$= 14.55 \text{ ksi}$$

Determine the allowable stresses.

For bending about the x-x axis, since the beam has full lateral support,

$$F_{bx} = 0.66F_y = (0.66)(36 \text{ ksi}) = 24 \text{ ksi}$$

For bending about the y-y axis,

$$F_{by} = 0.75F_y = (0.75)(36 \text{ ksi}) = 27 \text{ ksi}$$

Check the interaction equation, Eq. 59.28.

$$\frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \le 1$$

$$\frac{9.1 \text{ ksi}}{24 \text{ ksi}} + \frac{14.56 \text{ ksi}}{27 \text{ ksi}} = 0.92 < 1.0 \quad \text{[OK]}$$

Therefore, the W 8×21 section is adequate.

19. BRIDGE CRANE MEMBERS

A bridge crane member is a beam that carries a set of moving loads that remain equidistant as they travel across the beam. For a simply supported beam, (a) the absolute maximum moment occurs under one of the concentrated loads when that load and the resultant of the set of loads are equidistant from the centerline of the beam, and (b) the absolute maximum shear will occur just next to one of the supports when the load group is placed such that the resultant is at a minimum distance from the support.

Two other factors that are usually taken into consideration in the design of bridge crane members are fatigue and impact loading (see Chap. 58).

20. HOLES IN BEAMS

Beams are usually found as components of a structural system and not as isolated members. Therefore, they must be connected to other structural members. If such connections are made with bolts, holes are punched or drilled in the web or flanges of the beam. In addition, to provide space for utilities such as electrical conduits and ventilation ducts, sometimes relatively large holes are cut in the beam webs. Thus, holes in a beam occur commonly and result in capacity reduction. Two such reductions are recognized: (a) holes in beam webs reduce the shear capacity, and (b) holes in beam flanges reduce the moment capacity. In general, web holes should be located at sections of low shear and centered on the neutral axis to avoid high bending stresses, and the flange holes should be located at sections of low bending moment.

The effect of flange holes is to reduce the moment of inertia, and hence, reduce moment capacity. The reduced moment of inertia is based upon the effective tension flange area given by AISC ASD Eq. [B10-3].

21. BEAM BEARING PLATES

Not all beams are supported through connections to other structural steel members (e.g., beams or columns). Some beams are supported by bearing on concrete or masonry members, such as walls or pilasters. Since masonry and concrete are weaker than steel, the beam reaction must be distributed over a large enough area to keep the average bearing pressure on concrete or masonry within allowable limits. A *bearing plate* is used for this purpose.

The design of a bearing plate is based on the following criteria. (a) It must be long enough so that local web yielding or web crippling of the beam does not occur. (b) It must be large enough to ensure the actual bearing pressure, f_p, under the plate does not exceed the allowable bearing pressure, F_p. (c) It must be thick enough so that the bending stress in the plate at the assumed critical section is within the limit of allowable bending stress, $F_b = 0.75F_y$.

A procedure for the design of beam bearing plates on concrete supports is given in *AISC Manual*, Part 2. The required bearing plate area A_1 is obtained, based on the allowable bearing pressure F_p for masonry or concrete from the *AISC Manual*, Sec. J9. For a plate covering the full area of a concrete support,

$$A_1 = \frac{R}{0.35f'_c} \qquad 59.29$$

For a plate covering less than the full area of a concrete support, the area of steel concentrically bearing on a concrete support is given by Eq. 59.30. Area A_2 is the maximum area of the portion of the supporting surface that is geometrically similar to and concentric with the loaded area.

$$A_1 = \left(\frac{1}{A_2}\right)\left(\frac{R}{0.35f'_c}\right)^2 \qquad 59.30$$

The minimum bearing length, N (in inches), is obtained as the larger of the two values, using Eqs. 59.31 and 59.32 (corresponding to *AISC Manual* Eqs. [K1-3] and [K1-5]), based on local web yielding and web crippling criteria, respectively.

$$N = \frac{R - R_1}{R_2} \qquad 59.31$$

$$N = \frac{R - R_3}{R_4} \qquad 59.32$$

After establishing the bearing length, N, the width, B, is obtained as

$$B = \frac{A_1}{N} \qquad 59.33$$

The pressure developed under the plate, f_p, is assumed to be uniform and is calculated as

$$f_p = \frac{R}{BN} \qquad 59.34$$

The cantilever dimension n is determined from

$$n = \frac{B}{2} - k \qquad 59.35$$

The thickness, t, is

$$t = \sqrt{\frac{3f_p n^2}{F_b}} \qquad 59.36$$

From the *AISC Manual*, Sec. F2, the allowable bending stress for rectangular plates is the same as for weak-axis bending: $F_b = 0.75F_y$.

Example 59.7

A W 21×68 beam is supported on a 12 in thick concrete wall ($f'_c = 3500$ lbf/in^2). The beam reaction is 68 kips, and the length of bearing is limited to 8 in, considering a minimum edge distance of 2 in. Both the beam and the plate are A36 steel. Design the bearing plate.

Solution

From the *AISC Manual*, Allowable Loads on Beams Table, $R_1 = 36.7$ kips, $R_2 = 10.2$ kips/in, $R_3 = 47.6$ kips, and $R_4 = 3.36$ kips/in.

$$N = \frac{68 \text{ kips} - 36.7 \text{ kips}}{10.2 \dfrac{\text{kips}}{\text{in}}}$$

$$= 3.07 \text{ in} < 8 \text{ in} \quad \text{[OK]}$$

$$N = \frac{68 \text{ kips} - 47.6 \text{ kips}}{3.36 \dfrac{\text{kips}}{\text{in}}}$$

$$= 6.07 \text{ in} < 8 \text{ in} \quad \text{[OK]}$$

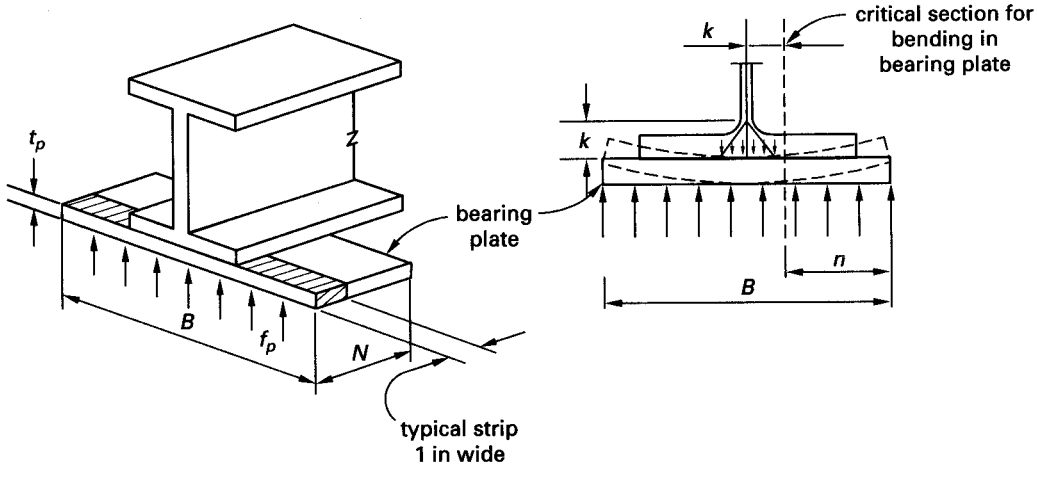


Figure 59.15 *Nomenclature for Beam Bearing Plate*

Conservatively estimate A_1.

$$A_1 \text{ (required)} = \frac{68 \text{ kips}}{(0.35)\left(3.5 \frac{\text{kips}}{\text{in}^2}\right)} = 55.5 \text{ in}^2$$

This requires a width of

$$B = \frac{55.5 \text{ in}^2}{8 \text{ in}} = 6.94 \text{ in} \quad \text{[say 7 in]}$$

But, for a W 21×68, the flange width is $b_f = 8.27$ in, so use $B = 10$ in.

The area of concrete support is

$$A_2 = \big(8 \text{ in} + (2)(2 \text{ in})\big)\big(10 \text{ in} + (2)(2 \text{ in})\big) = 168 \text{ in}^2$$

Recalculate.

$$A_1 \text{ (required)} = \left(\frac{1}{168 \text{ in}^2}\right)\left(\frac{68 \text{ kips}}{(0.35)\left(3.5 \frac{\text{kips}}{\text{in}^2}\right)}\right)^2$$
$$= 18.34 \text{ in}^2 < 55.5 \text{ in}^2$$

Try $N = 6$ in. The area of concrete support is

$$A_2 = \big(6 \text{ in} + (2)(2 \text{ in})\big)\big(10 \text{ in} + (2)(2 \text{ in})\big) = 140 \text{ in}^2$$

$$A_1 \text{ (required)} = \left(\frac{1}{140 \text{ in}^2}\right)\left(\frac{68 \text{ kips}}{(0.35)\left(3.5 \frac{\text{kips}}{\text{in}^2}\right)}\right)$$
$$= 22.0 \text{ in}^2 < 55.5 \text{ in}^2$$

Therefore, 6 in bearing length is adequate. The actual area is

$$A_1 = (6 \text{ in})(10 \text{ in}) = 60 \text{ in}^2$$

For W 21×68, $k = 1.44$ in. The plate cantilever dimension is

$$n = \frac{10 \text{ in}}{2} - 1.44 \text{ in} = 3.56 \text{ in}$$

The bending stress is limited to

$$F_b = 0.75F_y = (0.75)\left(36 \frac{\text{kips}}{\text{in}^2}\right) = 27 \text{ kips/in}^2$$

The actual bearing pressure is

$$f_p = \frac{68 \text{ kips}}{60 \text{ in}^2} = 1.133 \text{ kips/in}^2$$

From Eq. 59.36, the plate thickness is

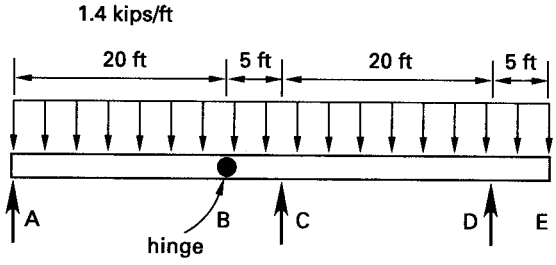
$$t = \sqrt{\frac{3f_p n^2}{F_b}}$$
$$= \sqrt{\frac{(3)\left(1.133 \frac{\text{kips}}{\text{in}^2}\right)(3.56 \text{ in})^2}{27 \frac{\text{kips}}{\text{in}^2}}}$$
$$= 1.263 \text{ in} \quad \text{[use } 1\tfrac{3}{8} \text{ in thick plate]}$$

The bearing plate is 1⅜ × 6 × 10.

PRACTICE PROBLEMS

1. A 25 ft beam of A36 steel is simply supported at its left end and 7 ft from its right end. A load of 3000 lbf/ft is uniformly distributed over its entire length. Lateral support is provided only at the reactions. Choose an economical W shape for this application. (Do not check shear stress.)

Answer: W 14 × 43



2. A beam spans 24 ft and has a deflection limited to $L/300$. The compression flange has complete lateral bracing. The beam carries a uniformly distributed load of 800 lbf/ft over its entire length, excluding the beam's self-weight. Select an economical A36 W shape.

Answer: W 14 × 26

3. Select an A36 W shape with lateral support at 5½ ft intervals to span 20 ft and carry a uniformly distributed load of 1 kip/ft. The load includes a uniform dead load allowance of 40 lbf/ft. The maximum deflection is limited to $L/240$.

Answer: W 14 × 22

4. (*Time limit: one hour*) The steel beam shown carries a load of 1.4 kips/ft, excluding self-weight, over its entire span. Assume lateral bracing only at the reaction points.

(Disregard the weight of the beam in the following questions.)

(a) The reaction at A is most nearly
(A) 12 kips
(B) 14 kips
(C) 16 kips
(D) 18 kips

The answer is (B).

(b) The reaction at C is most nearly
(A) 36 kips
(B) 37 kips
(C) 39 kips
(D) 42 kips

The answer is (C).

Structural

(c) The reaction at D is most nearly
(A) 13 kips
(B) 18 kips
(C) 19 kips
(D) 22 kips

The answer is (B).

(d) The absolute maximum value of shear is most nearly
(A) 12 kips
(B) 14 kips
(C) 18 kips
(D) 21 kips

The answer is (D).

(e) The absolute maximum shear occurs closest to
(A) support A
(B) hinge B
(C) support C
(D) support D

The answer is (C).

(f) The absolute maximum value of moment is most nearly
(A) 70 ft-kips
(B) 79 ft-kips
(C) 88 ft-kips
(D) 98 ft-kips

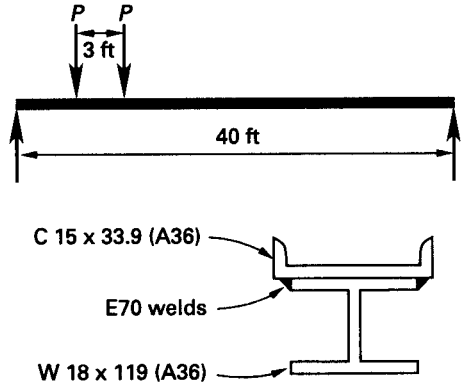
The answer is (C).

(g) The absolute maximum moment occurs
(A) halfway between A and B
(B) at support C
(C) halfway between C and D
(D) at support D

The answer is (B).

(h) Considering the unbraced length $L_b = 25$ ft, what is the lightest W 18 section of A36 steel that can be used from a consideration of the moments?
(A) W 18×76
(B) W 18×65
(C) W 18×60
(D) W 18×55

The answer is (C).



(i) For the lightest beam chosen in part (h), the actual maximum shear stress (ignoring the weight of the beam) is most nearly
(A) 2.0 ksi
(B) 2.4 ksi
(C) 2.8 ksi
(D) 3.4 ksi

The answer is (C).

(j) If the beam chosen in part (h) is constructed of 42 ksi steel, the maximum unbraced length that permits the development of $0.66F_y$ bending stress is most nearly
(A) 78 in
(B) 84 in
(C) 89 in
(D) 96 in

The answer is (C).

5. (*Time limit: one hour*) A beam is constructed from a W shape and a C shape, both of A36 steel, as shown. Two equal loads remain 3 ft apart as they move across a 40 ft span. Sufficient lateral support is provided so that the allowable bending stress is $0.6F_y$. The beam is not subjected to impact loading.

(a) The distance of the neutral axis of the beam cross section measured from the bottom of the section is most nearly
(A) 10.0 in
(B) 11.7 in
(C) 12.3 in
(D) 12.9 in

The answer is (B).

(b) The distance to the extreme compression fiber from the neutral axis is most nearly
(A) 10.7 in
(B) 11.3 in
(C) 12.0 in
(D) 12.4 in

The answer is (A).

(c) The distance to the extreme tension fiber from the neutral axis is most nearly
(A) 11.0 in
(B) 11.7 in
(C) 12.3 in
(D) 12.9 in

The answer is (B).

(d) The moment of inertia of the section (strong-axis bending) is most nearly

(A) 1950 in^4
(B) 2390 in^4
(C) 2960 in^4
(D) 3160 in^4

The answer is (C).

(e) For maximum moment to occur in the beam, the position of the loads will be such that their resultant will be located at a distance (measured from the left support) equal to

(A) 18.8 ft
(B) 19.3 ft
(C) 19.8 ft
(D) 20.0 ft

The answer is (B).

(f) The maximum moment obtained as a function of each unknown moving load of P (in kips) is most nearly

(A) 16.0P ft-kips
(B) 17.1P ft-kips
(C) 18.5P ft-kips
(D) 19.1P ft-kips

The answer is (C).

(g) Considering moment only, the maximum allowable value of P is most nearly

(A) 24.6 kips
(B) 25.3 kips
(C) 25.8 kips
(D) 26.5 kips

The answer is (A).

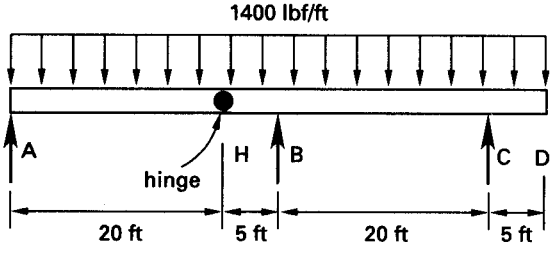
(h) The absolute maximum value of the actual shear stress (anywhere in the beam) corresponding to the value of P obtained in part (g) is most nearly

(A) 3.3 ksi
(B) 3.8 ksi
(C) 4.5 ksi
(D) 5.1 ksi

The answer is (B).

(i) The minimum beam bearing length required at the reaction point from local web yielding criteria is most nearly

(A) less than zero
(B) 0.60 in
(C) 1.1 in
(D) 2.3 in



The answer is (A).

(j) The minimum beam bearing length required at the reaction point from web crippling criteria is most nearly

(A) less than zero
(B) 0.65 in
(C) 1.0 in
(D) 2.2 in

The answer is (A).

6. An A36 steel beam is loaded as shown. Lateral support is provided only at the three reaction points. The beam carries a uniform load of 1400 lbf/ft over its entire span. (a) Determine the reactions. (b) Draw the shear and moment diagrams. (c) Choose the lightest W 14 beam that is capable of developing a bending stress of $0.60F_y$. (d) Specify the maximum unbraced length for the beam chosen.

Answers: (a) 14,000 lbf, 38,500 lbf, 17,500 lbf; (c) W 14×74; (d) 25.9 ft

1. INTRODUCTION

Tension members occur in a variety of structures including bridge and roof trusses, transmission towers, wind bracing systems in multistoried buildings, and suspension and cable-stayed bridges. Wire cables, rods, eyebars, structural shapes, and built-up members are typically used as tension members.

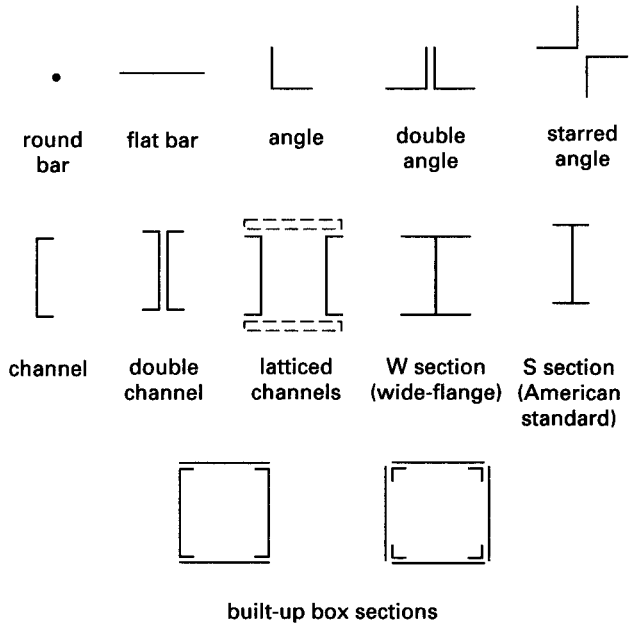

Figure 60.1 *Common Tension Members*

2. AXIAL TENSILE STRESS

Tension members are designed such that the average axial stress does not exceed the allowable value. The average tensile stress, f_t, in an axially loaded tension member is given by Eq. 60.1. The cross-sectional area, A, normal to the load can be a gross area, a net area, or an effective net area, depending on the situation.

$$f_t = \frac{P}{A} \qquad 60.1$$

3. GROSS AREA

The gross area A_g is the original unaltered cross-sectional area of the member. The gross area for the plate shown in Fig. 60.2 is

$$A_g = bt \qquad 60.2$$

4. NET AREA

Plates and shapes are connected to other plates and shapes by means of welds, rivets, and bolts. If rivets or

bolts are used, holes must be punched or drilled in the member. As a result, the member's cross-sectional area at the connection is reduced. The load-carrying capacity of the member may also be reduced, depending on the size and location of the holes. The *net area* actually available to resist tension is illustrated in Fig. 60.2(b).

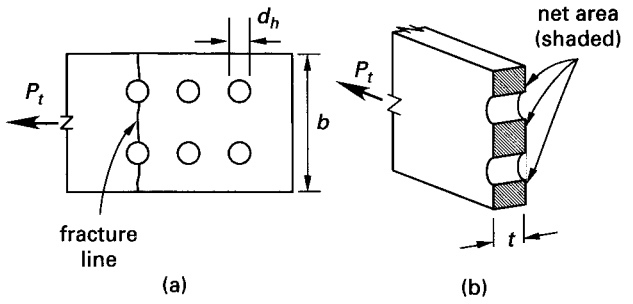

Figure 60.2 *Tension Member with Holes*

In a multiconnector connection, the *gage spacing*, g, is the lateral center-to-center spacing of two adjacent holes perpendicular to the direction of the applied load. The *pitch spacing*, s, is the longitudinal spacing of any two adjacent holes in the direction for the applied load.

When space limitations (such as a limit on dimension x in Fig. 60.3(a) or odd connection geometry as in Fig. 60.3(b)) make it necessary to use more than one row of fasteners, the reduction in cross-sectional area can be minimized by using a staggered arrangement of fasteners. For multiple rows of fasteners (staggered or not) at a connection, more than one potential fracture line may exist. For each possible fracture line, the net width, b_n, is calculated by subtracting the hole diameters, d_h, in the potential failure path from the gross width, b, and then adding a correction factor $s^2/4g$ for each diagonal leg in the failure path. (There is one diagonal leg BC in the failure path ABCD in Fig. 60.3(c). Thus, the term $s^2/4g$ would be added once.)

$$b_n = b - \sum d_h + \sum \frac{s^2}{4g} \qquad 60.3$$

Punched bolt holes should be $^1/_{16}$ in larger than nominal fastener dimensions. (This is sometimes referred to as a *standard hole*.) However, due to difficulties in producing uniform punched holes in field-produced assemblies, another $^1/_{16}$ in should be added to the hole diameter [AISC Specification B2]. Thus, the hole diameter, d_h, in Eq. 60.3 is taken as the fastener diameter d plus $^1/_8$ in.

For members of uniform thickness (e.g., plates), the net area A_n is calculated as the net width b_n times the thickness t.

$$A_n = b_n t \qquad 60.4$$

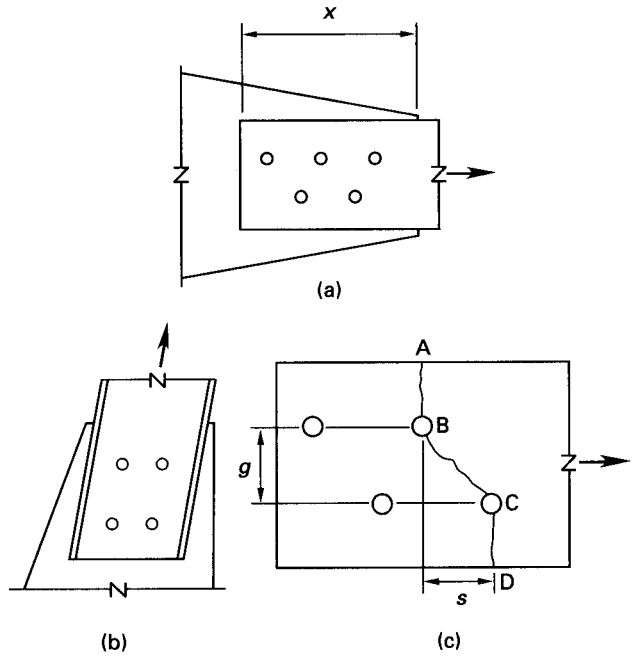

Figure 60.3 *Tension Members with Staggered Holes*

For members of nonuniform thickness (e.g., channels), sometimes the more useful formula for net area A_n is as follows.

$$A_n = A_g - \sum d_h t + \left(\frac{\sum s^2}{4g}\right) t \qquad 60.5$$

The *critical net area* is the net area having the least value. It is obtained by checking all possible failure paths. For example, in Fig. 60.3(c), paths ABCD and ABE must both be checked. In Fig. 60.4, where the number of bolts is not the same in all rows, both paths ABDE and ABCDE must be checked.

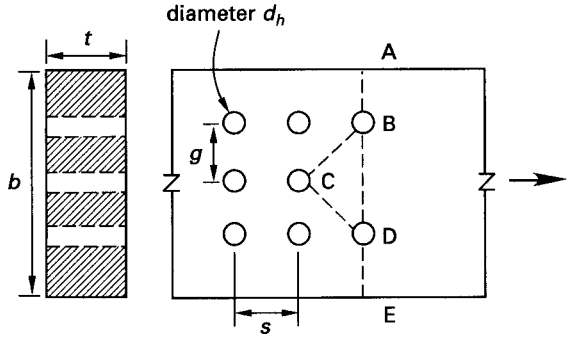

Figure 60.4 *Tension Member with Uniform Thickness*

If connectors in a tension lap splice are arranged in two or more unstaggered rows and if the rows have unequal numbers of fasteners, each fracture line should be checked for tension capacity assuming that the previous fracture lines have absorbed a proportionate share of the load. For example, if three bolts are arranged in two rows—one row with two bolts and the next row

with one bolt—the net section of the first fracture line (the width less two bolt diameters) should be checked for tension capacity with two-thirds of the total applied load.

5. EFFECTIVE NET AREA

When a tension member frames into a supporting member, some of the load-carrying ability will be lost unless all connectors are in the same plane and all elements of the tension member are connected to the support. (An angle connected to its support only by one of its legs is a case in which load-carrying ability would be lost.) A reduction coefficient, U, is used to calculate the effective net area. U can be taken as 1.0 if all cross-sectional elements are connected to the support to transmit the tensile force. When the load is transmitted by bolts through only some of the cross-sectional elements of the tension member, the *effective net area*, A_e, is computed from Eq. 60.6 [AISC Specification B3-1]. U takes on values of 0.90, 0.85, or 0.75 as shown in Table 60.1.

$$A_e = UA_n \qquad 60.6$$

Table 60.1 *Reduction Coefficient (U) Values for Bolted Connections*

a. For W, M, or S shapes with flange widths not less than two thirds of the depth, and for structural tees cut from these shapes (provided the connection is to the flanges) with three or more fasteners per line in the direction of stress): $U = 0.90$.

b. For W, M, or S structural shapes not meeting the conditions of subparagraph (a), structural tees cut from these shapes, and all other shapes, including built-up cross sections, with three or more fasteners per line in the direction of stress: $U = 0.85$.

c. For all members with at least two fasteners per line in the direction of stress: $U = 0.75$.

Source: AISC Specification B3

When the load is transmitted by welds through only some of the cross-sectional elements of the member, the effective net area, A_e, shall be computed from Eq. 60.7 [AISC Specification B3-2]. U takes on the values in Table 60.1, except that subparagraph (c) is not applicable.

$$A_e = UA_g \qquad 60.7$$

AISC Specification B3 furnishes two special cases of welded connection.

a. When a load is transmitted by transverse welds to some but not all of the cross-sectional elements of W, M, or S shapes and structural tees cut from these shapes, the effective net area A_e shall be taken as the area of the directly connected elements.

b. When a load is transmitted to a plate by longitudinal weld along both edges at the end of the plate, the length of each weld shall not be less than the width of the plate. The effective net area A_e shall be computed by Eq. 60.7, where $U = 1.0$, 0.87, or 0.75 as shown in Table 60.2.

Table 60.2 *Reduction Coefficient (U) Values for Welded Connections*[a]

$l > 2w$	$U = 1.0$
$2w > l > 1.5w$	$U = 0.87$
$1.5w > l > w$	$U = 0.75$

[a] l = weld length, in; w = plate width (distance between welds), in

Source: AISC Specification B3

In addition to the reduction in the net area by U, the effective net area for splice and gusset plates must not exceed 85% of the gross area, regardless of the number of holes. Tests have shown that as few as one hole in a plate will reduce the strength of a plate by at least 15%. It is a good idea to limit the effective net area to 85% of the gross area for all connections (not just splices and gusset plates) with holes in plates.

6. ALLOWABLE TENSILE STRESS

The allowable tensile stress, F_t, must not exceed $0.60F_y$ on the gross area or $0.50F_u$ on the effective net area [AISC Specification D1]. The two values are based upon two possible failure modes of the member: excessive elongation (or yielding) and fracture.

7. BLOCK SHEAR STRENGTH

For tension members, another possible failure mode exists. In this mode, a segment or "block" of material at the end of the member tears out as shown in Fig. 60.5. Depending on the connection at the end of a tension member, such *block shear* failure can occur in either the tension member itself or in the member to which it is attached (e.g., a gusset plate). Block shear failure represents a combination of two failures—a shear failure along a plane through the bolt holes or welds and a tension failure along a perpendicular plane—occurring simultaneously.

Block shear strength, P_t, is computed from Eq. 60.8. A_v is the net shear area, F_v is the allowable shear stress, A_t is the net tension area, and F_t is the allowable tensile stress. The allowable stresses F_v and F_t are obtained from Eq. 60.9 [AISC Specification J4-1] and 60.10 [AISC Specification J4-2], respectively.

$$P_t = A_vF_v + A_tF_t \qquad 60.8$$

$$F_v = 0.30F_u \qquad 60.9$$

$$F_t = 0.50F_u \qquad 60.10$$

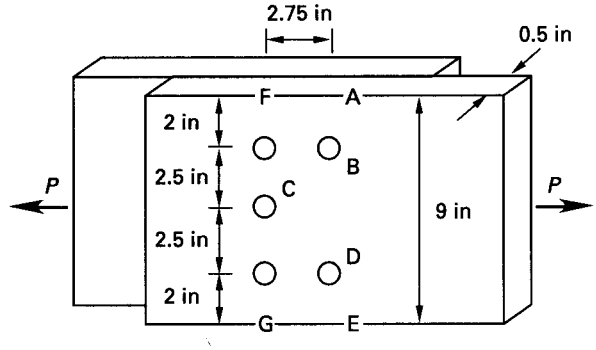
Figure 60.6 *Flowchart for Analysis of Tension Members*

8. SLENDERNESS RATIO

Where structural shapes are used in tension, AISC Specification B-7 lists a preferred (but not required) maximum slenderness ratio of 300. Rods and wires are excluded from this recommendation.

9. ANALYSIS OF TENSION MEMBERS

The analysis of a tension member is essentially the determination of its tensile capacity P_t as the smallest of the three values obtained from Eqs. 60.11, 60.12, and 60.13. A flowchart for tension member analysis is shown in Fig. 60.6.



$$P_t = 0.60F_yA_g \quad \text{[yielding]} \qquad 60.11$$

$$P_t = 0.50F_uA_e \quad \text{[fracture]} \qquad 60.12$$

$$P_t = 0.30F_uA_v + 0.50F_uA_t \quad \text{[block shear]} \qquad 60.13$$

Example 60.1

A long tensile member is constructed by connecting two plates as shown. Each plate is 1/2 in × 9 in. A36 steel with an ultimate strength of 58 ksi is used. The fasteners are 1/2 in diameter bolts and determine the maximum tensile load the connection can support. Disregard the shear strength of the bolts and disregard eccentricity.

Solution

The gross area of the plate is

$$A_g = (0.5 \text{ in})(9 \text{ in}) = 4.5 \text{ in}^2$$

The effective hole diameter includes 1/8 in allowance for clearance and manufacturing tolerances.

$$d = 0.5 \text{ in} + 0.125 \text{ in} = 0.625 \text{ in}$$

The net area of the connection must be evaluated in three ways: paths ABDE, ABCDE, and FCG. Path ABDE does not have any diagonal runs. The net area is given by Eq. 60.5.

$$A_{n,\text{ABDE}} = (0.5 \text{ in})\left(9 \text{ in} - (2 \text{ holes})\left(0.625 \frac{\text{in}}{\text{hole}}\right)\right)$$

$$= 3.875 \text{ in}^2$$

To determine the net area of path ABCDE, the quantity $s^2/4g$ must be calculated. The *pitch*, s, is shown as 2.75 in, and the *gage*, g, is shown as 2.5 in.

$$\frac{s^2}{4g} = \frac{(2.75 \text{ in})^2}{(4)(2.5 \text{ in})} = 0.756 \text{ in}$$

The net area of path ABCDE is

$$\begin{aligned} A_{n,\text{ABCDE}} &= (0.5 \text{ in})\big((9 \text{ in} - (3)(0.625 \text{ in}) \\ &\quad + (2)(0.756 \text{ in})\big) \\ &= 4.319 \text{ in}^2 \end{aligned}$$

The net area of path EFG is

$$\begin{aligned} A_{n,\text{FCG}} &= (0.5 \text{ in})\big((9 \text{ in} - (3)(0.625 \text{ in})\big) \\ &= 3.5625 \text{ in}^2 \end{aligned}$$

The smallest area is $A_{n,\text{FCG}}$, which is less than 85% of A_g. The capacity of the connection based on the gross section is given by Eq. 60.11.

$$\begin{aligned} P_t &= 0.60F_yA_g = (0.60)\left(36 \frac{\text{kips}}{\text{in}^2}\right)(4.5 \text{ in}^2) \\ &= 97.2 \text{ kips} \end{aligned}$$

Since all of the connections are in the same plane, $U = 1$. Based on the net section, the capacity from Eqs. 60.6 and 60.12 is

$$\begin{aligned} P_t &= 0.50F_uUA_n = (0.50)\left(58 \frac{\text{kips}}{\text{in}^2}\right)(1)(3.5625 \text{ in}^2) \\ &= 103.3 \text{ kips} \end{aligned}$$

The tensile capacity is the smaller value of 97.2 kips.

Since the fracture line ABDE has fewer connectors than fracture line FCG (two compared to three), a further check is required. If bolts B and D carry two fifths of the load, the stress in section FCG will be

$$f_t = \frac{\left(\frac{3}{5}\right)(97.2 \text{ kips})}{3.5625 \text{ in}^2} = 16.4 \text{ kips/in}^2 \quad \text{[OK]}$$

10. DESIGN OF TENSION MEMBERS

The design of a tension member involves selection of a cross-sectional shape that is suitable for simple connections and has adequate measures of gross area, net area, block shear strength, and radius of gyration (for a preferred limit on slenderness ratio). A flowchart for tension member design is shown in Fig. 60.7.

Example 60.2

Select a 25 ft long W shape of A36 steel to carry dead and live tensile loads of 468 kips. The shape will be used as a main member with loads transmitted to framing members through the flanges only.

Solution

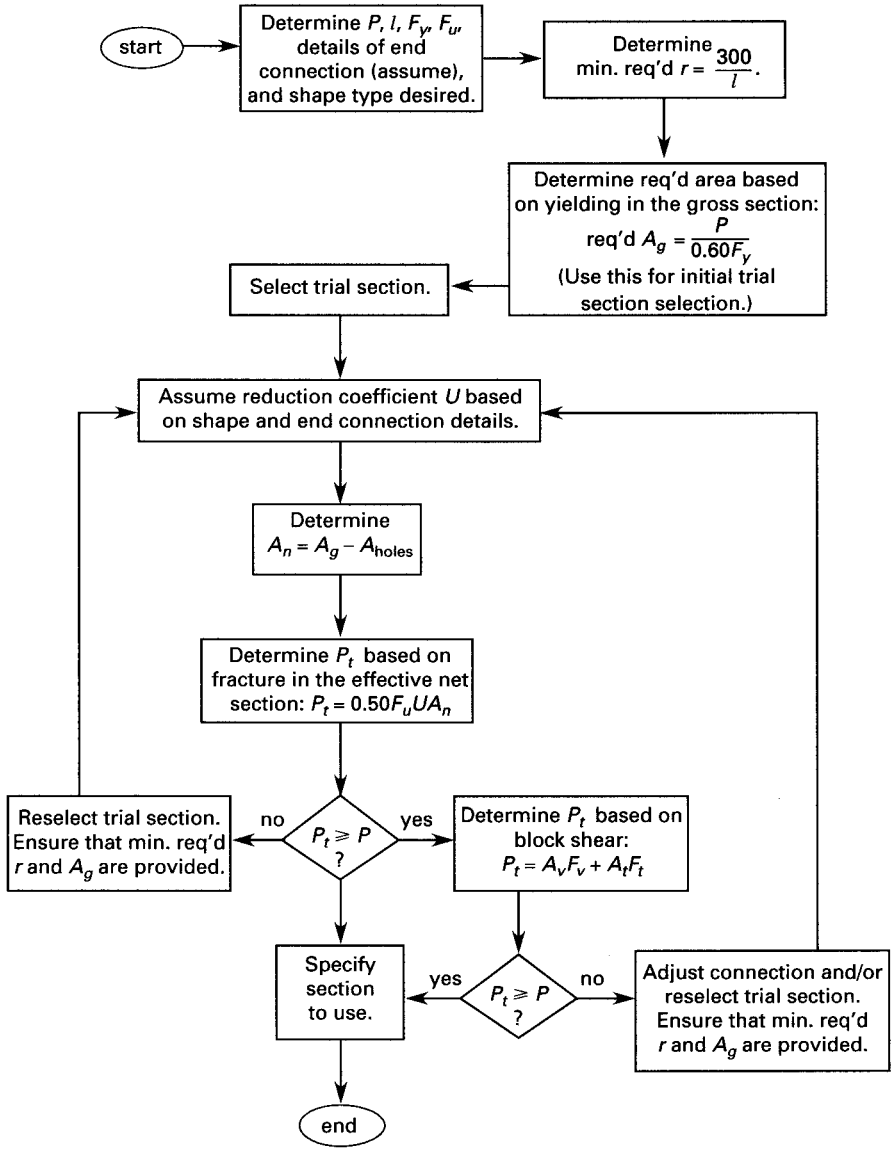
Without additional information on the hole pattern, the gross and net areas are taken as the same. The allowable tensile stress in the member is the minimum of

$$\begin{aligned} F_t &= 0.6F_y = (0.6)\left(36 \frac{\text{kips}}{\text{in}^2}\right) \\ &= 21.6 \text{ kips/in}^2 \quad \text{[controls]} \\ F_t &= 0.5F_u = (0.5)\left(58 \frac{\text{kips}}{\text{in}^2}\right) \\ &= 29 \text{ kips/in}^2 \end{aligned}$$

Since the web does not transmit the tensile strength, $U = 0.90$ is used. The required area is

$$\begin{aligned} A_n &= \frac{P}{F_tU} = \frac{468 \text{ kips}}{\left(21.6 \frac{\text{kips}}{\text{in}^2}\right)(0.90)} \\ &= 24.07 \text{ in}^2 \end{aligned}$$

A W21 × 83 member has an area of 24.3 in^2. The minimum radius of gyration is $r_y = 1.83$ in. So, the maximum slenderness ratio is



$$\begin{aligned} SR &= \frac{L}{r_y} = \frac{(25 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{1.83 \text{ in}} \\ &= 163.9 \end{aligned}$$

This slenderness ratio is less than the suggested limit of 300.

11. THREADED MEMBERS IN TENSION

Allowable tensile stress on threaded parts made from approved steels may not exceed $0.33F_u$ [*AISC Specifications* Table J3.2]. This limit applies to static loading, regardless of whether or not threads are present in the shear plane. The area to be used with this allowable stress when calculating the maximum tensile load is the gross or nominal area, as determined from the outer extremity of the threaded section. The nominal area of bolts is calculated from the nominal bolt diameter [*AISC Specifications* Table J3.1]. When threads are included in the shear plane, the lower of the loads based on $0.33F_u$ and $0.60F_y$ controls the design.

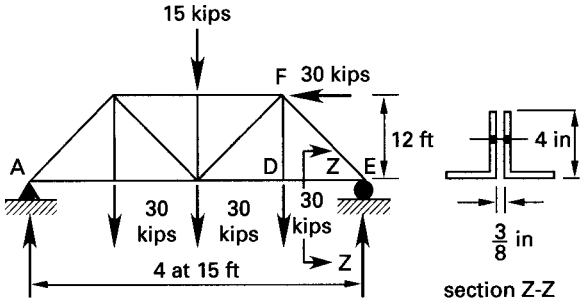
Figure 60.7 *Flowchart for the Design of Tension Members*

PRACTICE PROBLEMS

1. A single-angle tension member (L7 × 4 × 5/8) of A36 steel has two gage lines in its long leg and one in its short leg for 3/4 in diameter bolts arranged as shown. Determine the tensile capacity of the member, neglecting block shear.

(A) 70 kips
(B) 110 kips
(C) 140 kips
(D) 180 kips



The answer is (C).

2. Design a plate eyebar of A36 steel to carry a tensile load of 300 kips.

Answers: PL1½ × 9½; 8.5 in hole; 21.5 in outside diameter

3. (*Time limit: one hour*) For the truss shown, member DE is made of 2L4 × 3½ × ¼, of A36 steel. All joints are assumed to be pin-connected with one gage line of ¾ in high-strength bolts through one leg of each angle. Each end of member DE is connected with four bolts on the gage line with an edge distance of 1¼ in and a 2¼ in pitch.

(a) The support reaction at E is most nearly
(A) 38 kips
(B) 47 kips
(C) 52 kips
(D) 58 kips

The answer is (B).

(b) The axial force in member DE is most nearly
(A) 38 kips
(B) 46 kips
(C) 52 kips
(D) 58 kips

The answer is (D).

(c) The effective net area of member DE is most nearly
(A) 1.7 in^2
(B) 2.4 in^2
(C) 2.7 in^2
(D) 2.9 in^2

The answer is (B).

(d) The tensile load capacity of member DE, based on the fracture criterion, is most nearly
(A) 58 kips
(B) 64 kips
(C) 69 kips
(D) 79 kips

The answer is (C).

(e) The tensile load capacity of member DE, based on the yielding criterion, is most nearly
(A) 58 kips
(B) 68 kips
(C) 75 kips
(D) 78 kips

The answer is (D).

(f) In the computation of the block shear strength of member DE, the area in shear is most nearly
(A) 0.8 in^2
(B) 1.4 in^2
(C) 2.5 in^2
(D) 3.0 in^2

The answer is (C).

(g) In the computation of the block shear strength of member DE, the area in tension is most nearly
(A) 0.5 in^2
(B) 0.9 in^2
(C) 1.3 in^2
(D) 2.8 in^2

The answer is (A).

(h) The tensile load capacity of member DE, based on the block shear criterion, is most nearly
(A) 55 kips
(B) 58 kips
(C) 68 kips
(D) 73 kips

The answer is (B).

(i) The tensile load capacity of member DE, based on yielding, fracture, and block shear criteria, is most nearly
(A) 55 kips
(B) 58 kips
(C) 68 kips
(D) 78 kips

The answer is (B).

(j) The maximum slenderness ratio of the member DE is most nearly
(A) 140
(B) 200
(C) 250
(D) 300

The answer is (A).

4. (*Time limit: one hour*) A 25 ft long W-shape member is to carry an axial tensile load of 420 kips. It is assumed that there will be two lines of holes for ⅞ in diameter bolts in each flange. There will be at least three bolts in each line.

(For parts (a) through (e), assume A36 steel is used.)

(a) The required gross area based on the yielding criterion is most nearly

(A) 10 in^2
(B) 15 in^2
(C) 19 in^2
(D) 25 in^2

The answer is (C).

(b) The required effective net area based on the fracture criterion is most nearly

(A) 10 in^2
(B) 15 in^2
(C) 20 in^2
(D) 25 in^2

The answer is (B).

(c) The required net area based on the fracture criterion is most nearly

(A) 10 in^2
(B) 16 in^2
(C) 20 in^2
(D) 25 in^2

The answer is (B).

(d) The minimum radius of gyration required to satisfy the preferred slenderness limit for the member is most nearly

(A) 0.55 in
(B) 0.75 in
(C) 0.85 in
(D) 1.0 in

The answer is (D).

(e) The lightest W 12 (A36) section suitable for this member is

(A) W 12 × 50
(B) W 12 × 65
(C) W 12 × 79
(D) W 12 × 106

The answer is (C).

(For parts (f) through (j), assume A572, grade-50 steel is used.)

(f) The required gross area based on the yielding criterion is most nearly

(A) 10 in^2
(B) 14 in^2
(C) 20 in^2
(D) 25 in^2

The answer is (B).

(g) The required net effective area based on the fracture criterion is most nearly

(A) 10 in^2
(B) 13 in^2
(C) 20 in^2
(D) 25 in^2

The answer is (B).

(h) The required net area based on the fracture criterion is most nearly

(A) 10 in^2
(B) 14 in^2
(C) 20 in^2
(D) 25 in^2

The answer is (B).

(i) The minimum radius of gyration required to satisfy the preferred slenderness limit for the member is most nearly

(A) 0.55 in
(B) 0.75 in
(C) 0.85 in
(D) 1.0 in

The answer is (D).

(j) The lightest 50 kips/in^2 W 12 section suitable for this member is

(A) W 12 × 50
(B) W 12 × 65
(C) W 12 × 79
(D) W 12 × 106

The answer is (B).

1. INTRODUCTION

Structural members subjected to axial compressive loads are often called by names identifying their functions. Of these, the best-known are *columns*, the main vertical compression members in a building frame. Other common compression members include *chords* in trusses and *bracing members* in frames.

The selection of a particular shape for use as a compression member depends on the type of structure, the availability, and the connection methods. Load-carrying capacity varies approximately inversely with the slenderness ratio, so stiff members are generally required. Rods, bars, and plates, commonly used as tension members, are too slender to be used as compression members unless they are very short or lightly loaded.

For building columns, *W shapes* having nominal depths of 14 in or less are commonly used. These sections, being rather square in shape, are more efficient than others for carrying compressive loads. (Deeper sections are more efficient as beams.) *Pipe sections* are satisfactory for small or medium loads. Pipes are often used as columns in long series of windows, in warehouses, and in basements and garages. In the past, square and *rectangular tubing* saw limited use, primarily due to the difficulty in making bolted or riveted connections at the ends. Modern welding techniques have essentially eliminated this problem.

Built-up sections are needed in large structures for very heavy loads that cannot be supported by individual rolled shapes. For bracing and compression members in light trusses, *single-angle members* are suitable. However, *equal-leg angles* may be more economical than *unequal-leg angles* because their least radius of gyration values are greater for the same area of steel. For *top chord* members of bolted roof trusses, a pair of angles (usually unequal legs, with long legs back-to-back to give a better balance between the radius of gyration values about the x- and y- axes) are used with or without gusset plates. In welded roof trusses, where gusset plates are unnecessary, *structural tees* are used as top chord members.

Box sections have large radii of gyration. The section shown in Fig. 61.1(i) is often seen in towers and crane booms. In Fig. 61.1(i) through 61.1(m), solid lines represent the main elements of *box sections* that are continuous for the full length of the compression member. The dashed lines represent discontinuous elements—typically plates, *lacing bars*, or *perforated cover plates*. The discontinuous elements, such as lacing bars, do not usually contribute to load-carrying capacity; they serve only to space the continuous elements. Depending on the design, *cover plates* may or may not contribute load-carrying capacity.

Single *channels* are not satisfactory for the average compression member because the radii of gyration about their weak axes are almost negligible unless additional lateral support in the weak direction is provided.

There are three general modes by which axially loaded compression members can fail. These are flexural buckling, local buckling, and torsional buckling. *Flexural buckling* (also called *Euler buckling*) is the primary type of buckling. *Local buckling* is where one or more parts of a member's cross section fail in a small region, before the other modes of failure can occur. This type of failure is a function of the width-thickness ratios of the parts of the cross-section. *Torsional buckling*, not covered in this chapter, occurs in some members but is not significant in a majority of cases.

2. EULER'S COLUMN BUCKLING THEORY

Column design and analysis are based on the Euler buckling load theory. However, specific factors of safety and slenderness ratio limitations distinguish design and analysis procedures from purely theoretical concepts.

When loaded to the *buckling* (or *Euler*) *load*, a column will fail by sudden buckling (bending). An *ideal column* is initially perfectly straight, isotropic, and free of residual stresses. The Euler column buckling load for an ideal, pin-ended, concentrically loaded column is given by Eq. 61.1. The modulus of elasticity term, E, implies that Eq. 61.1 is valid as long as the loading remains in the elastic region.

$$P_e = \frac{\pi^2 EI}{L^2} \qquad 61.1$$

The *buckling stress* is derived by dividing both sides of Eq. 61.1 by the area, A, and using the relationship $I = Ar^2$, where r is the radius of gyration.

$$F_e = \frac{P_e}{A} = \frac{\pi^2 E}{\left(\frac{L}{r}\right)^2} \qquad 61.2$$

As Eq. 61.2 shows, the buckling stress is not a function of the material strength. Rather, it is a function of the ratio L/r, known as the *slenderness ratio*, SR. As the slenderness ratio increases, the buckling stress decreases, meaning that as a column becomes longer and more slender, the load that causes buckling becomes smaller. Equation 61.2 is convenient for design and is valid for all types of cross sections and all grades of steel.

3. EFFECTIVE LENGTH

Real columns usually do not have pin-connected ends. The restraints placed on a column's ends greatly affect its stability. Therefore, an *effective length factor*, K

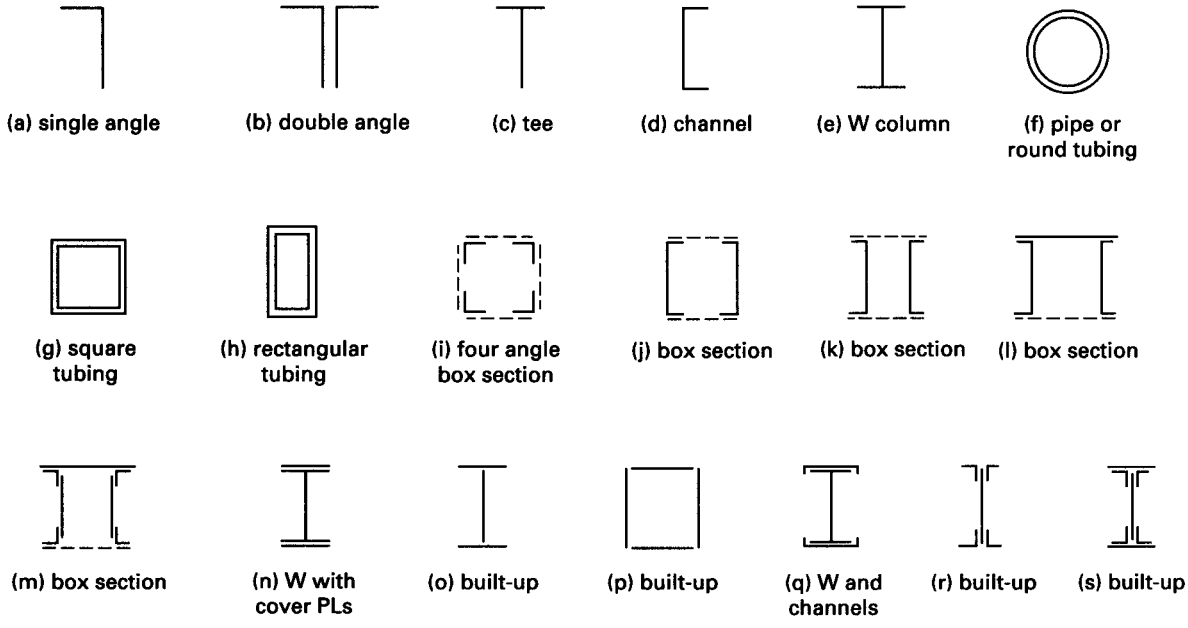

Figure 61.1 *Typical Compression Members' Cross Sections*

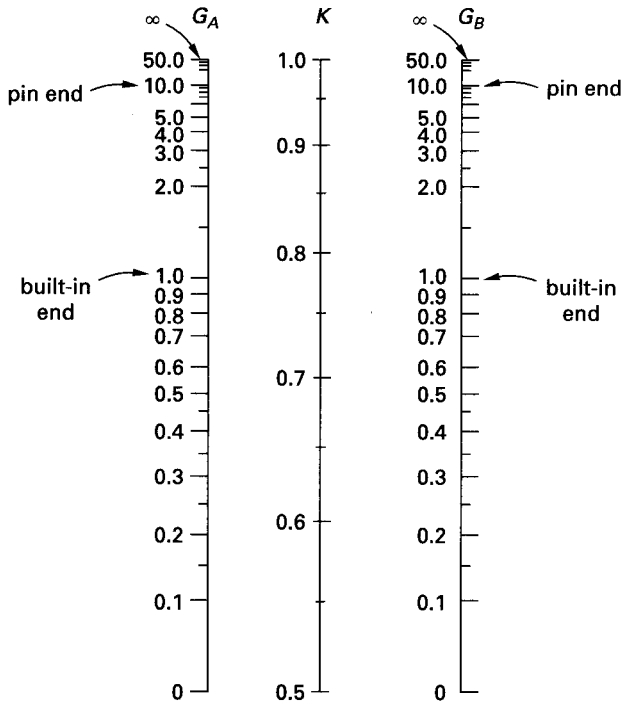
(also known as an *end-restraint factor*), is used to modify the unbraced length. The product, KL, of the effective length factor and the unbraced length is known as the *effective length* of the column. The effective length approximates the length over which a column actually buckles. The effective length can be longer or shorter than the actual unbraced length.

$$F_e = \frac{\pi^2 E}{\left(\frac{KL}{r}\right)^2} \qquad 61.3$$

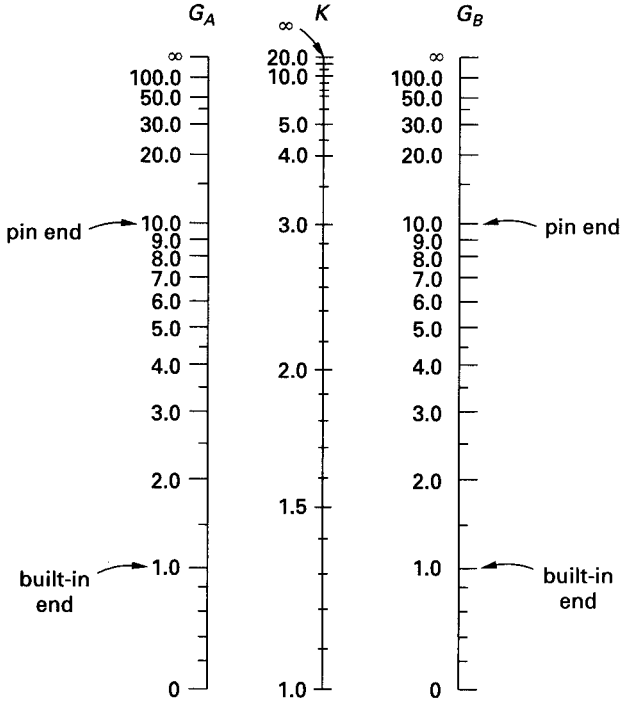
Values of the effective length factor depend upon the rotational restraint at the column ends as well as on the resistance provided against any lateral movement along the column length (i.e., whether or not the column is braced against sidesway). Theoretically, restraint at each end can range from complete *fixity* (though this is impossible to achieve in practice) to zero fixity (e.g., as with a freestanding signpost or flagpole end). Table 61.1 lists recommended values of K for use with steel columns. For braced columns (sidesway inhibited), $K \leq 1$, whereas for unbraced columns (sidesway uninhibited), $K > 1$.

Table 61.1 *Effective Length Factors*[a]



end no. 1	end no. 2	K
built-in	built-in	0.65
built-in	pinned	0.80
built-in	rotation fixed, translation free	1.2
built-in	free	2.1
pinned	pinned	1.0
pinned	rotation fixed, translation free	2.0

[a]These are slightly different from the theoretical values often quoted for use with Euler's equation.



Source: *AISC Commentary*, Table C-C2.1

The values of K in Table 61.1 do not require prior knowledge of the column size or shape. However, if the columns and beams of an existing design are known, the alignment charts in Fig. 61.2 can be used to obtain a more accurate effective length factor.

To use Fig. 61.2, the *end condition coefficients*, G_A and G_B, are first calculated from Eq. 61.4 for the two column ends. (The alignment charts are symmetrical. Either end can be designated A or B.)

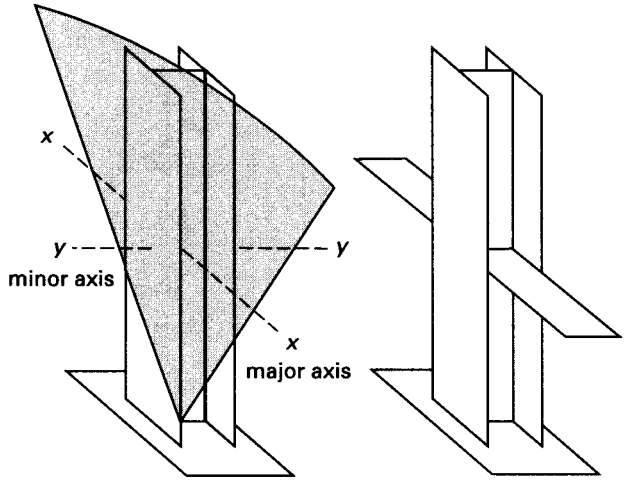
Figure 61.2 *Effective Length Factor Alignment Charts*

Structural

$$G = \frac{\Sigma\left(\frac{I}{L}\right)_{\text{columns}}}{\Sigma\left(\frac{I}{L}\right)_{\text{beams}}} \qquad 61.4$$



In calculating G, only beams and columns in the plane of bending (i.e., that resist the tendency to buckle) are included in the summation. Also, only rigidly attached beams and columns are included, since pinned connections do not resist moments. For ground-level columns, one of the column ends will not be framed to beams or other columns. In that case, $G = 10$ (theoretically, $G = \infty$) is used for pinned ends and $G = 1$ (theoretically, $G = 0$) is used for rigid footing connections.

4. GEOMETRIC TERMINOLOGY

Figure 61.3 shows a W shape used as a column. The I_y moment of inertia is smaller than I_x. In this case, the column is said to "buckle about the minor axis" if the failure (buckling) mode is as shown.

Since buckling about the minor axis is the expected buckling mode, bracing for the minor axis is usually provided at intermediate locations to reduce the unbraced length. Associated with each column are two unbraced lengths, L_x and L_y. In Fig. 61.3(b), L_x is the full column height. However, L_y is half the column height, assuming that the brace is placed at midheight.

Another important geometric characteristic is the *radius of gyration*. Since there are two moments of inertia, there are also two radii of gyration. Since I_y is smaller than I_x, r_y will be smaller than r_x. r_y is known as the *least radius of gyration*.

(a) minor axis buckling (b) minor axis bracing

Figure 61.3 *Minor Axis Buckling and Bracing*

5. SLENDERNESS RATIO

Steel columns are categorized as long columns and intermediate columns, depending on their slenderness ratios, SR. Since there are two values of the radius of gyration, r (and two values of K and L), corresponding to the x- and y-directions, there will be two slenderness ratios.

$$\text{SR} = \frac{KL}{r} \qquad 61.5$$

The *critical slenderness ratio*, C_c, corresponds to the upper limit of elastic buckling failure, which is defined by an average column stress equal to $0.5F_y$. (Equation 61.6 is obtained by substituting $0.5F_y$ for F_e in Eq. 61.3.) Thus, for a certain grade of steel, C_c represents the boundary between *long columns* and *intermediate columns*. An A36 column is considered long if the maximum SR is greater than $C_c = 126.1$ and is intermediate otherwise. For 50 ksi steel, $C_c = 107.0$. Slenderness ratios greater than 200 are not recommended [*AISC Specification* [B7]].

$$C_c = \sqrt{\frac{2\pi^2 E}{F_y}} \qquad 61.6$$

6. BUCKLING OF REAL COLUMNS

Euler's buckling load formula assumes concentrically loaded, perfect columns—conditions that are difficult to achieve in the real world. Real columns always have some flaws—curvature, variations in material properties, and residual stresses (of 10 to 15 ksi, mainly due to uneven cooling after hot-rolling). Furthermore, concentric loading is not possible.

Residual stresses are of particular importance with slenderness ratios of 40 to 120—a range that includes a very large percentage of columns. Because of the residual stresses, early localized yielding occurs at points in the column cross section, and buckling strength is appreciably reduced.

7. ALLOWABLE COMPRESSIVE STRESS

The allowable column stress varies with the slenderness ratio. Figure 61.4 shows two different regions, representing *inelastic buckling* and *elastic buckling*, separated by the critical slenderness ratio, C_c. (Very short compression members—those with effective lengths less than about 2 ft—are governed by different requirements.)

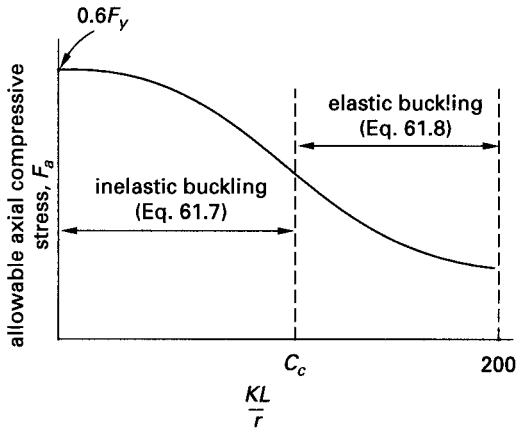


Figure 61.4 *Allowable Compressive Stress Versus Slenderness Ratio*

For intermediate columns ($KL/r \leq C_c$) that fail by inelastic buckling, Eq. 61.7 gives the allowable stress [AISC Eq. E2-1].

$$F_a = \frac{\left(1 - \frac{\left(\frac{KL}{r}\right)^2}{2C_c^2}\right) F_y}{\frac{5}{3} + \frac{3\left(\frac{KL}{r}\right)}{8C_c} - \frac{\left(\frac{KL}{r}\right)^3}{8C_c^3}} \qquad 61.7$$

The parabolic curve of Eq. 61.7 accounts for the inelastic behavior due to residual stresses and initial crookedness in a real column. The denominator in the equation represents a varying factor of safety from 5/3 to 23/12 corresponding to KL/r from 0 to C_c. The allowable stress ranges from $0.6F_y$ to $0.26F_y$.

For long columns ($KL/r > C_c$) that fail by elastic buckling, Eq. 61.8 must be used [AISC Eq. E2-2]. Equation 61.8 is the Euler buckling strength (Eq. 61.3) divided by a factor of safety of 23/12. Although Eq. 61.7 is a function of F_y, Eq. 61.8 is independent of F_y.

$$F_a = \frac{12\pi^2 E}{23\left(\frac{KL}{r}\right)^2} \qquad 61.8$$

For the two common grades of steel ($F_y = 36$ ksi and $F_y = 50$ ksi), there is no need to calculate F_a, as it is listed in the Allowable Stress for Compression Members Tables C-36 and C-50 in Part 3 of the *AISC Manual*.

For slenderness ratios up to C_c, an alternate method of calculating the allowable compressive stress for steels with nonstandard yield strengths is used. Equation 61.9 calculates F_a from the yield strength and a reduction coefficient, C_a. Values of C_a are listed in Table 3 of the numerical values section of the *AISC Specifications*.

$$F_a = C_a F_y \qquad 61.9$$

Allowable compressive stress on members subject to wind loading can be increased by one third.

8. ANALYSIS OF COLUMNS

Column analysis is done simply by verifying that the actual compressive stress does not exceed the allowable stress.

step 1: Determine the shape properties A, r_x, and r_y from the *AISC Manual*. Determine the unbraced lengths, L_x and L_y.

step 2: Obtain K_x and K_y from Table 61.1 or from the alignment chart, Fig. 61.2.

step 3: Calculate the maximum slenderness ratio as

$$\text{SR} = \text{larger of} \left\{ \begin{array}{c} \frac{K_x L_x}{r_x} \\ \\ \frac{K_y L_y}{r_y} \end{array} \right\} \qquad 61.10$$

step 4: Use Eq. 61.6 to calculate the critical slenderness ratio, C_c. (For 36 ksi steel, $C_c = 126.1$; for 50 ksi steel, $C_c = 107.0$.) (This step is not necessary if the AISC Allowable Stress for Compression Members table is used.)

step 5: Use the Allowable Stress for Compression Members table to obtain the allowable compressive stress. Alternatively, use either Eq. 61.7 or 61.8, depending on the value of SR.

step 6: Compare the actual load to the maximum allowable load on the column.

$$P_{\max} = F_a A \qquad 61.11$$

9. DESIGN OF COLUMNS

Trial-and-error column selection is difficult. Accordingly, Part 3 of the *AISC Manual* contains column selection tables that make it fairly easy to select a column based on the required column capacity. These tables assume that buckling will occur first about the minor axis. Steps 4 through 7 in the following procedure accommodate the case where buckling occurs first about the major axis.

step 1: Determine the load to be carried. Include an allowance for the column weight.

step 2: Determine the effective length factors, K_y and K_x, for the column. (If Eq. 61.4 is to be used, an initial column may need to be assumed.) Calculate the effective length assuming that buckling will be about the minor axis.

$$\text{effective length} = K_y L_y \qquad 61.12$$

Structural

step 3: Enter the table and locate a column that will support the required load with an effective length of K_yL_y.

step 4: Check for buckling in the strong direction. Calculate $K_xL'_x$ from Eq. 61.13. (The ratio r_x/r_y is tabulated in the column tables.)

$$K_xL'_x = \frac{K_xL_x}{\frac{r_x}{r_y}} \qquad 61.13$$

step 5: If $K_xL'_x < K_yL_y$, the column is adequate and the procedure is complete. Go to step 8.

step 6: If $K_xL'_x > K_yL_y$ but the column chosen can support the load at a length of $K_xL'_x$, the column is adequate and the procedure is complete. Go to step 8.

step 7: If $K_xL'_x > K_yL_y$ but the column chosen cannot support the load at a length of $K_xL'_x$, choose a larger member that will support the load at a length of $K_xL'_x$. (The ratio r_x/r_y is essentially constant.)

step 8: If sufficient information on other members framing into the column is available, use the alignment charts (Fig. 61.2) to check the values of K.

Example 61.1

Select an A36 steel W 14 shape to support a 2000 kip concentric load. The unbraced length is 11 ft in both directions. Use $K_y = 1.2$ and $K_x = 0.80$.

Solution

step 1: Assume the weight of the column is approximately 500 lbf/ft. The load to be carried is

$$P = 2000 \text{ kips} + \frac{\left(500 \frac{\text{lbf}}{\text{ft}}\right)(11 \text{ ft})}{1000 \frac{\text{lbf}}{\text{kip}}}$$

$$= 2005 \text{ kips}$$

step 2: From Eq. 61.12, the effective length for minor axis bending is

$$K_yL_y = (1.2)(11 \text{ ft}) = 13.2 \text{ ft} \quad \text{[say 13 ft]}$$

step 3: From the column table for 36 ksi steel, select a W 14×370 shape with a capacity of 2121 kips.

step 4: From the column table, $r_x/r_y = 1.66$. From Eq. 61.13,

$$K_xL'_x = \frac{K_xL_x}{\frac{r_x}{r_y}}$$

$$= \frac{(0.80)(11 \text{ ft})}{1.66} = 5.30 \text{ ft}$$

step 5: Since 5.30 ft < 13 ft, the column selected is adequate.

Example 61.2

Select a 25 ft A36 W shape column to support a live load of 375 kips. The base is rigidly framed in both directions. The top is rigidly framed in the weak direction and fixed against rotation in the strong direction, but translation in the strong direction is possible.

Solution

step 1: Assume the column weight is approximately 80 lbf/ft. The load to be carried is

$$P = 375 \text{ kips} + \frac{\left(80 \frac{\text{lbf}}{\text{ft}}\right)(25 \text{ ft})}{1000 \frac{\text{lbf}}{\text{kip}}}$$

$$= 377 \text{ kips}$$

step 2: From Table 61.1, the end restraint coefficients are $K_y = 0.65$ and $K_x = 1.2$. The effective lengths are

$$K_yL_y = (0.65)(25 \text{ ft}) = 16.25 \text{ ft}$$

$$K_xL_x = (1.2)(25 \text{ ft}) = 30 \text{ ft}$$

step 3: From the column table for 36 ksi steel, find a column capable of supporting 377 kips with an effective length of 16 ft. Try a W 12×79 shape with a capacity of 398 kips.

step 4: From the column table, $r_x/r_y = 1.75$. Using Eq. 61.13,

$$K_xL'_x = \frac{K_xL_x}{\frac{r_x}{r_y}}$$

$$= \frac{30 \text{ ft}}{1.75} = 17.1 \text{ ft}$$

step 5: Since 17.1 ft > 16.25 ft, the strong-axis buckling controls. Use the column table again to find an effective length of 17.1 ft. The column capacity is found by interpolation to be 388 kips. Since 388 kips > 377 kips, this column is adequate.

10. LOCAL BUCKLING

Local buckling of a plate element in a rolled shape or built-up compression member may occur before Euler buckling. The ability of plate sections to carry compressive loads without buckling is determined by the *width-thickness ratio*, b/t. If a shape is selected from the AISC column-selection tables, the width-thickness ratios do not generally need to be evaluated. However, compression members constructed from double tees, structural tubing, and plates must be checked.

For the purpose of specifying limiting width-thickness ratios, compression elements are divided into stiffened elements and unstiffened elements. *Stiffened elements* are supported along two parallel edges. Examples are webs of W shapes and the sides of box beams. *Unstiffened elements* are supported along one edge only. Flanges of W shapes and legs of angles are unstiffened elements.

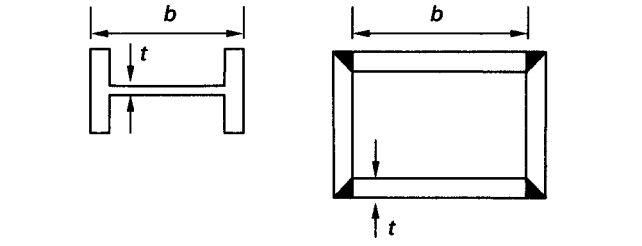

Figure 61.5 *Stiffened and Unstiffened Compressive Elements*

To prevent local buckling, *AISC Specifications* Sec. B5 requires Eq. 61.14 to be met if the plate element is to be fully effective. Values of H are listed in Table 61.2.

$$\frac{b}{t} \leq \frac{H}{\sqrt{F_y}} \qquad 61.14$$

Circular tubular sections whose ratios of outside diameter to wall thickness satisfy Eq. 61.15 are considered to be fully effective.

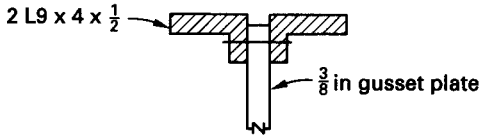
$$\frac{D}{t} \leq \frac{3300}{F_y} \qquad 61.15$$

If the width-thickness ratios of unstiffened compression members are exceeded, the allowable compressive stress is reduced by a strength reduction factor. However, the allowable stress, F_a, is not the same as for members that meet the width-thickness criteria. The reduction is incorporated into both the critical slenderness ratio, C_c, and the allowable compressive stress.

$$F_a' = Q_s F_a \qquad 61.16$$

Stiffened compression elements exceeding the width-thickness ratios are handled differently. An effective width, b_e, is used in place of the actual width when calculating the flexural design properties and the permissible axial stress. The specific provisions for determining Q_s and b_e are contained in Chapter B of the *AISC Specifications*.

Table 61.2 *H Values for Width-Thickness Ratios*[a]



element	H
unstiffened elements	
stems of tees	127
double angles in contact	95
compression flanges of beams	95
angles or plates projecting from girders, columns, or other compression members, and compression flanges of plate girders[b]	$95\sqrt{k_c}$
stiffeners on plate girders	95
flanges of tees and I-beams (use $b_f/2$)	95
single-angle struts or separated double-angle struts	76
stiffened elements	
square and rectangular box sections	238
cover plates with multiple access holes	317
other uniformly compressed elements	253

[a] Allowable stress design only
[b] $k_c = 4.05/(h/t)^{0.46}$ if $h/t > 70$; otherwise, $k_c = 1$. Other provisions govern the width-thickness ratios of plate girder flanges, as well.

Source: *AISC Specifications* Table B5.1

Example 61.3

Two A36 L 9 × 4 × ½ angles are used with a ⅜ in gusset plate to create a truss compression member. The short legs are back to back, making the long legs unstiffened elements. Can the combination fully develop compressive stresses?

Solution

The limitation on the unstiffened separated double angles is given by Eq. 61.14.

$$\frac{76}{\sqrt{F_y}} = \frac{76}{\sqrt{36\ \frac{\text{kips}}{\text{in}^2}}} = 12.67$$

The actual width-thickness ratio is

$$\frac{b}{t} = \frac{9 \text{ in}}{0.5 \text{ in}} = 18$$

Since $18 > 12.67$, local buckling will control. A reduced stress factor must be used when calculating the allowable compressive load on the truss member.

11. MISCELLANEOUS COMBINATIONS IN COMPRESSION

Miscellaneous shapes, including round and rectangular tubing, single and double angles, and built-up sections, can be used as compression members, as shown in Fig. 61.6.

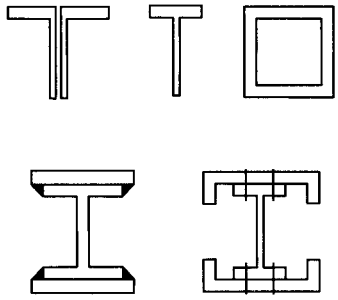


Figure 61.6 *Miscellaneous Compression Members*

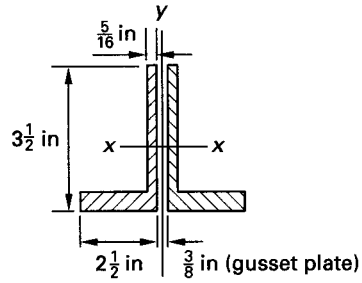
Generally, sections with distinct strength advantages in one plane (e.g., double angles or tees) should be used when bending is confined to that plane. For example, a double-angle member could be used as a compression strut in a roof truss or as a spreader bar for hoisting large loads.

Design and analysis of these miscellaneous compression members is similar to the design and analysis of W-shape columns. The same equations are used for calculating the allowable stress, F_a. It is essential to check the width-thickness ratios for all elements in the compression members, including both flanges and stems of tees.



Where spot welding or stitch riveting is used to combine two shapes into one (as is done with double angles), the spacing of the connections must be sufficient to prevent premature buckling of one of the shapes. Once the maximum slenderness ratio has been determined (based on x- and y-directions), the spacing between connections can be calculated from Eq. 61.17, in which r_z is the least radius of gyration for a single angle (as read from the shape table).

$$L_b = \frac{\text{SR}_{\max} r_z}{K} \qquad 61.17$$

Column load tables have been prepared for many combinations of double angles, tees, round pipe, and structural tubing. Single-angle compression members are difficult to load concentrically, and special attention is required when designing the connections.

Example 61.4

Design a 10 ft long A36 double-angle strut to support an axial compressive load of 40 kips. Assume $K = 1$ in both directions. Gusset plates at the ends are $^3/_8$ in thick.

Solution

Self-weight is disregarded since the weight of the strut will be insignificant compared to the axial load.

From the Double-Angle Column tables in the *AISC Manual*, try two L $3^1/_2 \times 2^1/_2 \times {}^5/_{16}$ angles, with long legs back to back. This configuration has a capacity of 42 kips in the x-direction and 40 kips in the y-direction. (Note that a slightly more economical selection would be $4 \times 3 \times {}^1/_4$, with a capacity of 44 kips in the x-direction and 40 kips in the y-direction.) From the table, the properties are

$$A = 3.55 \text{ in}^2$$

$$r_x = 1.11 \text{ in}$$

$$r_y = 1.10 \text{ in}$$

The controlling slenderness ratio is the larger value of KL/r.

$$\frac{K_x L}{r_x} = \frac{(1)(10 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{1.11 \text{ in}}$$

$$= 108.1$$

$$\frac{K_y L}{r_y} = \frac{(1)(10 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{1.10 \text{ in}}$$

$$= 109.1 \quad \text{[controls]}$$

The allowable compressive stress can be calculated from Eq. 61.7 or read directly from *AISC Specifications* Part 3, Table C-36 as $F_a = 11.81$ ksi. The actual compressive stress is

$$f_a = \frac{P}{A} = \frac{40 \text{ kips}}{3.55 \text{ in}^2} = 11.3 \text{ ksi} < 11.81 \text{ ksi} \quad \text{[OK]}$$

All combinations of double angles in the *AISC Manual* meet the width-thickness ratio requirements. However, the width-thickness ratio is easily calculated from the angle designation.

$$\frac{b}{t} = \frac{3.5 \text{ in}}{\frac{5}{16} \text{ in}} = 11.2$$

The maximum width-thickness ratio for separated double-angle struts is

$$\frac{76}{\sqrt{F_y}} = \frac{76}{\sqrt{36\ \frac{\text{kips}}{\text{in}^2}}} = 12.67 \quad \text{[OK]}$$

From the shape table, the least radius of gyration is $r_z = 0.54$ in. Use Eq. 61.17. Since the maximum slenderness ratio is 109.1, the distance between points where the two angles are joined should not exceed

$$L = \frac{\text{SR}_{\text{max}} r_{\text{min}}}{K} = \frac{(109.1)(0.54\text{ in})}{1} = 58.9\text{ in}$$

12. COLUMN BASE PLATES

Column loads transmitted to masonry and concrete foundations must meet the same bearing pressure limitations as beam loads. The required *base plate* area can be found from the total column load and allowable bearing pressure.

$$A_{\text{plate}} = \frac{\text{column load}}{F_p} \qquad 61.18$$

The required bearing plate area will be minimized when the allowable bearing pressure is maximized. This occurs when the area of the supporting masonry or concrete plane is more than four times the area of the base plate. When $A_{\text{support}}/A_{\text{bearing}} = 4$, the corresponding allowable bearing stress is $F_p = 0.70f'_c$, the maximum value permitted for concrete. This value of F_p should be used unless the support area is limited in some way, as it could be with a pedestal-mounted column.

It is common to specify base plate dimensions in whole inches. Therefore, the actual plate area will be somewhat larger than the required plate area. The actual bearing pressure is

$$f_p = \frac{\text{column load}}{\text{actual plate area}} \qquad 61.19$$

It is generally desirable to have $m = n$. This approximately occurs when

$$A_1 = \frac{\text{column load}}{F_p}$$

$$N \approx \sqrt{A_1} + \tfrac{1}{2}(0.95d - 0.80b_f)$$

$$B = \frac{\sqrt{A_1}}{N}$$

It is assumed that part of the base plate outboard from a $0.95d \times 0.8b$ rectangle acts as a uniformly loaded cantilever. The tensile bending stress, F_b, in the cantilever portion is limited to a maximum value of $0.75F_y$. Once the column and base plate size has been determined, the

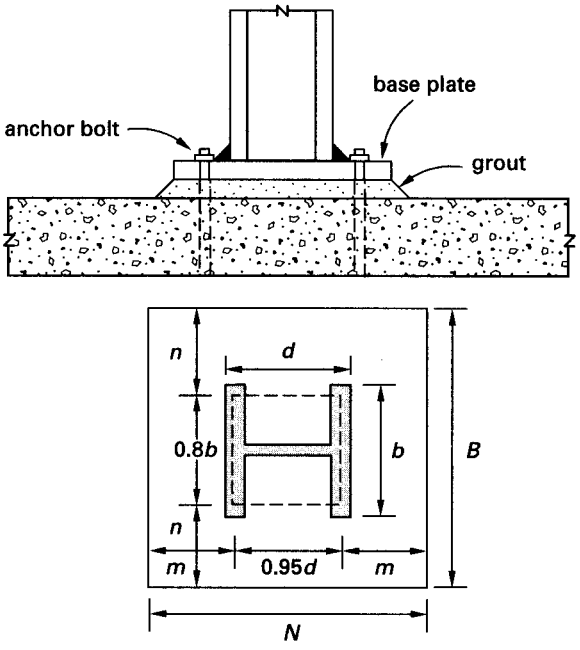


Figure 61.7 *Column Base Plate*

distances m and n can be determined. Then, Eq. 61.20 can be used to calculate the required plate thickness. The larger plate thickness is required, since either m or n will be larger.

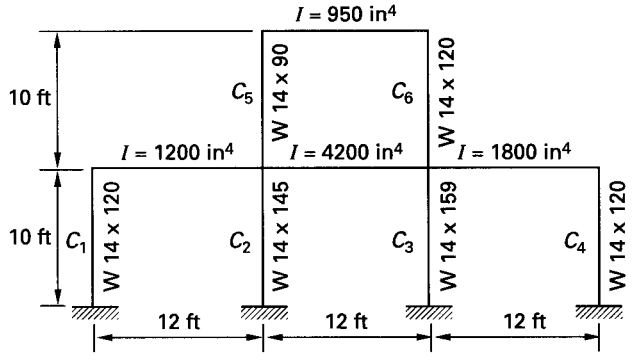
$$t = \text{larger}\left\{\begin{matrix} m \\ n \end{matrix}\right\}\sqrt{\frac{3f_p}{F_b}}$$

$$= \text{larger}\left\{\begin{matrix} 2m \\ 2n \end{matrix}\right\}\sqrt{\frac{f_p}{F_y}} \qquad 61.20$$

Although Eq. 61.20 is theoretically correct, an additional check is required when m and n are small (i.e., the base plate is just large enough to accommodate the column profile). In that case, the column load is assumed to be distributed to an area much smaller than the base plate. The required thickness is determined as the larger of Eq. 61.20 or 61.21.

$$t = L\sqrt{\frac{3f_p}{F_b}} \qquad 61.21$$

The distance L is solved from the quadratic Eq. 61.22. If L is imaginary, Eq. 61.21 is disregarded.



$$F_p = \frac{P}{A} = \frac{P}{2L(d + b - 2L)} \qquad 61.22$$

PRACTICE PROBLEMS

1. (*Time limit: one hour*) The two-story, unbraced frame of A36 steel shown is one of several placed on 30 ft centers. All columns are pinned (rotation free and

translation fixed) in the weak axis direction (i.e., perpendicular to the plane of the frame). The following loadings are applied.

roof dead load: 4 in thick reinforced concrete slab (unit weight = 150 lbf/ft^3) and roofing material (weight = 6 lbf/ft^2)
roof live load: 30 lbf/ft^2
floor dead load: 6 in thick reinforced concrete slab
floor live load: 90 lbf/ft^2

(a) Based on the framing member information provided, the effective length factor K_x of column C_2 for buckling about the strong axis is most nearly

(A) 0.70
(B) 0.85
(C) 1.0
(D) 1.2

The answer is (D).

(b) Based on the framing member information provided, the effective length factor K_x of column C_5 for buckling about the strong axis is most nearly

(A) 0.78
(B) 0.95
(C) 1.4
(D) 1.7

The answer is (C).

(c) The slenderness ratios of columns C_2 and C_5 with respect to the strong axis are most nearly

(A) 23 and 27, respectively
(B) 49 and 54, respectively
(C) 62 and 67, respectively
(D) 78 and 85, respectively

The answer is (A).

(d) The maximum slenderness ratio for column C_2 is most nearly

(A) 24
(B) 30
(C) 48
(D) 63

The answer is (B).

(e) The maximum slenderness ratio for column C_5 is most nearly

(A) 28
(B) 32
(C) 45
(D) 68

The answer is (B).

(f) The allowable axial compressive load on column C_2 is most nearly

(A) 580 kips
(B) 680 kips
(C) 850 kips
(D) 920 kips

The answer is (C).

(g) The allowable axial compressive load on column C_5 is most nearly

(A) 520 kips
(B) 650 kips
(C) 790 kips
(D) 940 kips

The answer is (A).

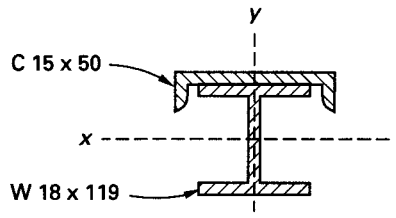
(h) The computed axial compressive load on column C_5 is most nearly

(A) 16 kips
(B) 78 kips
(C) 180 kips
(D) 220 kips

The answer is (A).

(i) The computed axial compressive load on column C_2 is most nearly

(A) 18 kips
(B) 78 kips
(C) 180 kips
(D) 220 kips



The answer is (B).

(j) Considering axial loads only,

(A) both columns C_2 and C_5 are adequate.
(B) both columns C_2 and C_5 are inadequate.
(C) column C_2 is adequate, but column C_5 is inadequate.
(D) column C_5 is adequate, but column C_2 is inadequate.

The answer is (A).

2. (*Time limit: one hour*) A 20 ft high column, pinned at both ends, is constructed from an A36 channel and an A36 wide flange shape as shown. The column is constrained against bending in the x-plane by bracing at midheight.

(a) The cross-sectional area of the column is most nearly
(A) 35 in^2
(B) 42 in^2
(C) 50 in^2
(D) 55 in^2

The answer is (C).

(b) The centroidal moment of inertia of the column for bending about the x-axis is most nearly
(A) 2700 in^4
(B) 2900 in^4
(C) 3100 in^4
(D) 3300 in^4

The answer is (C).

(c) The centroidal moment of inertia of the column for bending about the y-axis is most nearly
(A) 570 in^4
(B) 660 in^4
(C) 790 in^4
(D) 820 in^4

The answer is (B).

(d) The radius of gyration of the column with respect to the x-axis is most nearly
(A) 4.9 in
(B) 5.7 in
(C) 6.9 in
(D) 7.9 in

The answer is (D).

(e) The radius of gyration of the column with respect to the y-axis is most nearly
(A) 2.9 in
(B) 3.1 in
(C) 3.6 in
(D) 4.1 in

The answer is (C).

(f) The slenderness ratio of the column with respect to the x-axis is most nearly
(A) 28
(B) 30
(C) 33
(D) 41

The answer is (B).

(g) The slenderness ratio of the column with respect to the y-axis is most nearly
(A) 28
(B) 30
(C) 33
(D) 41

The answer is (C).

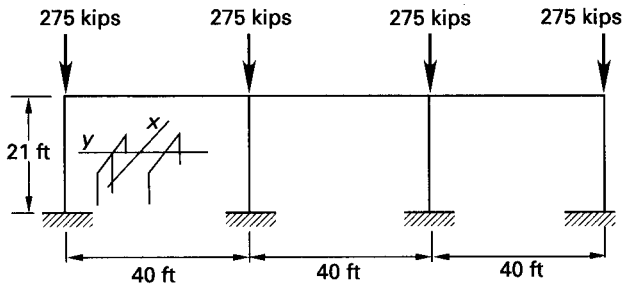
(h) The maximum slenderness ratio for the column is most nearly
(A) 28
(B) 30
(C) 33
(D) 41

The answer is (C).

(i) The allowable compressive stress for the column is most nearly
(A) 12 ksi
(B) 15 ksi
(C) 18 ksi
(D) 20 ksi

The answer is (D).

(j) The allowable axial compressive load on the column is most nearly
(A) 590 kips
(B) 680 kips
(C) 980 kips
(D) 1200 kips



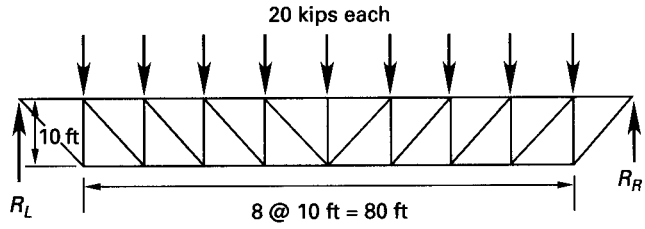
The answer is (C).

3. Select the lightest W section of A36 steel to serve as a column 30 ft long and to carry an axial compressive load of 160 kips. The member is pinned at its top and bottom. It is supported at midheight in its weak direction.
(A) W 8 × 35
(B) W 10 × 39
(C) W 12 × 45
(D) W 14 × 48

The answer is (B).

4. Select A36 interior columns of the frame shown. Assume columns are braced in the plane perpendicular to the frame and pinned at the top and bottom. Sidesway is uninhibited. Girders are W 12×96.

Structural



(A) W 12 × 40
(B) W 12 × 45
(C) W 12 × 53
(D) W 12 × 65

The answer is (D).

5. (*Time limit: one hour*) The truss shown is constructed of a variety of members, all of which are assumed to be pin-ended. Determine whether all members are adequate. If members are not adequate, specify replacements with the same nominal depth.

top and bottom chords	W 8 × 28 (A36)
diagonal bracing	L $3\frac{1}{2} \times 3\frac{1}{2} \times \frac{5}{16}$ (pair)
vertical members	L 4 × 4 × $\frac{3}{8}$ (pair)

Answers: top chords: inadequate; use W 8 × 58
bottom chords: inadequate; use W 8 × 40
diagonal bracing: inadequate;
use L $3\frac{1}{2} \times 3\frac{1}{2} \times \frac{1}{2}$ pair
vertical members: inadequate;
use L 4 × 4 × $\frac{1}{2}$ pair

1. INTRODUCTION

A member that is acted upon by a compressive force and a bending moment is known as a *beam-column*. The bending moment can be due to an eccentric load or a true lateral load.

For pure beams and columns, second-order effects are neglected. Only first-order effects based on undeformed geometry need to be considered. For a member subjected to a moment only, the stress is calculated from the flexure formula, $f = M/S$. When the same member carries an axial compressive load alone, the stresses are calculated as $f = P/A$.

When a member is acted upon by both bending moment and an axial load, the two stresses cannot be added directly to obtain the so-called combined stresses. Additional stresses resulting from a secondary moment must be taken into account, especially when the axial compressive load is large. The secondary moment is caused by the *P-Δ effect* and has a magnitude of $P\Delta$. The deflection, Δ, results from the initial lateral deflection due to the bending moment, but causes further bending of its own and produces secondary stresses.

The secondary moment and the associated stress are known as *second-order effects*, since they are dependent on the deformed geometry of the member. *Moment amplification factors* are used to account for the second-order effects. An expression for maximum combined stress can be written as Eq. 62.1. f_{bx} and f_{by} are the maximum bending stresses caused by bending moments about x- and y-axes, respectively. $(\text{AF})_x$ and $(\text{AF})_y$ are the corresponding amplification factors.

$$f_{\max} = f_a + (\text{AF})_x f_{bx} + (\text{AF})_y f_{by} \qquad 62.1$$

Unfortunately, even with the inclusion of secondary moment effects, computed values of combined stresses are not particularly useful, since there are no code-specified allowable combined stresses for beam-columns. Design and analysis of beam-columns generally attempt to transform moments into equivalent axial loads (i.e., the *equivalent axial compression method*) or make use of interaction equations. Interaction-type equations are best suited for beam-column analysis and validation, since so much (e.g., area, moment of inertia) needs to be known about a shape. Equivalent axial compression methods are better suited for design.

Structural

Equation 62.1 is converted to an *interaction equation* by dividing both sides by f_{max} and then by substituting applicable allowable stresses for f_{max}. In Eq. 62.2, if one or more applied stresses is zero, the member acts as an axially loaded column, a beam bending about one or both axes, or a beam-column bending about one axis only.

$$\frac{f_a}{F_a} + (\mathrm{AF})_x \left(\frac{f_{bx}}{F_{bx}}\right) + (\mathrm{AF})_y \left(\frac{f_{by}}{F_{by}}\right) = 1.0 \qquad 62.2$$

2. SMALL AXIAL COMPRESSION

An axial compressive load on a beam-column is considered "small" when f_a/F_a does not exceed 0.15. Such a member is essentially a beam, and a simplified interaction equation is used without the amplification factors [AISC Eq. H1-3]. In Eq. 62.3, f_b is the actual maximum compressive bending stress as calculated from the standard bending stress equation. F_b is the compressive bending stress that would be permitted if the bending moment acted alone.

$$\frac{f_a}{F_a} + \frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \leq 1.0 \qquad 62.3$$

3. LARGE AXIAL COMPRESSION

A beam-column is said to be under "large" compression when f_a/F_a exceeds 0.15. In this case, two criteria—a stability interaction criterion and a strength interaction criterion—must be satisfied. Equation 62.4 ([H1-1]) is the *stability interaction criterion.*

$$\frac{f_a}{F_a} + \frac{C_{mx} f_{bx}}{\left(1 - \dfrac{f_a}{F'_{ex}}\right) F_{bx}} + \frac{C_{my} f_{by}}{\left(1 - \dfrac{f_a}{F'_{ey}}\right) F_{by}} \leq 1.0 \qquad 62.4$$

The two terms $1/(1 - (f_a/F'_e))$ are the moment amplification factors that account for the secondary stresses. F'_e is the Euler stress divided by a factor of safety of 23/12. In Eq. 62.5, L_b and r_b are the unbraced length and radius of gyration, respectively, in consistent units, both in the plane of bending.

$$F'_e = \frac{12\pi^2 E}{23\left(\dfrac{KL_b}{r_b}\right)^2} \qquad 62.5$$

Equation 62.4 can be considered to be Eq. 62.3 modified by two factors—an amplification factor and a reduction coefficient—for when $f_a/F_a > 0.15$. Equation 62.4 applies where stability of a member is a concern, and the critical buckling stresses are assumed to occur away from the points of bracing.

The amplification factor tends to overestimate the secondary moment under some load combinations. To compensate for this situation, the amplification factor is modified by a reduction coefficient C_m. If the compression member is subject to joint translation (i.e., sidesway), then $C_m = 0.85$. If the compression member is braced against joint translation in the plane of loading and also experiences transverse loading between the supports, C_m may be taken as 0.85 if the member's ends are restrained against rotation, and 1.0 otherwise.

If a compression member is braced against joint translation in the plane of loading and does not experience transverse loads between the supports, C_m is calculated from Eq. 62.6.

$$C_m = 0.6 - 0.4\left(\frac{M_1}{M_2}\right) \qquad 62.6$$

M_1/M_2 is the ratio of the smaller to larger moments at the ends of the compression member in the plane of bending. The ratio is positive when the member is bent in reverse curvature, and it is negative when bent in single curvature.

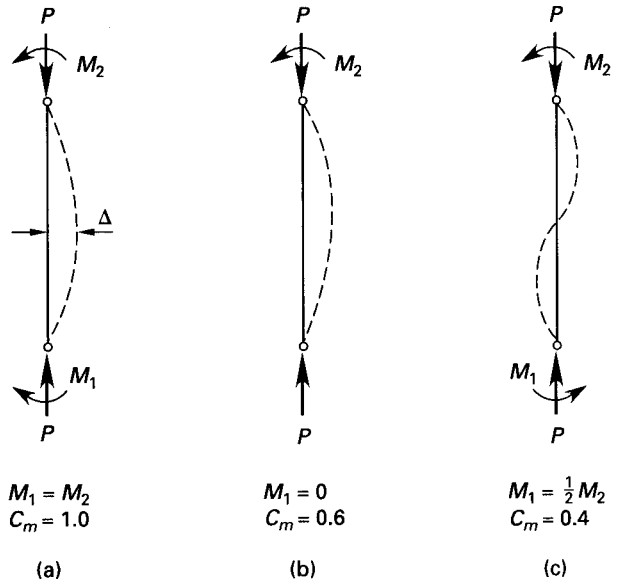

Figure 62.1 *Values of C_m*

Equation 62.7 is the *strength interaction criterion* [AISC Eq. H1-2]. This is basically an interaction equation using $0.60F_y$ as the allowable compressive stress. The purpose of this equation is to prevent overstressing at one end of a member where no buckling action is present.

$$\frac{f_a}{0.60F_y} + \frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} \leq 1.0 \qquad 62.7$$

For members subject to wind and seismic forces, AISC Specification A5.2 permits a one-third increase in allowable stresses. Therefore, 4/3 can be used in place of 1.0 on the right-hand side of Eqs. 62.3, 62.4, and 62.7.

4. ANALYSIS OF BEAM-COLUMNS

The following procedure can be used for beam-column analysis.

step 1: Calculate the axial stress f_a due to the axial load acting alone as P/A.

step 2: Calculate the slenderness ratios for both bending modes.

step 3: Based on the larger slenderness ratio, determine the allowable column stress F_a. Use Eq. 61.7 or 61.8. Alternatively, F_a can be obtained directly from the Allowable Stress for Compression Members table.

step 4: Calculate the ratio f_a/F_a.

step 5: Calculate the actual bending stresses f_{bx} and f_{by} due to primary bending moments M_x and M_y acting alone about the x and y axes, respectively.

step 6: Calculate the allowable bending stresses F_{bx} and F_{by}. (Refer to Chap. 59.)

step 7: Determine the adequacy of the design by using the applicable interaction equation(s). If $f_a/F_a \leq 0.15$, use Eq. 62.3. If $f_a/F_a > 0.15$, use both Eqs. 62.4 and 62.7.

Example 62.1

A W14×120 A36 shape has been chosen to carry an axial compressive load of 200 kips and a 250 ft-kips moment about its strong axis. The unsupported length is 20 ft. Sidesway is permitted in the direction of bending. Use $K = 1$. Determine if the column is adequate.

Solution

Check to see if the axial load can be considered small. The column properties are

$$A = 35.3 \text{ in}^2$$
$$r_y = 3.74 \text{ in}$$
$$L_c = 15.5 \text{ ft}$$
$$S_x = 190 \text{ in}^3$$
$$r_x = 6.24 \text{ in}$$
$$L_u = 44.1 \text{ ft}$$

The axial stress is

$$f_a = \frac{P}{A} = \frac{200 \text{ kips}}{35.3 \text{ in}^2} = 5.67 \text{ kips/in}^2$$

The maximum slenderness ratio is

$$\text{SR} = \frac{KL}{r_y} = \frac{(1)(20 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{3.74 \text{ in}}$$
$$= 64.2 \quad \text{[say 64]}$$

The allowable compressive stress from Eq. 62.3 (or from Table C-36, *AISC Manual*, the Allowable Stress for Compression Members table) is 17.04 ksi. The stress ratio is

$$\frac{f_a}{F_a} = \frac{5.67 \frac{\text{kips}}{\text{in}^2}}{17.04 \frac{\text{kips}}{\text{in}^2}} = 0.33 > 0.15$$

Therefore, the large axial compression criterion must be used. Since sidesway is permitted, $C_{mx} = 0.85$. The bending stress due to the applied moment is

$$f_{bx} = \frac{M_x}{S_x} = \frac{(250 \text{ ft-kips})\left(12 \frac{\text{in}}{\text{ft}}\right)}{190 \text{ in}^3}$$
$$= 15.79 \text{ kips/in}^2$$

$M_y = 0$, so $f_{by} = 0$.

Since the unbraced length of 20 ft is greater than L_c but less than L_u,

$$F_{bx} = 0.60F_y = (0.60)\left(36 \frac{\text{kips}}{\text{in}^2}\right) = 21.6 \text{ kips/in}^2$$

From Eq. 62.5,

$$F'_e = \frac{12\pi^2 E}{23\left(\frac{KL_b}{r_b}\right)^2} = \frac{12\pi^2\left(29{,}000 \frac{\text{kips}}{\text{in}^2}\right)}{23\left(\frac{(1)(20 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{6.24 \text{ in}}\right)^2}$$
$$= 100 \text{ kips/in}^2$$

From the strength criterion, Eq. 62.7,

$$\frac{f_a}{0.60F_y} + \frac{f_{bx}}{F_{bx}} + \frac{f_{by}}{F_{by}} = \frac{5.67 \text{ ksi}}{(0.60)(36 \text{ ksi})} + \frac{15.79 \text{ ksi}}{21.6 \text{ ksi}} + 0$$
$$= 0.99 < 1.0 \quad \text{[OK]}$$

From the stability criterion, Eq. 62.4,

$$\frac{f_a}{F_a} + \frac{C_{mx}f_{bx}}{\left(1 - \frac{f_a}{F'_{ex}}\right)F_{bx}} + \frac{C_{my}f_{by}}{\left(1 - \frac{f_a}{F'_{ey}}\right)F_{by}}$$
$$= \frac{5.67 \text{ ksi}}{17.04 \text{ ksi}} + \frac{(0.85)(15.79 \text{ ksi})}{\left(1 - \frac{5.67 \text{ ksi}}{100 \text{ ksi}}\right)(21.6 \text{ ksi})} + 0$$
$$= 0.99 \leq 1.0 \quad \text{[OK]}$$

5. DESIGN OF BEAM-COLUMNS

In order to minimize the trial-and-error process of selecting a shape for combined axial and bending loads, Eqs. 62.3, 62.4, and 62.7 can be modified to allow the

use of the column tables in the *AISC Manual*. Nevertheless, such modifications still require a considerable amount of calculation. The *AISC Manual* suggests an alternate procedure that determines an equivalent axial load.

step 1: Determine the effective length, KL, based on the weak axis bending and bracing.

step 2: Use Table B in Part 3, Column Design, of the *AISC Manual* to obtain a value of the *equivalency factor*, m, for the first iteration.

step 3: Assume a value of U of 3. (Values of U for subsequent iterations can be read directly from the column table.)

step 4: Calculate the equivalent (effective) axial load. P is the actual axial load.

$$P_{\text{eff}} = P + M_x m + M_y m U \qquad 62.8$$

step 5: Select a column from the column table to support P_{eff} with an effective length of KL.

step 6: Return to Table B in the *AISC Manual* to obtain a revised value of m.

step 7: Read the U value for the column from the column table.

step 8: Repeat steps 4 through 7 to reduce the member weight until m and U remain constant.

This procedure tends to oversize beam-columns. More economical members can be found if the member initially selected is used as a starting point for a subsequent trial-and-error solution.

Example 62.2

Select an A36 W shape to carry an axial load of 200 kips and a moment of 250 ft-kips about the strong axis. The unsupported length is 20 ft. Assume $K = 1$.

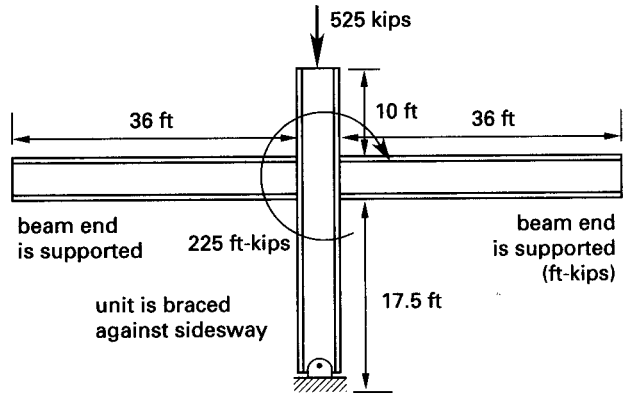
Solution

step 1: $KL = (1)(20 \text{ ft}) = 20 \text{ ft}$

step 2: $m = 2.0$ [all shapes, 20 ft]

step 3: $U = 3$ [not needed in this example]

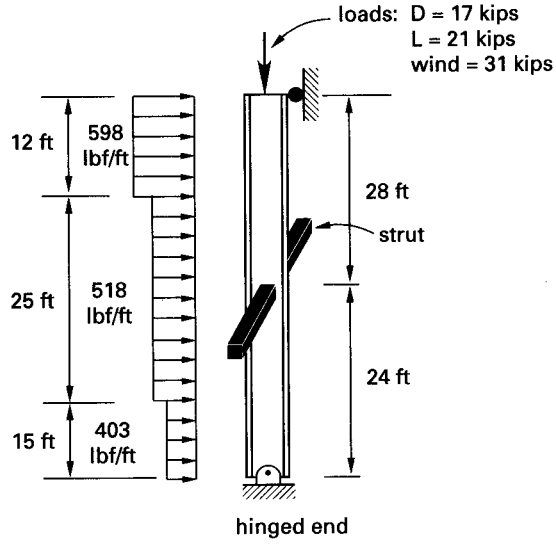
step 4: $P_{\text{eff}} = P + M_x m$
$= 200 \text{ kips} + (250 \text{ ft-kips})(2) = 700 \text{ kips}$



step 5: Try W 14×132, which has a capacity of 662 kips (close to 700 kips) at an unbraced length of 20 ft.

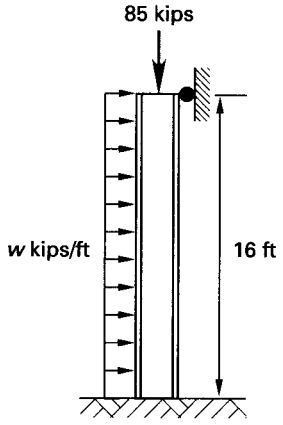
step 6: $m = 1.7$

step 7: $P_{\text{eff}} = P + M_x m$
$= 200 \text{ kips} + (250 \text{ kips})(1.7)$
$= 625 \text{ kips} < 662 \text{ kips}$ [OK]



PRACTICE PROBLEMS

1. (*Time limit: one hour*) A column carries an axial load of 525 kips as shown. The beams framing into it apply a moment of 225 ft-kips. Bracing is provided to prevent bending about the weak axis, which can be disregarded. All members are grade-50 steel. (a) If the column is W 14×82 and the beams are W 14×53, determine if the column is adequate. (b) If the design is inadequate, specify an acceptable W 14 grade-50 column.



Answers: (a) The column is inadequate. (b) The W 14×132 column is adequate.

2. (*Time limit: one hour*) A tall column in an industrial storage building carries the load shown. The lateral wind loads are carried into a braced frame. The column is braced in its weak direction by a strut 24 ft from the bottom hinged end. There is no support of the column compression flange along its length. Select an economical A36 W 24 section based on stress and deflection criteria.

Answer: W 24 × 117

3. (*Time limit: one hour*) A 16 ft column is acted upon by an axial gravity load of 85 kips and a uniform wind load of w (in kips/ft) as shown. The W 12×58 column is made of A572 grade-50 steel. The lower end is built in. The upper end is not supported in the weak direction.

(a) The actual axial stress in the member is most nearly
(A) 2.5 ksi
(B) 4.0 ksi
(C) 5.0 ksi
(D) 6.5 ksi

The answer is (C).

(b) The critical slenderness ratio is most nearly
(A) 39
(B) 98
(C) 160
(D) 190

The answer is (C).

(c) The allowable axial stress is most nearly
(A) 3 ksi
(B) 6 ksi
(C) 9 ksi
(D) 15 ksi

The answer is (B).

(d) The allowable bending stress is most nearly
(A) 22 ksi
(B) 27 ksi
(C) 30 ksi
(D) 33 ksi

The answer is (C).

(e) The actual bending stress, assuming $w = 4$ kips/ft, is most nearly
(A) 2 ksi
(B) 8 ksi
(C) 12 ksi
(D) 20 ksi

The answer is (D).

(f) The beam-column is subjected to
(A) small compression and is adequate.
(B) large compression and is adequate.
(C) small compression and is inadequate.
(D) large compression and is inadequate.

The answer is (D).

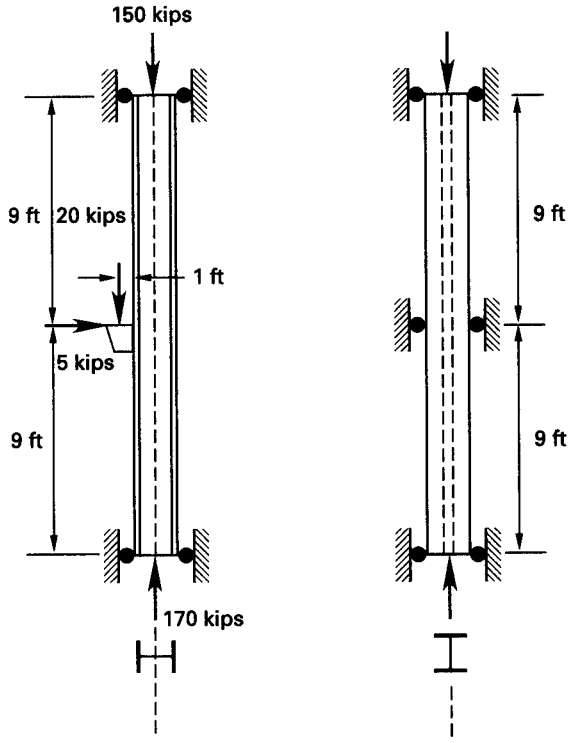
For parts (g) through (j), assume lateral bracing (pinned support) is provided in the weak direction at mid-height as well as at the top of the member.

(g) The critical slenderness ratio is most nearly
(A) 39
(B) 98
(C) 160
(D) 190

The answer is (A).

(h) The allowable axial stress is most nearly
(A) 18 ksi
(B) 21 ksi
(C) 26 ksi
(D) 32 ksi

The answer is (C).



(i) The allowable bending stress with respect to the strong axis is most nearly
(A) 22 ksi
(B) 27 ksi
(C) 30 ksi
(D) 33 ksi

The answer is (D).

(j) The maximum lateral wind load w the member can safely carry is most nearly
(A) 5.5 kips/ft
(B) 6.5 kips/ft
(C) 7.5 kips/ft
(D) 9.5 kips/ft

The answer is (C).

4. (*Time limit: one hour*) A W 14 × 48 member of A36 steel carries the service loads shown. The member is part of a braced system, and has support in the weak direction at mid-height, but it has support only at top and bottom for the strong direction.

(a) The maximum primary bending moment about the strong axis occurs

(A) at the top.
(B) at one-quarter height from top.
(C) at mid-height.
(D) at three-quarter height from top.

The answer is (C).

(b) The maximum primary bending moment about the strong axis is most nearly

(A) 28 ft-kips
(B) 33 ft-kips
(C) 40 ft-kips
(D) 43 ft-kips

The answer is (B).

(c) The slenderness ratio with respect to buckling about the weak axis is most nearly

(A) 27
(B) 37
(C) 47
(D) 57

The answer is (D).

(d) The slenderness ratio with respect to buckling about the strong axis is most nearly

(A) 27
(B) 37
(C) 47
(D) 57

The answer is (B).

(e) The critical slenderness ratio is most nearly

(A) 27
(B) 37
(C) 47
(D) 57

The answer is (D).

(f) The allowable axial stress is most nearly

(A) 9 ksi
(B) 12 ksi
(C) 18 ksi
(D) 21 ksi

The answer is (C).

(g) The actual bending stress is most nearly

(A) 5.5 ksi
(B) 6.7 ksi
(C) 10 ksi
(D) 14 ksi

The answer is (A).

(h) The ratio of actual axial stress to allowable axial stress is most nearly

(A) 0.12
(B) 0.37
(C) 0.51
(D) 0.68

The answer is (D).

(i) The allowable bending stress is most nearly

(A) 16 ksi
(B) 18 ksi
(C) 22 ksi
(D) 24 ksi

The answer is (C).

(j) The beam-column is subjected to

(A) small compression and is adequate.
(B) large compression and is adequate.
(C) small compression and is inadequate.
(D) large compression and is inadequate.

The answer is (B).

1. INTRODUCTION

Plate girders are used when beams with moments of inertia larger than standard mill shapes are required. Figure 63.1 illustrates two different methods of constructing plate girders. One is built up by bolting or riveting. The other is welded. A *hybrid girder* is a plate girder that uses stronger steel for the flanges than for the web. Hybrid girders can be less expensive than traditional plate girders.

Two different definitions of "depth" are encountered with plate girders: the *web depth*, h, and the *girder depth*, d. Unlike for rolled shapes, only the web depth, h, is used for shear stress calculations. For depth thickness (h/t) ratios, the AISC Specifications require h to be the clear distance between flanges. For bolted or riveted flanges, this distance is the separation between the last row of fasteners. For welded flanges, the distinction is not made.

The girder depth, d, is generally chosen to be approximately one tenth of the span, although the ratio can vary from 1:5 to 1:15.

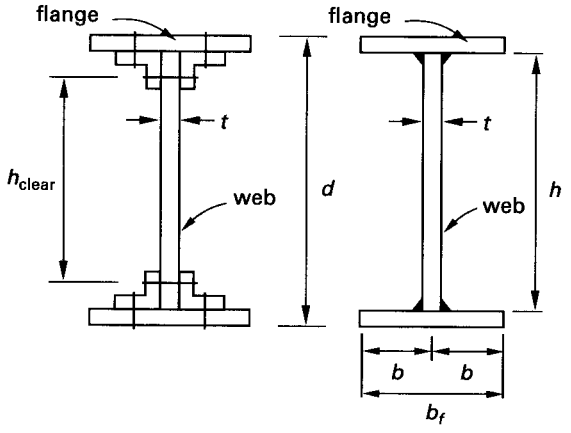

Figure 63.1 *Elements of a Plate Girder*

2. DEPTH-THICKNESS RATIOS

The required web thickness, t_w, depends on the spacing of intermediate stiffeners. If intermediate stiffeners are spaced no more than $1.5d$ (i.e., 150% of the girder depth), then Eq. 63.1 gives the maximum permissible depth-thickness ratio. If h is known, the required thickness, t_w, can be obtained [AISC Eq. G1-2].

$$\frac{h}{t_w} \leq \frac{2000}{\sqrt{F_y}} \qquad 63.1$$

If intermediate stiffeners are spaced more than $1.5d$, then Eq. 63.2 governs the depth-thickness ratio [AISC Eq. G1-1].

$$\frac{h}{t_w} \leq \frac{14{,}000}{\sqrt{F_{yf}(F_{yf}+16.5)}} \qquad 63.2$$

If h/t_w satisfies Eq. 63.2 and is also less than 260, and if the shear stress is less than the allowable value, no intermediate stiffeners are required. (Bearing stiffeners are still required at reaction and loading points, however.) In other cases, actual stiffener spacing will depend on the shear stress [*AISC Specifications* Sec. F5].

3. SHEAR STRESS

The average shear stress on the web is

$$f_v = \frac{V_{\max}}{ht_w} \qquad 63.3$$

Since it is a function of a/h (the ratio of stiffener spacing to web depth), the allowable shear stress, F_v, is usually obtained from Tables 1-36 and 1-50 of Part 2 of the *AISC Manual*. However, the allowable shear stress may also be calculated. For $h/t_w \leq 380/\sqrt{F_y}$, F_v is limited to $0.40F_y$. Equations 63.4 through 63.8 are used if $h/t_w > 380/\sqrt{F_y}$.

$$F_v = \frac{C_v F_y}{2.89} \leq 0.40F_y \qquad 63.4$$

$$C_v = \frac{45{,}000k_v}{F_y\left(\frac{h}{t_w}\right)^2} \quad [C_v < 0.8] \qquad 63.5$$

$$C_v = \left(\frac{190}{\frac{h}{t_w}}\right)\sqrt{\frac{k_v}{F_y}} \quad [C_v > 0.8] \qquad 63.6$$

$$k_v = 4.00 + \frac{5.34}{\left(\frac{a}{h}\right)^2} \quad \left[\frac{a}{h} < 1.0\right] \qquad 63.7$$

$$k_v = 5.34 + \frac{4.00}{\left(\frac{a}{h}\right)^2} \quad \left[\frac{a}{h} > 1.0\right] \qquad 63.8$$

In Eqs. 63.7 and 63.8, a is the clear distance between intermediate stiffeners. When a/h is very large or when there are no stiffeners, $k = 5.34$. In that case, Eq. 63.9 and 63.10 give the allowable shear stress. F_v is still limited to $0.40F_y$.

$$F_v = \frac{152\sqrt{F_y}}{\frac{h}{t}} \quad \left[\frac{h}{t} < \frac{548}{\sqrt{F_y}}\right] \qquad 63.9$$

$$F_v = \frac{83{,}150}{\left(\frac{h}{t}\right)^2} \quad \left[\frac{h}{t} > \frac{548}{\sqrt{F_y}}\right] \qquad 63.10$$

4. DESIGN OF GIRDER WEBS

Generally, plate girder web thickness is designed based on shear stress, using Eq. 63.3. Calculating the web thickness to achieve full flange compression (from Eq. 63.11) will result in thicker webs, more weight, and higher cost. However, this equation can be used to determine if the allowable flange stress will be reduced. If the thickness is less than that determined from Eq. 63.11, the allowable flange stress will be reduced from the basic bending allowance.

5. DESIGN OF GIRDER FLANGES

To design the girder flanges, an initial estimate of the allowable bending stress in the flanges must be made. Theoretically, $F_b = 0.60F_y$ could be chosen. However, the allowable bending stress is a function of the depth-thickness ratio when Eq. 63.11 holds. If h/t is greater than $760/\sqrt{F_b}$, a lower value of F_b must be used. (F_b can be reduced approximately 10%. Very large reductions in bending stress underutilize the flange area.)

$$\frac{h}{t} > \frac{760}{\sqrt{F_b}} \qquad 63.11$$

Equation 63.12, derived from basic mechanics principles, gives an initial estimate of the required flange area. Since the moment varies along the beam length, girder flanges do not have to be the same thickness along the entire plate girder length. It is possible to substitute thinner flanges near the ends of beams or to add cover plates near the midpoints of beams.

$$A_f = \frac{M_x}{F_b h} - \frac{th}{6} \qquad 63.12$$

Once the flange area is known, trial flange widths and thicknesses can be evaluated.

$$A_f = b_f t_f \qquad 63.13$$

The limitations in available plate thicknesses should be considered when choosing t_f. Alternatively, b_f can be chosen based on b_f/d ratios, which typically vary between 0.2 and 0.3. Flange plate widths are typically rounded to the nearest 2 in.

6. WIDTH-THICKNESS RATIOS

The width-thickness ratios specified in Chap. 61 apply to plate girders as well. Specifically, for unstiffened plates such as plate girder flanges, Eq. 63.14 should be used.

$$\frac{b}{t_f} < \frac{95}{\sqrt{\frac{F_y}{k_c}}} \qquad 63.14$$

$$b = \frac{b_f}{2} \qquad 63.15$$

For stiffened plates, such as plate girder webs, Eqs. 63.1 and 63.2 are applicable [AISC Eqs. G1-1 and G1-2].

7. REDUCTION IN FLANGE STRESS

Once a trial design of the plate girder has been made, its moment of inertia can be determined by standard methods. The expected stress based on assumed elastic behavior is calculated and compared to the allowable stress F_b'.

It was noted in Sec. 5 that the allowable bending stress must be reduced if $h/t_w > 760/\sqrt{F_b}$ (or $970/\sqrt{F_y}$, which is even larger). Equation 63.16 gives the reduced stress for nonhybrid girders. A_w is the area of the web and A_f is the area of the compression flange [AISC Sec. G2].

$$F_b' \le F_b\left(1.0 - 0.0005\left(\frac{A_w}{A_f}\right)\left(\frac{h}{t} - \frac{760}{\sqrt{F_b}}\right)\right) \quad 63.16$$

$$A_w = ht \quad 63.17$$

$$A_f = b_f t_f \quad 63.18$$

8. LOCATION OF FIRST (OUTBOARD) STIFFENERS

The first intermediate stiffeners can be located where the shear stress exceeds Eq. 63.4 ([F4-2]). In practice, a trial distance a ($a/h < 1.0$) is selected as the separation between the end panel and the first intermediate stiffener. F_v is calculated from Eq. 63.4 and compared to the maximum value of f_v obtained from Eq. 63.3 and the shear diagram. If F_v is greater than f_v, the location is adequate. Otherwise, a smaller value of the spacing, a, should be tried.

9. LOCATION OF INTERIOR STIFFENERS

The spacing, a, of interior intermediate stiffeners should not exceed the value determined from Eq. 63.19 [AISC Eq. F5-1].

$$\frac{a}{h} \le \left(\frac{260}{\left(\frac{h}{t_w}\right)}\right)^2 \le 3.0 \quad 63.19$$

The spacing calculated from Eq. 63.19 is valid as long as the shear stress does not exceed the value from Eq. 63.4. In beams where the maximum shear occurs near the ends, the spacing chosen for the first interior stiffener will be adequate for the entire beam length. However, this explains the need to work with the largest shear when establishing an initial trial spacing.

If Eq. 63.19 is met and if $C_v \le 1.0$, then Eq. 63.20 [AISC Eq. G3-1] can be used in place of Eq. 63.4 [AISC Eq. F4-2]. This is the *tension field action equation.* Use of Eq. 63.20 places an additional restraint on the allowable bending stress in the girder web.

$$F_v = \frac{F_y}{2.89}\left(C_v + \frac{1 - C_v}{1.15\sqrt{1 + \left(\frac{a}{h}\right)^2}}\right) \le 0.40F_y \quad 63.20$$

In lieu of Eq. 63.20, Tables 2-36 and 2-50 of the *AISC Manual* Part 2 can be used.

10. MAXIMUM BENDING STRESS

Plate girders that have been designed according to tension field concepts (i.e., that have used Eq. 63.20 to determine stiffener spacing) are limited to the web bending stress in Eq. 63.21 [AISC Eq. G5-1]. F_v in Eq. 63.21 is calculated from the tension field action equation, Eq. 63.20. If the computed bending stress limitation of Eq. 63.21 is not satisfied, the stiffener spacing must be reduced.

$$f_b \le \left(0.825 - 0.375\left(\frac{f_v}{F_v}\right)\right)F_y < 0.60F_y \quad 63.21$$

11. DESIGN OF INTERMEDIATE STIFFENERS

Intermediate stiffeners are used to support the flange and prevent buckling. They may be constructed from plates or angles and may be used either singly or in pairs. Unlike stiffeners that transmit reactions and loads, intermediate stiffeners do not need to extend completely from the top to bottom flanges, but they must be fastened to the compression flange to resist uplift. The *AISC Specifications* contains limitations on weld and rivet spacing.

Intermediate stiffeners are sized by their gross steel area, as calculated from the steel area in contact with the compression flange. Thus, the width and thickness are used to calculate the stiffener area, not the width and depth. Equation 63.22 gives the steel area at a particular location [AISC G4-2]. This area can be divided between two stiffeners or given to a single stiffener. In Eq. 63.22, D is 1.0 for stiffeners furnished in pairs and is 2.4 for single plate stiffeners. D is 1.8 for single-angle stiffeners.

$$A_{st} = \left(\frac{1 - C_v}{2}\right)\left(\frac{a}{h} - \frac{\left(\frac{a}{h}\right)^2}{\sqrt{1 + \left(\frac{a}{h}\right)^2}}\right)\left(\frac{F_{y,\text{web}}}{F_{y,\text{stiffener}}}\right)Dht_w \quad 63.22$$

Structural

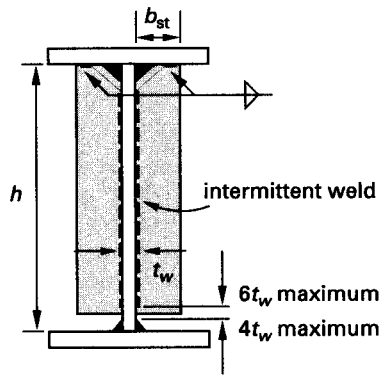

Figure 63.2 *Intermediate Stiffeners*

If the actual stress, f_v, at the point where the bearing stiffener is located is less than the allowable shear stress as calculated from Eq. 63.20, then the stiffener area may be reduced proportionally [*AISC Specifications* Sec. G4].

$$A'_{st} = \left(\frac{f_v}{F_v}\right) A_{st} \qquad 63.23$$

The stiffener's moment of inertia, I_{st}, is taken with respect to an axis in the plane of the girder web. If two stiffeners are used, b_{st} is the total of both their widths.

$$I_{st} = \frac{t_{st} b_{st}^3}{12} \qquad 63.24$$

To be significant, the stiffener must have sufficient stiffness itself. Equation 63.25 is a lower limit on the moment of inertia [AISC Eq. G4-1].

$$I_{st} \geq \left(\frac{h}{50}\right)^4 \qquad 63.25$$

12. DESIGN OF BEARING STIFFENERS

Bearing stiffeners are used to transmit loads and reactions from one flange to the others. Bearing stiffeners that transmit loads and reactions must extend from flange to flange. There is no single formula for calculating the thickness of bearing stiffeners. Stiffener thickness is the maximum thickness determined from evaluations of the bearing stress, width-thickness ratio, column stress, and compression yield criteria.

The bearing pressure on bearing stiffeners is limited to $0.90F_y$ [*AISC Specification* Sec. J8]. Such stiffeners must essentially extend from the web to the edge of the flanges. Therefore, this criterion establishes one method of determining the bearing stiffener thickness. However, other criteria must also be met (see Sec. 13). The width is essentially fixed by the flange dimension. So only the thickness needs to be determined. Also, bearing stiffeners should have close contact against the flanges.

Since the stiffener is loaded as a column, it must satisfy the width-thickness ratio for an unstiffened element.

$$\frac{b_{st}}{t_{st}} \leq \frac{95}{\sqrt{F_y}} \qquad 63.26$$

The stiffener should be designed as a column with an effective length equal to $0.75h$, with a cross section composed of a pair of stiffeners, and a strip of the web having a width of either (a) $25t_w$ at interior concentrated loads or (b) $12t_w$ at the ends of members [*AISC Specification* Sec. K1.8].

For the purpose of determining the slenderness ratio, the radius of gyration, r, can be determined exactly or it can be approximated as 0.25 times the stiffener edge-to-edge distance.

$$\frac{l}{r} = \frac{0.75h}{0.25(2b_{st} + t_w)} \qquad 63.27$$

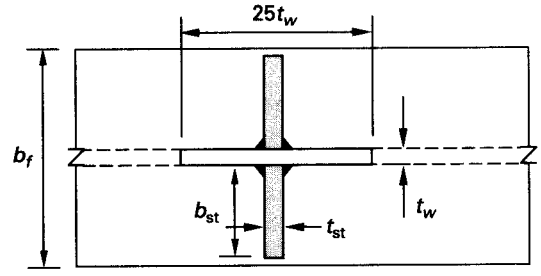

Figure 63.3 *Bearing Stiffener (top view)*

Once the l/r ratio is known, it can be used (as Kl/r) to determine the allowable compressive stress, F_a. However, some of the web supports the load. Specifically, 25 times the web thickness is the contributing area at an interior concentrated load. Therefore, the required stiffener thickness based on column stress is

$$t_{st} = \frac{\dfrac{\text{load}}{F_a} - 25t_w^2}{2b_{st}} \qquad 63.28$$

Compression yielding of stiffeners should also be considered when determining stiffener thickness. Compressive stress is limited to $0.60F_y$. Therefore, the thickness is

$$t_{st} = \frac{\dfrac{\text{load}}{0.60F_y}}{2b_{st}} \qquad 63.29$$

If column stability is not the factor controlling stiffener thickness, the larger thickness could conceivably increase the slenderness ratio and reduce the allowable compressive stress even further. This should be checked, but it is not likely to be a factor.

13. SPECIAL DESIGN CONSIDERATIONS FOR CONCENTRATED FORCES

The *AISC Specifications* Sec. K1 contains provisions to determine if the web is capable of supporting the concentrated forces (loads or reactions) without experiencing local web yielding, web crippling, or sidesway web buckling. The need for bearing stiffeners to preclude local web yielding is ascertained from AISC equations [K1-2] and [K1-3]. AISC equations [K1-4] and [K1-5] determine the maximum load that can be applied before stiffeners are required from web-crippling criterion. If stiffeners are provided and extend at least one-half the web depth, equations [K1-4] and [K1-5] need not be checked. Equations [K1-6] and [K1-7] are used to check if bearing stiffeners are needed to prevent sidesway web buckling. If the term $(d_c/t_w)/(l/b_f)$ in equations [K1-6] and [K1-7] exceeds 2.3 or 1.7, respectively, then these two equations need not be checked.

14. DESIGN PROCESS SUMMARY

The following steps summarize plate girder design. Using the design aids provided in the *AISC Manual* (Table of Welded Plate Girders—Dimensions and Properties and others in Part 2, and Numerical Values Table 5 in Part 5) will reduce computations significantly.

step 1: Select the overall depth.

step 2: Select a trial web size.

step 3: Estimate the flange size.

step 4: Determine the moment of inertia and check the bending stress.

step 5: Check for combined shear and bending stresses (for tension field action).

step 6: Design intermediate stiffeners, if any.

step 7: Check for web resistance to applied concentrated loads and/or support reactions and design bearing stiffeners, if needed.

step 8: Design the welds for flange-to-web and stiffener-to-web connections.

Example 63.1

Design a welded plate girder of A36 steel with no intermediate stiffeners to carry a load of 2.5 kips/ft on a simple span of 60 ft. The depth of the girder is restricted to 50 in. The compression flange is laterally supported throughout the girder span.

Solution

The maximum shear is

$$V_{\max} = \frac{wL}{2} = \frac{\left(2.5\ \frac{\text{kips}}{\text{ft}}\right)(60\ \text{ft})}{2} = 75\ \text{kips}$$

The maximum moment is

$$M_{\max} = \frac{wL^2}{8} = \frac{\left(2.5\ \frac{\text{kips}}{\text{ft}}\right)(60\ \text{ft})^2}{8} = 1125\ \text{ft-kips}$$

Assume the allowable bending stress is

$$F_b = 0.6F_y = (0.6)(36\ \text{ksi}) = 21.6\ \text{ksi}$$

The required elastic section modulus is

$$S_x = \frac{M_{\max}}{F_b} = \frac{(1125\ \text{ft-kips})\left(12\ \frac{\text{in}}{\text{ft}}\right)}{21.6\ \frac{\text{kips}}{\text{in}^2}} = 625\ \text{in}^3$$

Refer to the *AISC Manual*, Part 2, Welded Plate Girder Dimensions and Properties, and try a nominal size of 45×16.

web: 44 × 5/16 plate
flanges: two 16 × 3/4 plates
$S_x = 626\ \text{in}^3$

The area of the web is

$$A_w = 44\ \text{in} \times \tfrac{5}{16}\ \text{in} = 13.75\ \text{in}^2$$

The web depth-to-thickness ratio is

$$\frac{h}{t_w} = \frac{44\ \text{in}}{\frac{5}{16}\ \text{in}} = 141$$

From the *AISC Manual*, Part 2, Table 1-36 (by interpolation), for $h/t_w = 141$ and $a/h > 3$, $F_v = 4.15$ ksi. The allowable vertical shear is

$$V_{\text{allowable}} = F_v A_w = \left(4.15\ \frac{\text{kips}}{\text{in}^2}\right)(13.75\ \text{in}^2) = 57\ \text{kips} < 75\ \text{kips} \quad \text{[no good]}$$

Try a thicker, 3/8 in, web plate.

$$A_w = (44\ \text{in})\left(\tfrac{3}{8}\ \text{in}\right) = 16.5\ \text{in}^2$$

From the *AISC Manual*, Part 2, Table 1-36 (by interpolation), for $h/t_w = 117.3$ and $a/h > 3$, $F_v = 6.0$ ksi. The allowable vertical shear is

$$V_{\text{allowable}} = F_v A_w = \left(6.0\ \frac{\text{kips}}{\text{in}^2}\right)(16.5\ \text{in}^2) = 99\ \text{kips} > 75\ \text{kips} \quad \text{[OK]}$$

Check the allowable bending stress.

$$\frac{h}{t_w} = 117.3 < \frac{970}{\sqrt{F_y}} = 161.7$$

No reduction in allowable bending stress for flanges is required. The plate girder is constructed from one 3/8 in × 44 in plate for the web and two 3/4 in × 16 in plates for the flanges.

PRACTICE PROBLEMS

1. A simply supported plate girder spans 40 ft and is constructed with 3/8 in A36 steel plates. The flanges are 16 in wide and the web is 48 in deep. A uniform but unknown load is carried across the girder's entire length. (a) Based on shear consideration only, determine the maximum uniform load (in kips/ft) that the beam can carry. (b) A36 web stiffeners are used in pairs and are placed every 4 ft. Design the web stiffeners located 4 ft from the supports.

Answers: (a) 13 kips/ft, (b) use 3/8 in × 1 1/2 in × 3 ft 10 in stiffeners on each side.

2. A welded A36 plate girder with a 60 ft span has to carry a uniformly distributed load of 2 kips/ft, its own weight, and a concentrated load of 135 kips at midspan. Lateral support is provided for the compression flange at beam ends and at midspan. No intermediate stiffeners are to be used. The web-to-flange weld size is $w = 5/16$ in. The length of bearing under the concentrated load is $N = 10$ in. (a) Design the girder cross section such that the overall girder depth does not exceed 60 in. (b) Design the bearing stiffeners.

Answers: (a) web plate: 1/2 in × 52 in, flange plates: 1 3/4 in × 18 in; (b) 1/2 in × 7 1/2 in × 4 ft 7 1/4 in on each side

3. (*Time limit: one hour*) A simply supported plate girder with a 60 ft span is composed of 1 1/2 in × 16 in flanges and a 3/8 in × 64 in web. A36 steel is used. The girder supports a uniformly distributed service load of 2 kips/ft (including the girder weight) over the entire span and two concentrated service loads of 50 kips magnitude each, placed symmetrically one third of the span from each end. Lateral supports for the compression flange are provided at the beam ends and the concentrated load points. Except for bearing stiffeners at the supports and concentrated loads, no transverse stiffeners are provided.

(a) The actual value and the allowable limit of web depth-thickness ratio to prevent vertical buckling of the compression flange into the web are, respectively, most nearly

(A) 171 and 322
(B) 171 and 333
(C) 179 and 322
(D) 179 and 333

The answer is (A).

(b) The moment of inertia about the strong axis is most nearly

(A) 50,000 in^4
(B) 54,000 in^4
(C) 60,000 in^4
(D) 61,000 in^4

The answer is (C).

(c) The maximum service load shear is most nearly

(A) 85 kips
(B) 110 kips
(C) 130 kips
(D) 160 kips

The answer is (B).

(d) The maximum service load moment is most nearly

(A) 1600 ft-kips
(B) 1800 ft-kips
(C) 1900 ft-kips
(D) 2000 ft-kips

The answer is (C).

(e) The maximum computed bending stress due to service loads is most nearly

(A) 12 ksi
(B) 13 ksi
(C) 19 ksi
(D) 23 ksi

The answer is (B).

(f) The allowable bending stress in the compression flange (at the location of maximum computed bending stress) is most nearly

(A) 18.6 ksi
(B) 19.4 ksi
(C) 21.3 ksi
(D) 23.8 ksi

The answer is (C).

(g) The maximum computed shear stress due to service loads is most nearly

(A) 4.6 ksi
(B) 5.8 ksi
(C) 6.8 ksi
(D) 7.1 ksi

The answer is (A).

(h) The allowable shear stress is most nearly

(A) 1.6 ksi
(B) 2.9 ksi
(C) 4.5 ksi
(D) 8.2 ksi

The answer is (B).

(i) The plate girder is adequate for
(A) moment only
(B) shear only
(C) both moment and shear
(D) neither moment nor shear

The answer is (A).

(j) Assuming the web plate thickness is changed to $^5/_8$ in, the plate girder is adequate for
(A) moment only
(B) shear only
(C) both moment and shear
(D) neither moment nor shear

The answer is (C).

4. (*Time limit: one hour*) A simply supported welded plate girder having a 72 ft span carries a uniformly distributed load of 2 kips/ft and a concentrated load of 120 kips 24 ft from the left end. A572 grade-50 steel is used. The web is $^3/_8$ in thick and 48 in deep. Each flange is $1^1/_2$ in thick and 16 in wide. Bearing stiffeners are provided at the reaction points and at the concentrated load.

(a) The maximum shear force the plate girder can carry without any intermediate stiffener is most nearly
(A) 83 kips
(B) 91 kips
(C) 100 kips
(D) 120 kips

The answer is (B).

(b) The maximum allowable spacing for the first intermediate stiffener from the left end is most nearly
(A) 51 in
(B) 55 in
(C) 60 in
(D) 70 in

The answer is (A).

(c) If the first intermediate stiffener is placed 48 in from the left end, the maximum allowable spacing for the next stiffener is most nearly
(A) 50 in
(B) 55 in
(C) 60 in
(D) 70 in

The answer is (B).

(d) Assuming a single plate is to be used, the minimum size required for the first intermediate stiffener from the left end is most nearly
(A) 1.3 in^2
(B) 1.8 in^2
(C) 2.1 in^2
(D) 2.5 in^2

The answer is (B).

(e) The maximum bending stress at the concentrated load is most nearly
(A) 18 ksi
(B) 24 ksi
(C) 29 ksi
(D) 32 ksi

The answer is (C).

(f) Assuming that intermediate stiffeners are provided every 4 ft throughout the girder span, the actual shear stress and the allowable tensile stress, respectively, at the concentrated load are most nearly
(A) 4.6 ksi and 32 ksi
(B) 5.8 ksi and 30 ksi
(C) 6.5 ksi and 28 ksi
(D) 7.3 ksi and 26 ksi

The answer is (B).

(g) The bearing stiffener size that will satisfy the width-thickness ratio requirement is most nearly
(A) $^1/_4$ in × 6 in
(B) $^3/_8$ in × 7 in
(C) $^3/_8$ in × $7^1/_2$ in
(D) $^1/_2$ in × $6^1/_2$ in

The answer is (D).

(h) Assuming two matched $^1/_2$ in × 7 in bars are used for end bearing stiffening, the total radius of gyration of the bearing stiffener is most nearly
(A) 2.0 in
(B) 2.6 in
(C) 3.8 in
(D) 4.1 in

The answer is (C).

(i) The computed stress and the allowable stress, respectively, in the end bearing stiffener are most nearly
(A) 7.6 ksi and 17.8 ksi
(B) 8.4 ksi and 29.3 ksi
(C) 10.1 ksi and 24.2 ksi
(D) 12.3 ksi and 32.1 ksi

The answer is (B).

(j) Assume that no intermediate stiffeners are to be used and only bearing stiffeners are to be provided at the beam ends and the concentrated load. The required minimum thickness of the web is most nearly
(A) $^7/_{16}$ in
(B) $^1/_2$ in
(C) $^9/_{16}$ in
(D) $^5/_8$ in

The answer is (B).

1. INTRODUCTION

Composite construction usually refers to a construction method in which a cast-in-place concrete slab is bonded to steel beams, girders, or decking below, such that the two materials act as a single unit. Although there are varying degrees of composite action, the concrete usually becomes the compression flange of the composite beam, and the steel carries the tension.

There are two types of composite beams: (a) steel beams fully encased in concrete so that the natural bond between the two materials holds them together, and (b) nonencased steel beams attached to the concrete slab (solid or on formed steel deck) by mechanical anchorage (i.e., shear connectors). In this chapter, only the more common second type is discussed.

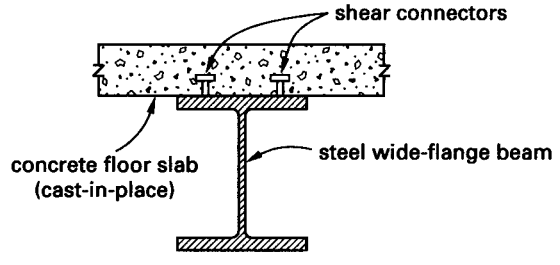

Figure 64.1 *Typical Composite Beam Cross Section*

Structural

Composite construction is often used for bridge decks and building floors. In general, a composite floor system is stronger and stiffer than its noncomposite counterpart using the same size beams. For a given steel member cross section, the advantages of composite construction are increased load capacity and span length. Although there are no major disadvantages in composite construction, two limitations—the effect of continuity and long-term deflection (creep)—should be recognized.

Composite construction is carried out with or without temporary *shoring*. If the steel is erected and concrete is poured without temporary shoring (i.e., construction is unshored), the combination will act compositely to carry only the loads that are applied after the concrete cures. Conversely, in fully shored construction, a temporary support carries both the steel and concrete weights until the concrete has cured. When the shore is removed, the beam acts compositely to carry the steel and concrete weights in addition to live loads applied later.

The design of steel beams/girders can be based on the assumption of composite action in accordance with the *AISC Specifications* Ch. I, provided that (a) the concrete slab supported by the steel beams is adequate to effectively serve as the flange of a composite T-beam, and (b) the concrete and steel are adequately tied together with mechanical anchorage (shear connectors) to act as one unit with no relative slippage. Development of full or partial composite action depends on the quantity of shear connectors. However, usually it is not necessary, and sometimes it is not feasible, to provide full composite action.

2. EFFECTIVE WIDTH OF CONCRETE SLAB

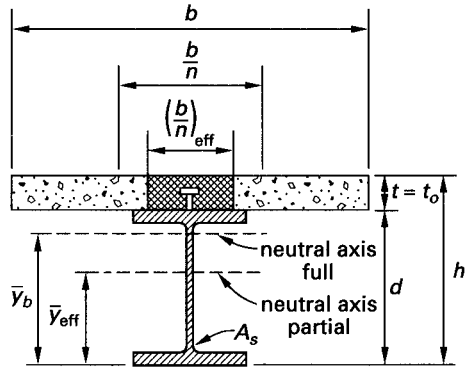
In a composite beam, the bending stresses in the concrete slab depend on the spacing of the steel beams. The slab bending stresses are uniformly distributed across the compression zone for closely spaced beams. However, the stresses vary considerably and are nonlinear across the compression flange when beams are placed far apart: The farther away a part of the slab is from the steel beam, the smaller is the stress in it.

AISC Specifications Sec. I1 simplifies this issue of varying stresses by replacing the actual slab with an "equivalent" narrower or "effective" slab that has a constant stress. This equivalent slab is considered to carry the same total compression as that supported by the actual slab. For an interior beam with slab extending on both sides, the effective width, b, of the concrete slab is given by Eq. 64.1, where L is the beam span and s is the spacing between beam centerlines. (For an exterior beam, s is replaced by $e + s/2$, where e is the distance from the beam centerline to the edge of the slab.)

$$b = \text{smaller of} \left\{ \begin{array}{c} \dfrac{L}{4} \\ s \end{array} \right\} \quad \text{[interior beams]} \qquad 64.1$$

3. SECTION PROPERTIES

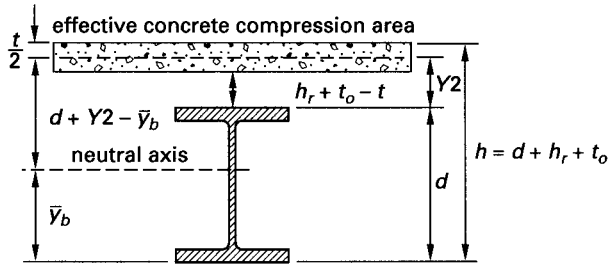
The moment of inertia and section modulus of a composite beam are computed in accordance with the elastic theory, using the transformed area method. Unlike reinforced concrete design (where the steel area is transformed into an equivalent concrete area), however, the actual area of effective concrete flange is transformed into an equivalent steel area by dividing it by the *modular ratio*, n. The concrete modulus of elasticity is calculated from the ACI formula for a secant modulus as a function of unit weight.



$$n = \frac{E}{E_c} \qquad 64.2$$

To determine the section properties of a fully composite beam (with a solid slab or a slab on formed steel deck), the distance from the neutral axis to the bottom of the steel beam, $\overline{y}_b$, is first determined using Eq. 64.3. A_s is the area of the steel beam, and d is the depth of the steel beam [Part 2 of the *AISC Manual*, General Notes: Composite Design, Eq. 5].

$$\overline{y}_b = \frac{A_s\left(\dfrac{d}{2}\right) + A_{\text{ctr}}(d + Y2)}{A_s + A_{\text{ctr}}} \qquad 64.3$$



The transformed area of concrete is given by Eq. 64.4, where t is the thickness of concrete in compression.

$$A_{\text{ctr}} = \left(\frac{b}{n}\right) t \qquad 64.4$$

[a]This figure depicts the neutral axis as being located within the steel beam, which is usually the case.

Figure 64.2 *Nomenclature for Composite Beam with Solid Slab*[a]

[a]This figure depicts the neutral axis as being located within the steel beam, which is usually the case.

Figure 64.3 *Nomenclature for Fully Composite Beam with Steel Deck*[a]

The *transformed moment of inertia*, I_{tr}, and the section modulus, S_{tr}, of the transformed section referred to the bottom of the steel beam are obtained from Eqs. 64.5 [AISC Sec. 2, Composite Design, Eq. 7] and 64.6, respectively. In Eq. 64.8, h_r is the nominal rib height for the steel deck and t_o is the thickness of the concrete slab above the steel deck. (For concrete on a steel deck, t in Eq. 64.5 is often conservatively assumed to be only the thickness, t_o, of the concrete topping above the deck.)

$$I_{tr} = I_s + A_s\left(\overline{y}_b - \frac{d}{2}\right)^2 + \left(\tfrac{1}{12}\right)\left(\frac{b}{n}\right)t^3 + A_{ctr}(d + Y2 - \overline{y}_b)^2 \qquad 64.5$$

$$S_{tr} = \frac{I_{tr}}{\overline{y}_b} \qquad 64.6$$

$$Y2 = \frac{t}{2} \quad \text{[with solid slab]} \qquad 64.7$$

$$Y2 = h_r + \frac{t_o}{2} \quad \text{[with slab on metal deck]} \qquad 64.8$$

The *section modulus*, S_t, of the transformed section referred to the top of concrete is calculated using Eq. 64.9. h is the total depth from the bottom of the steel beam to the top of concrete. For a given steel beam and a concrete slab, the b/n term in Eq. 64.4 is the transformed effective width of the concrete slab for full composite action, assuming an adequate number of shear connectors are provided to develop the largest possible section properties I_{tr}, S_{tr}, and S_t.

$$S_t = \frac{I_{tr}}{h - \overline{y}_b} \qquad 64.9$$

For partial composite action to any degree, the *transformed effective width* of the concrete slab, denoted by $(b/n)_{eff}$, can be obtained from Eq. 64.10 (for solid slabs) or Eq. 64.11 (for slabs on a steel deck).

$$\left(\frac{b}{n}\right)_{eff} = \left(\frac{A_s}{t}\right)\left(\frac{\overline{y}_{eff} - \frac{d}{2}}{d + \frac{t}{2} - \overline{y}_{eff}}\right) \le \frac{b}{n} \quad \text{[solid slab]} \qquad 64.10$$

$$\left(\frac{b}{n}\right)_{eff} = \left(\frac{A_s}{t}\right)\left(\frac{\overline{y}_{eff} - \frac{d}{2}}{d + Y2 - \overline{y}_{eff}}\right) \le \frac{b}{n} \quad \text{[slab on steel deck]} \qquad 64.11$$

The distance of the neutral axis from the bottom of the steel beam for partial composite action to any degree is obtained from Eq. 64.12 [*AISC Specifications* Sec. 2, Composite Design, Eq. 1].

$$\overline{y}_{eff} = \frac{I_{eff}}{S_{eff}} \qquad 64.12$$

The *effective section modulus*, S_{eff} in Eq. 64.12, corresponding to the partial composite section is determined by Eq. 64.13 [*AISC Specifications*, Eq. I2-1]. In Eq. 64.13, S_s is the section modulus of the steel beam referred to its bottom flange, and S_{tr} is the section modulus of the transformed composite section referred to its bottom flange, based upon the maximum permitted effective width of concrete flange.

$$S_{eff} = S_s + \sqrt{\frac{V'_h}{V_h}}(S_{tr} - S_s) \qquad 64.13$$

V_h is the total horizontal shear to be resisted by the connectors between the point of maximum positive moment and points of zero moment under full composite action, obtained as the smaller value using Eqs. 64.14 and 64.15 [*AISC Specifications*, Eqs. I4-1 and I4-2]. A_c is the actual area of effective concrete flange. (For continuous composite beams where longitudinal reinforcing steel is considered to act compositely with the steel beam in the negative moment region, *AISC Specifications* Eq. I4-3 is used to determine the total horizontal shear V_h between an interior support and an adjacent point of contraflexure.)

$$V_h = \frac{0.85 f'_c A_c}{2} \qquad 64.14$$

$$V_h = \frac{F_y A_s}{2} \qquad 64.15$$

V'_h is the total horizontal shear to be resisted by the connectors between the point of maximum positive moment and points of zero moment under partial composite action, obtained from Eq. 64.16 [*AISC Specifications* I4]. q is the allowable horizontal shear load for one connector as obtained from AISC Tables I4.1 and I4.2. (For composite beams or girders with formed steel deck, tabulated q values must be multiplied by a reduction factor determined by AISC Eqs. I5-1 or I5-2.) $N1$ is the number of connectors furnished between the point of maximum moment and the nearest point of zero moment. The value of V'_h is not permitted to be less than one-quarter of the smaller value from Eqs. 64.14 and 64.15.

$$V'_h = qN_1 \qquad 64.16$$

Equation 64.13 provides the effective section modulus for composite action to any degree depending on the number of shear connectors actually provided. The smallest value of S_{eff} is S_s, representing no composite action (i.e., when no shear connectors are provided and hence V'_h equals zero). Conversely, the largest value of S_{eff} is S_{tr}, which represents full composite action (i.e., when all the required shear connectors are provided and the quantity under the square root becomes 1.0).

The *effective moment of inertia*, I_{eff}, in Eq. 64.12 is found from Eq. 64.17 [AISC Eq. I4-4]. I_s is the moment of inertia of the steel beam, and I_{tr} is the moment of inertia of the transformed composite section.

$$I_{eff} = I_s + \sqrt{\frac{V'_h}{V_h}}(I_{tr} - I_s) \qquad 64.17$$

Structural

The section modulus of a partially composite beam referred to the top of concrete, $S_{t,\text{eff}}$, is obtained from Eq. 64.18 [*AISC Specifications* Sec. 2, Composite Design, Eq. 3].

$$S_{t,\text{eff}} = \frac{I_{\text{eff}}}{h - \overline{y}_{\text{eff}}} \qquad 64.18$$

Although composite beam design includes calculating the working stresses, *AISC Specifications*, Sec. I, which governs composite construction, is based on ultimate load theory. (This is apparent from Eq. 64.14.) The ultimate strength of a composite beam is the same whether or not temporary shores are used during construction.

4. WORKING STRESSES WITH SHORING

When shoring is provided, the composite section composed of the slab and the beam acts as a single unit and carries the entire dead and live load. The maximum stress in the steel beam (occurring at bottom flange), f_s, and the maximum stress in the concrete, f_c, are calculated as follows.

- For full composite action,

$$f_s = \frac{M_D + M_L}{S_{\text{tr}}} \qquad 64.19$$

$$f_c = \frac{M_D + M_L}{S_t} \qquad 64.20$$

- For partial composite action,

$$f_s = \frac{M_D + M_L}{S_{\text{eff}}} \qquad 64.21$$

$$f_c = \left(\frac{M_D + M_L}{S_{t,\text{eff}}}\right)\left(\frac{\left(\frac{b}{n}\right)_{\text{eff}}}{b}\right) \qquad 64.22$$

5. WORKING STRESSES WITHOUT SHORING

When shoring is not provided, the beam must initially support the uncured concrete slab as well as its own weight. During the pour and subsequent curing, the maximum stress in the steel beam will be given by Eq. 64.23. M_D is the moment caused by the dead loads of the beam and slab. (The concrete stress is zero at this stage.)

$$f_s = \frac{M_D}{S_s} \qquad 64.23$$

When a composite section cast without shoring is placed into service, it resists the live loads (plus any additional dead loads) imposed after the concrete has achieved 75% of its required strength, while the original stress in the beam remains. Thus, the maximum stress in a steel beam (at the bottom flange), f_s, and the maximum stress in concrete, f_c, are calculated as follows. (M_L is the moment produced by additional loads imposed after the concrete has hardened and attained 75% of its required strength.)

- For full composite action,

$$f_s = \frac{M_D}{S_s} + \frac{M_L}{S_{\text{tr}}} \qquad 64.24$$

$$f_c = \frac{M_L}{S_t} \qquad 64.25$$

- For partial composite action,

$$f_s = \frac{M_D}{S_s} + \frac{M_L}{S_{\text{eff}}} \qquad 64.26$$

$$f_c = \frac{M_L}{S_{t,\text{eff}}}\left(\frac{\left(\frac{b}{n}\right)_{\text{eff}}}{b}\right) \qquad 64.27$$

6. ALLOWABLE STRESSES

The allowable bending stress in the steel beam or decking is $0.66F_y$ under total load (dead load plus live load) for both shored and unshored construction. Also, for unshored construction, the sum of the precomposite and composite stresses at the bottom of the steel beam must not exceed $0.9F_y$ in order to prevent permanent deformation under service loads. (If the computed value of combined stress exceeds $0.9F_y$, shored construction must be used.)

The maximum permitted compressive stress in concrete is $0.45f'_c$. The tensile strength of concrete is neglected.

7. SHEAR CONNECTORS

Although a natural bond is created between a steel beam and a concrete slab, this bond cannot be relied upon to ensure composite action. Mechanical *shear connectors* (also called *stud connectors*) attached to the top of the steel beam must be provided as a means of positive connection between the steel beam and the concrete slab. *AISC Specifications* Sec. I4 specifies that the entire horizontal shear at the junction of the steel beam and the concrete slab is assumed to be transferred by shear connectors.

The connectors required on each side of the point of maximum moment in an area of positive moment may be uniformly distributed between that point and adjacent points of zero moment. The required number of such connectors, N_1, is calculated from Eq. 64.28 or 64.29.

$$N_1 = \frac{V_h}{q} \quad \text{[full composite action]} \qquad 64.28$$

$$N_1 = \frac{V'_h}{q} \quad \text{[partial composite action]} \qquad 64.29$$

However, the number of shear connectors, N_2, required between any concentrated load in the positive moment area and the nearest point of zero moment cannot be less than that determined by AISC Eq. I4-5.

8. DESIGN OF COMPOSITE BEAMS

Design of composite beams is based on the criteria of bending stress, shear stress, and instantaneous deflection. Since a trial-and-error method is impractical, the *AISC Manual*, Part 2, provides Composite Beam Selection Tables. These tables list $\overline{I}_{tr}$ and $\overline{S}_{tr}$ values for several steel sections, along with Composite Design General Notes. These tables can be used for full composite action with a solid concrete slab or slab on formed-steel-deck without any restriction on concrete strength, f'_c, modular ratio, n, or effective width, b. Optional corrections to tabulated values through the use of Design Notes Eqs. 9 and 10 will result in more exact values of section properties. For steel beams not listed in the tables, section properties I_{tr} and S_{tr} can be obtained using Eqs. 64.3 through 64.8.

Example 64.1

Check the adequacy of an interior floor beam of composite construction (shored), assuming full composite action. Use the following data.

modular ratio	$n = 9$
steel strength	$F_y = 36$ ksi
beam	W 21 × 62
beam span	$L = 40$ ft
beam spacing	$s = 8$ ft
concrete strength	$f'_c = 3$ ksi
unit weight	150 lbf/ft^3
slab thickness	$t = 4$ in
floor live load	100 psf
partition load	20 psf

Solution

From the *AISC Manual*, for W 21 × 62, $A = 18.3$ in^2, $d = 21.0$ in, and $t_w = 0.4$ in.

The loading from the 4 in slab is

$$\left(\frac{4 \text{ in}}{12 \frac{\text{in}}{\text{ft}}}\right)(8 \text{ ft})\left(150 \frac{\text{lbf}}{\text{ft}^3}\right) = 400 \text{ lbf/ft}$$

The loading from the W 21 × 62 steel beam is 62 lbf/ft.

The total dead load is

$$w_D = \frac{400 \frac{\text{lbf}}{\text{ft}} + 62 \frac{\text{lbf}}{\text{ft}}}{1000 \frac{\text{lbf}}{\text{kip}}}$$

$$= 0.462 \text{ kip/ft}$$

The dead load moment is

$$M_D = \frac{w_D L^2}{8} = \frac{\left(0.462 \frac{\text{kip}}{\text{ft}}\right)(40 \text{ ft})^2}{8}$$

$$= 92.4 \text{ ft-kips}$$

After the concrete has hardened, the loading from the live load and partition will be 100 psf+20 psf = 120 psf.

$$w_L = \frac{\left(120 \frac{\text{lbf}}{\text{ft}^2}\right)(8 \text{ ft})}{1000 \frac{\text{lbf}}{\text{kip}}}$$

$$= 0.96 \text{ kip/ft}$$

$$M_L = \frac{w_L L^2}{8} = \frac{\left(0.96 \frac{\text{kip}}{\text{ft}}\right)(40 \text{ ft})^2}{8}$$

$$= 192 \text{ ft-kips}$$

The maximum moment is

$$M_{max} = M_D + M_L = 92.4 \text{ ft-kips} + 192 \text{ ft-kips}$$

$$= 284.4 \text{ ft-kips}$$

The maximum shear is

$$V_{max} = \frac{(w_D + w_L)L}{2}$$

$$= \frac{\left(0.462 \frac{\text{kip}}{\text{ft}} + 0.96 \frac{\text{kip}}{\text{ft}}\right)(40 \text{ ft})}{2} = 28.44 \text{ kips}$$

The effective width of the concrete slab is the smaller of

$$b = \frac{L}{4} = \frac{(40 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{4} = 120 \text{ in}$$

$$b = s = (8 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right) = 96 \text{ in} \quad \text{[governs]}$$

To determine the section properties of the transformed composite section, refer to the *AISC Manual*, Part 2, Composite Design for Building Construction, General Notes, and Figs. 1 and 2. The concrete transformed area in compression is given by Eq. 64.4.

$$A_{ctr} = \left(\frac{b}{n}\right)t = \left(\frac{96 \text{ in}}{9}\right)(4 \text{ in}) = 42.67 \text{ in}^2$$

The distance from the top of the steel beam to the centroid of the concrete area in compression is given by Eq. 64.7.

$$Y2 = \frac{t}{2} = \frac{4 \text{ in}}{2} = 2 \text{ in}$$

From the Composite Beam Selection Table, Transformed Section Properties, for W 21 × 62, $Y2 = 2$ in and $A_{ctr} = 42.67$ in^2. By interpolation, $\overline{I}_{tr} = 3325$ in^4 and $\overline{S}_{tr} = 173.4$ in^3. From Eq. 64.12,

$$\overline{y}_b = \frac{\overline{I}_{tr}}{\overline{S}_{tr}} = \frac{3325 \text{ in}^4}{173.4 \text{ in}^3} = 19.2 \text{ in}$$

Add the optional corrections from Eqs. 9 and 10 of *AISC Manual*, Part 2, Composite Design for Building Construction, General Notes.

$$I_{tr} = \overline{I}_{tr} + \frac{A_{ctr}(t^2 - 1)}{12}$$

$$= 3325 \text{ in}^4 + \frac{(42.67 \text{ in}^2)((4 \text{ in})^2 - 1)}{12} = 3378 \text{ in}^4$$

$$S_{tr} = \left(\frac{I_{tr}}{\overline{I}_{tr}}\right)\overline{S}_{tr}$$

$$= \left(\frac{3378 \text{ in}^4}{3325 \text{ in}^4}\right)(173.4 \text{ in}^3) = 176.2 \text{ in}^3$$

$$\overline{y}_b = \frac{I_{tr}}{S_{tr}} = \frac{3378 \text{ in}^4}{176.2 \text{ in}^3}$$

$$= 19.2 \text{ in}$$

Check the concrete stress for shored construction.

$$S_t = \frac{I_{tr}}{d + t - \overline{y}_b}$$

$$= \frac{3378 \text{ in}^4}{21.0 \text{ in} + 4 \text{ in} - 19.2 \text{ in}} = 582.4 \text{ in}^3$$

$$f_c = \frac{M_{max}}{nS_t}$$

$$= \frac{(284.4 \text{ ft-kips})\left(12 \frac{\text{in}}{\text{ft}}\right)}{(9)(582.4 \text{ in}^3)} = 0.65 \text{ kip/in}^2$$

$$< 0.45f'_c = (0.45)\left(3 \frac{\text{kips}}{\text{in}^2}\right)$$

$$= 1.35 \text{ kips/in}^2 \quad \text{[OK]}$$

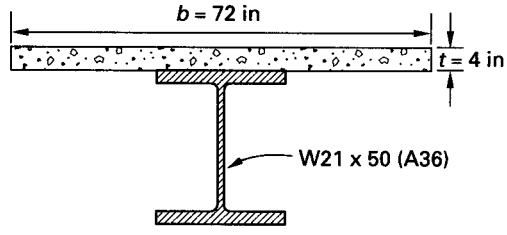
Check the steel stresses. Use Eq. 64.25.

$$f_s = \frac{M_{max}}{S_{tr}} = \frac{(284.4 \text{ ft-kips})\left(12 \frac{\text{in}}{\text{ft}}\right)}{176.2 \text{ in}^3}$$

$$= 19.4 \text{ kips/in}^2$$

$$F_b = 0.66F_y = (0.66)(36 \text{ ksi}) = 23.8 \text{ ksi}$$

$$> 19.4 \text{ ksi} \quad \text{[OK]}$$



$$f_v = \frac{V_{max}}{d_{tw}} = \frac{28.44 \text{ kips}}{(21.0 \text{ in})(0.4 \text{ in})}$$

$$= 3.4 \text{ ksi} < F_v = 0.4F_y = 14.5 \text{ ksi} \quad \text{[OK]}$$

The beam is adequate.

PRACTICE PROBLEMS

1. A cross section of a composite beam is shown. The steel beam is an A36 W 21 × 50, and the concrete strength is $f'_c = 4000$ psi. The modular ratio is 9. Assume shored construction and full composite action. Calculate the resisting moment of the beam.

(A) 180 ft-kips
(B) 230 ft-kips
(C) 270 ft-kips
(D) 350 ft-kips

The answer is (C).

2. The floor framing system of an office building consists of A36 steel, simply supported beams of 40 ft span, spaced at 9 ft on center, that act compositely with a 4 in thick concrete slab ($f'_c = 3$ ksi). The unit weight of concrete is 150 lbf/ft^3, and the modular ratio is $n = 9$. No temporary shoring is to be used during construction. The loads to be applied after the concrete hardens are: floor live (service) load = 100 psf, and ceiling load = 10 psf. (a) Design an A36 interior beam such that the dead-load deflection is limited to 1 in and the live load deflection to $L/360$. (b) Design the shear connectors.

Answers: (a) W 21 × 57 beam; (b) 3^3/$_4$ in diameter × 3 in studs, 18 on each side of midspan

3. *(Time limit: one hour)* A building floor framing consists of A36 W 21 × 68 beams of 30 ft span placed at 12 ft center-to-center spacing. The beams are attached to a 4 in thick concrete slab ($f'_c = 3$ ksi, unit weight = 150 lbf/ft^3) through stud connectors. Assume shored construction, full composite action, and a modular ratio of 9. All loads applied after the concrete has hardened are uniformly distributed live loads. The following questions relate to an interior beam.

(a) The effective concrete flange width is most nearly
(A) 64 in
(B) 74 in
(C) 84 in
(D) 90 in

The answer is (D).

(b) The neutral axis of the transformed composite section is located at a distance (measured from the bottom of the steel beam) most nearly
(A) 18.9 in
(B) 20.5 in
(C) 21.7 in
(D) 22.4 in

The answer is (A).

(c) The moment of inertia of the transformed composite section is most nearly
(A) 3100 in^4
(B) 3600 in^4
(C) 4400 in^4
(D) 5100 in^4

The answer is (B).

(d) The allowable concrete stress is most nearly
(A) 0.85 ksi
(B) 0.97 ksi
(C) 1.1 ksi
(D) 1.3 ksi

The answer is (D).

(e) The allowable steel stress is most nearly
(A) 14 ksi
(B) 22 ksi
(C) 24 ksi
(D) 30 ksi

The answer is (C).

(f) The resisting moment of the composite beam is most nearly
(A) 240 ft-kips
(B) 380 ft-kips
(C) 410 ft-kips
(D) 520 ft-kips

The answer is (B).

(g) The maximum service dead load moment is most nearly
(A) 68 ft-kips
(B) 75 ft-kips
(C) 88 ft-kips
(D) 110 ft-kips

The answer is (B).

(h) The maximum service uniformly distributed live load capacity of the composite beam is most nearly
(A) 120 lbf/ft^2
(B) 180 lbf/ft^2
(C) 230 lbf/ft^2
(D) 270 lbf/ft^2

The answer is (C).

(i) For full composite action, the total horizontal shear V_h to be resisted at service loads between the point of maximum moment and the end of the beam is most nearly
(A) 260 kips
(B) 360 kips
(C) 440 kips
(D) 490 kips

The answer is (B).

(j) Assuming 3/4 in dia. × 3 in stud connectors are used, the total number of studs required for the entire beam is most nearly
(A) 52
(B) 64
(C) 72
(D) 88

The answer is (B).

4. *(Time limit: one hour)* A floor framing system of composite construction (unshored) consists of simply supported, W 21 × 50 A36 steel beams of 40 ft span, equally spaced at 8 ft between beam centerlines, and a 3 in thick lightweight concrete slab (f'_c = 3000 psi, unit weight = 115 lbf/ft^3) on a 3 in deep formed steel deck with ribs running perpendicular to the beams. The average width of concrete rib (w_r) is 3 in. The steel beams are connected to the concrete slab by headed studs that have 3/4 in diameters and 5 in lengths. The beams support a service dead load of 65 lbf/ft^2 due to slab and deck, and a live load of 100 lbf/ft^2 (applied after the concrete has hardened). Use a modular ratio of $n = 9$. The following questions relate to an interior beam.

(a) The moment of inertia of the composite section is most nearly
(A) 2600 in^4
(B) 3200 in^4
(C) 4100 in^4
(D) 5100 in^4

The answer is (B).

(b) Under combined service dead and live loads, the maximum computed concrete stress is most nearly
(A) 0.4 ksi
(B) 0.8 ksi
(C) 1.0 ksi
(D) 1.4 ksi

The answer is (A).

Structural

(c) Under combined service dead and live loads, the maximum beam stress at the bottom of the steel is most nearly

(A) 16 ksi
(B) 19 ksi
(C) 27 ksi
(D) 32 ksi

The answer is (C).

(d) Assuming full composite action, the total horizontal shear, V_h, to be resisted at service loads between the point of maximum moment and the point of zero moment is most nearly

(A) 270 kips
(B) 370 kips
(C) 410 kips
(D) 440 kips

The answer is (A).

(e) Assuming 1 stud per rib, the stud reduction factor is most nearly

(A) 0.41
(B) 0.46
(C) 0.51
(D) 0.57

The answer is (D).

(f) Assuming full composite action under service loads, the number of studs required between the beam ends is most nearly

(A) 76
(B) 82
(C) 92
(D) 98

The answer is (B).

(g) Assuming partial composite action (75%) under service loads, the total number of studs required between the beam ends is most nearly

(A) 52
(B) 62
(C) 72
(D) 82

The answer is (B).

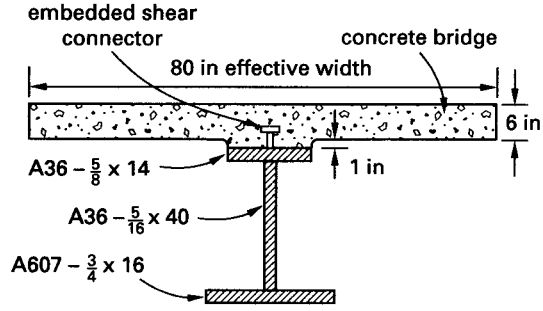
(h) Assuming the ratio $V_h'/V_h = 0.75$, the effective section modulus, S_{eff}, is most nearly

(A) 110 in^3
(B) 150 in^3
(C) 180 in^3
(D) 220 in^3

The answer is (B).

(i) Considering full composite action, the service live load deflection is most nearly

(A) 0.34 in
(B) 0.49 in
(C) 0.58 in
(D) 0.68 in



The answer is (B).

(j) Assuming partial composite action (75%) and studs provided accordingly, the service live load deflection is most nearly

(A) 0.39 in
(B) 0.54 in
(C) 0.62 in
(D) 0.78 in

The answer is (B).

5. *(Time limit: one hour)* A portion of a bridge is supported by a simply supported plate girder. Bridge loads are applied after construction and are resisted by composite action. The girder is 80 ft long. It will not be shored during construction. Flange support is provided at 20 ft intervals. The girder is loaded by a moving 40 kip load and a 1 kip/ft dead load (which includes an allowable for the concrete). The concrete strength is 3000 psi. The modular ratio is 10. The yield stress for all steel plates is 36 ksi. Impact loading is negligible. Assume a worst-case stiffener placement. Determine if the plate girder is adequate.

Answer: The plate girder is not adequate due to excessive steel bending and shear stresses.

1. INTRODUCTION

There are two types of structural *connectors* (also referred to as *fasteners*): rivets and bolts. *Rivets*, however, have become virtually obsolete because of their low strength, high cost of installation, installed variability, and other disadvantages. The two types of *bolts* generally used in the connections of steel structures are common bolts and high-strength bolts. *Common bolts* are classified by ASTM as A307 bolts. The two basic types of *high-strength bolts* have ASTM designations of A325 and A490.

A *concentric connection* is one for which the applied load passes through the centroid of the fastener group. If the load is not directed through the fastener group centroid, the connection is said to be an *eccentric connection.*

At low loading, the distribution of forces among the fasteners is very nonuniform, since friction carries some of the load. However, at higher stresses (i.e., those near yielding), the load is carried equally by all fasteners in the group. Stress concentration factors are not normally applied to connections with multiple redundancy.

In many connection designs, materials with different strengths will be used. The material with the minimum strength is known as the *critical part*, and the critical part controls the design.

Connections using bolts and rivets are analyzed and designed similarly. Such connections can place fasteners in direct shear, torsional shear, tension, or any combination of shear and tension. Theoretical methods based on elastic design can be used for design, and in some instances, procedures based on ultimate strength concepts are available.

The analysis presented in this chapter for connection design and analysis assumes static loading. Other provisions for fatigue loading are contained in the *AISC Specifications* App. K.

2. HOLE SPACING AND EDGE DISTANCES

The minimum distance between centers of fastener holes is $^8/_3$ times the nominal fastener diameter. In addition, along the longitudinal connection direction (i.e., along the line of applied force), the minimum distance between the centers of standard holes is given by Eq. 65.1.

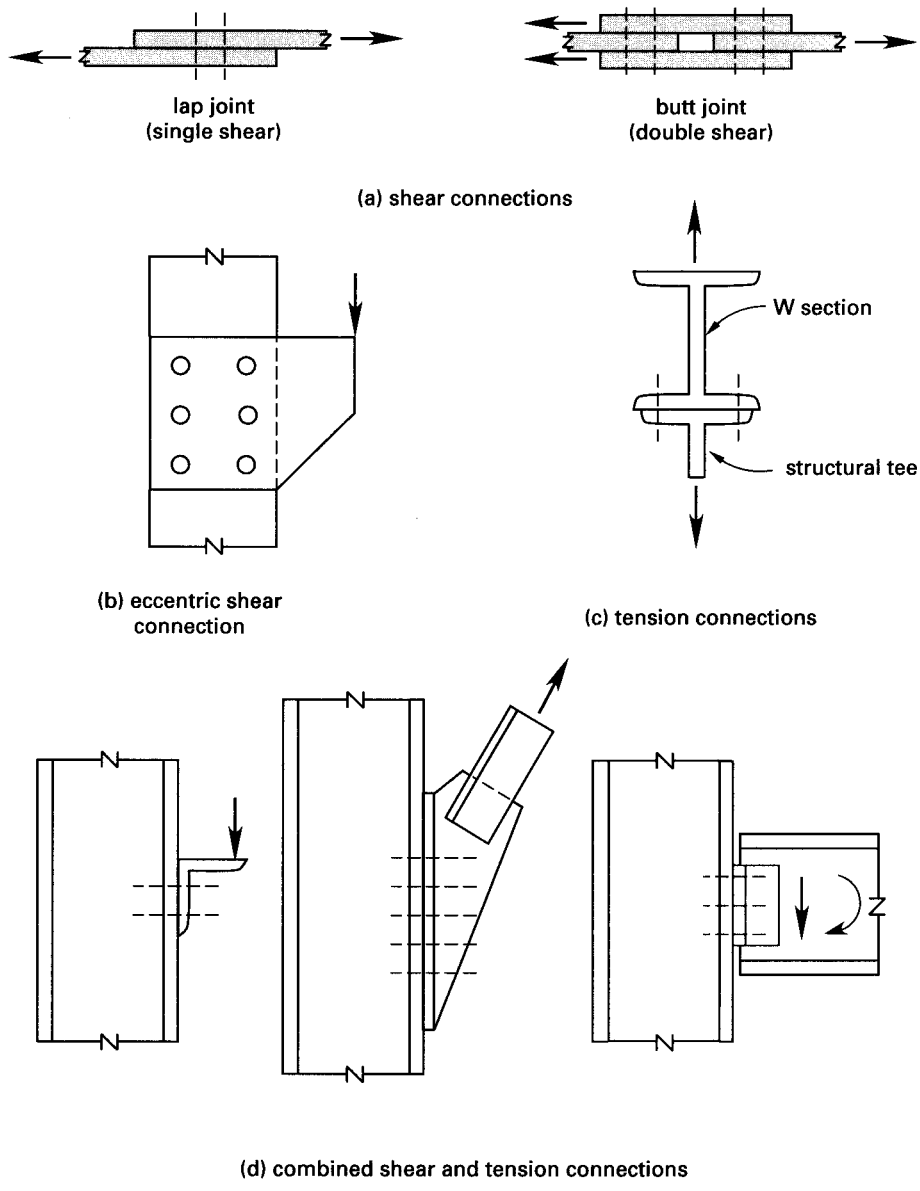

Figure 65.1 *Typical Bolted Connections*

P is the force carried by one fastener in the connector group. t is the thickness of the critical (i.e., the thinnest) part [*AISC Specifications* J3.8].

$$s \geq \frac{2P}{F_u t} + \frac{d}{2} \qquad 65.1$$

The minimum distance from the hole center to the edge of a member is approximately 1.75 times the nominal diameter for sheared edges, and approximately 1.25 times the nominal diameter for rolled or gas-cut edges, both rounded to the nearest $\frac{1}{8}$ in [*AISC Specifications* J3-9]. (For exact values, refer to Table J3.5 in the *AISC Specifications*.) Along the line of transmitted force, the distance from a hole center to the edge of the connected part (in the direction of force), L_e, is not permitted to be less than specified by Eq. 65.2 [*AISC Specifications* J3-9].

$$L_e \geq \frac{2P}{F_u t} \qquad 65.2$$

For parts in contact, the maximum edge distance from the center of a fastener to the edge in contact is 12 times the plate thickness or 6 in, whichever is less [*AISC Specifications* J3.10].

3. BEARING AND SLIP-CRITICAL CONNECTIONS

A distinction is made between bearing and slip-critical connections. A *bearing connection* relies on the shearing

resistance of the fasteners to resist loading. In effect, it is assumed that the fasteners are loose enough to allow the plates to slide slightly, bringing the fastener shank into contact with the hole. The area surrounding the hole goes into bearing, hence the name. Connections using rivets, welded studs, and A307 bolts are always considered to be bearing connections.

If the fasteners are constructed from high-strength steel, a high preload can be placed on the bolts. This preload will clamp the plates together, and friction alone will keep the plates from sliding. Such connections are known as *slip-critical connections*. The fastener shanks never come into contact with the plate holes. Bolts constructed from A325 and A490 steels are suitable for slip-critical connections. However, high-strength bolts can also be used in bearing connections.

4. ALLOWABLE LOADS FOR FASTENERS

The *AISC Manual* contains tables of allowable loads for common connector types and materials. The allowable load on a fastener can also be determined by multiplying its area by an allowable stress. Except for rods with upset ends, the area to be used is calculated simply from the fastener's nominal (unthreaded and undriven) dimension.

Table 65.1 lists allowable stresses for common connector types for tension and shear. (Allowable bearing stress is covered in Sec. 5.) Reductions are required for use with oversized holes and connector patterns longer than 50 in. Allowable stresses in fasteners can be increased by one third for temporary exposure to wind and seismic loading.

Table 65.1 *Allowable Fastener Stresses for Static Loading*

		F_v (ksi)	
type of connector	F_t (ksi)	slip-critical	bearing
A502 hot-driven rivets			
grade 1	23.0	don't use	17.5
grade 2	29.0	don't use	22.0
A307 common bolts	20.0	don't use	10.0
A325 high-strength bolts			
no threads in shear plane	44.0	17.0	30.0
threads in shear plane	44.0	17.0	21.0
A490 high-strength bolts			
no threads in shear plane	54.0	21.0	40.0
threads in shear plane	54.0	21.0	28.0

Source: Based on *AISC Specifications* Table J3.2.

For fasteners made from approved steels, including A449, A572, and A588 alloys, the allowable tensile stress is $F_t = 0.33F_u$, whether or not threads are in the shear plane. For bearing connections using the same approved steels, the allowable shear stress is $F_v = 0.17F_u$ if threads are present in the shear plane and $F_v = 0.22F_u$ if threads are excluded from the shear plane [*AISC Specifications* Table J3.2].

If fasteners are exposed to both tension and shear, *AISC Specifications* Table J3.3 should be used to determine the maximum tensile stress.

For A325 and A490 bolts used in slip-critical connections with tension, the allowable shear stresses given in Table 65.1 must be multiplied by a reduction factor. In Eq. 65.3, f_t is the average tensile stress in the bolt group, A_b is the nominal body area of the bolt, and T_b is the bolt pretension.

$$\text{reduction factor} = 1 - \frac{f_t A_b}{T_b} \qquad 65.3$$

The bolt pretension (preload) is needed in Eq. 65.3, which calculates a reduction factor to be used with bolts in combined and shear. Table 65.2 gives the minimum pretension for specific bolt sizes and types. For bolts of other sizes, or for bolts manufactured from other steels, the minimum pretension is

$$T_{b,\min} = 0.70A_bF_u \quad \text{[rounded]} \qquad 65.4$$

Table 65.2 *Minimum Bolt Tension (kips)*[a]

bolt size (in)	A325 bolts	A490 bolts
$\frac{1}{2}$	12	15
$\frac{5}{8}$	19	24
$\frac{3}{4}$	28	35
$\frac{7}{8}$	39	49
1	51	64
$1\frac{1}{8}$	56	80
$1\frac{1}{4}$	71	102
$1\frac{3}{8}$	85	121
$1\frac{1}{2}$	103	148

[a] A325 and A490 bolts are required to be tightened to 70% of their tensile strength.

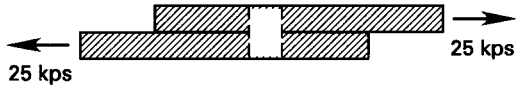
Based on *AISC Specifications* Table J3.7.

5. ALLOWABLE BEARING STRESS

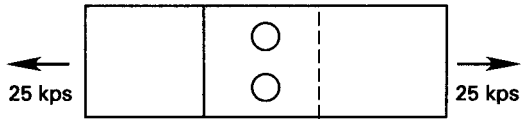
Bearing stress should be evaluated in bearing connections. Theoretically, bearing should not be a problem in friction-type connections because the bolts never bear on the pieces assembled. However, in the event there is slippage due to insufficient tension in the connectors, bearing should be checked anyway.

The allowable bearing stress on projected areas of bolts and rivets in shear connections is given by Eq. 65.5 [*AISC Specifications* Eq. J3-4].

$$F_p = 1.50F_u \qquad 65.5$$



If the connectors, plates, or shapes have different strengths, then the lowest value of F_u will govern.



6. CONCENTRIC SHEAR CONNECTIONS

In a concentric shear connection, fasteners are subject to direct shear only. The number of fasteners required in the connection is determined by considering the fasteners in shear, the plate in bearing, and the effective net area of the plate in tension.

Example 65.1

Two 1/4 × 8 A36 steel plates are joined with a lap joint using 3/4 in grade 1 A502 rivets. Design the connection to carry a concentric load of 25 kips. Disregard effects of eccentricity.

Solution

The area of the 3/4 in rivet is

$$A_v = \frac{\pi d^2}{4} = \frac{\pi(0.75\text{ in})^2}{4} = 0.442\text{ in}^2$$

From Table 65.1, the allowable shear stress is 17.5 ksi. So, the number of rivets determined by the shear stress criterion is

$$n = \frac{\text{load}}{F_v A_v} = \frac{25\text{ kips}}{\left(17\ \frac{\text{kips}}{\text{in}^2}\right)(0.442\text{ in}^2)}$$
$$= 3.33 \quad \text{[shear criterion]}$$

The bearing area is

$$A_p = t_d = (0.25\text{ in})(0.75\text{ in})$$
$$= 0.1875\text{ in}^2$$

The allowable bearing stress is found from Eq. 65.5.

$$F_p = 1.5F_u = (1.5)\left(58\ \frac{\text{kips}}{\text{in}^2}\right)$$
$$= 87\text{ kips/in}^2$$

The number of rivets determined by bearing is

$$n = \frac{\text{load}}{F_p A_p} = \frac{25\text{ kips}}{\left(87\ \frac{\text{kips}}{\text{in}^2}\right)(0.1875\text{ in}^2)}$$
$$= 1.53 \quad \text{[bearing criterion]}$$

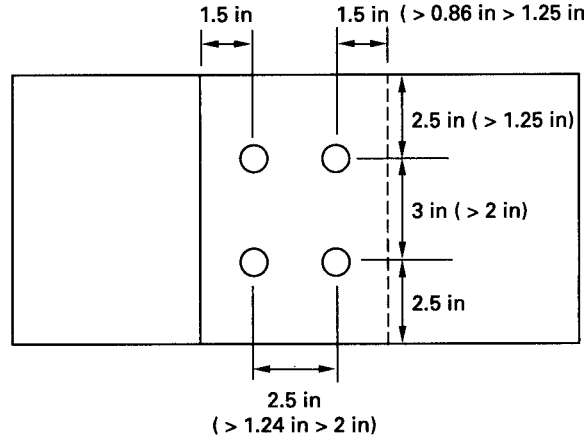
Shear governs. Four rivets are used.

The minimum distance between holes is

$$s_{\min} = \frac{8d}{3} = \frac{(8)(0.75\text{ in})}{3} = 2\text{ in}$$

The longitudinal spacing is further limited by Eq. 65.1.

$$s \geq \frac{2P}{F_u t} + \frac{d}{2}$$
$$= \frac{(2)\left(\frac{25\text{ kips}}{4}\right)}{\left(58\ \frac{\text{kips}}{\text{in}^2}\right)(0.25\text{ in})} + \frac{0.75\text{ in}}{2}$$
$$= 1.24\text{ in}$$



Assuming sheared edges, the minimum edge spacing is

$$(1.75)\left(\tfrac{3}{4}\text{ in}\right) \approx 1\tfrac{1}{4}\text{ in}$$

The first row cannot be closer to the short edge than

$$s_{\min} = \frac{2P}{F_u t} = \frac{(2)\left(\frac{25\text{ kips}}{4}\right)}{\left(58\ \frac{\text{kips}}{\text{in}^2}\right)(0.25\text{ in})}$$
$$= 0.86\text{ in}$$

Based on these requirements, a trial layout is made.

Assuming a hole that is 1/16 in larger than the nominal fastener diameter, each hole subtracts 13/16 in from the

net effective area in tension. The tension area across the first row of holes is

$$A_{\text{net}} = b_{\text{net}}t = \left(8 \text{ in} - (2)\left(\tfrac{13}{16} \text{ in}\right)\right)\left(\tfrac{1}{4} \text{ in}\right)$$
$$= 1.59 \text{ in}^2$$

The maximum tensile stress on the net effective section is

$$F_t = 0.50F_u = (0.50)(58 \text{ ksi}) = 29 \text{ ksi}$$

The maximum allowable load based on the net effective section is

$$P = F_t A_{\text{net}} = \left(29 \frac{\text{kips}}{\text{in}^2}\right)(1.39 \text{ in}^2)$$
$$= 40.3 \text{ kips} \quad \text{[OK]}$$

The maximum tensile stress in the gross section is

$$F_t = 0.60F_y = (0.60)(36 \text{ ksi}) = 21.6 \text{ ksi}$$

The maximum allowable load based on the gross section is

$$P = F_t A = (21.6 \text{ ksi})(8 \text{ in})\left(\tfrac{1}{4} \text{ in}\right)$$
$$= 43.2 \text{ kips} \quad \text{[OK]}$$

7. ECCENTRIC SHEAR CONNECTIONS

An *eccentric shear connection* is illustrated in Fig. 65.2. The connection's tendency to rotate around the centroid of the fastener group is the torsion (or torque) on the connection, equal to the product Pe. This torsion is resisted by the shear stress in the fasteners. Friction is not assumed to contribute to the rotational resistance of the connection.

Basically, two analytic methods are available: the traditional elastic approach (called the "Alternate Method 1—Elastic" in *AISC Manual*, Part 4) and ultimate strength analysis. The traditional elastic approach has been covered in Ch. 45. This method, although providing a simplified solution, greatly underestimates the capacity of an eccentric shear connection. In some cases, the actual capacity may be as much as twice the capacity calculated from the elastic model. The *AISC Manual* does not specify or require either method.

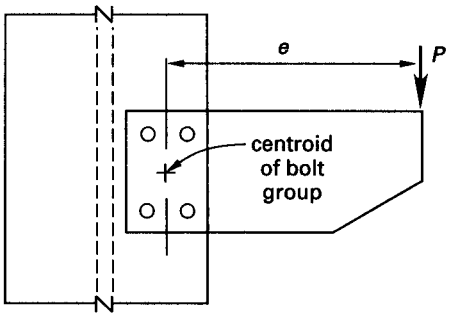


Figure 65.2 *Eccentric Shear Connection*

8. ULTIMATE STRENGTH ANALYSIS OF ECCENTRIC SHEAR CONNECTIONS

Design and analysis using one of several available ultimate strength procedures is preferred over the use of elastic methods. In practice, these procedures involve more table look-up than theory. The allowable load on a fastener group is calculated from the product of tabulated coefficients and allowable fastener loads. For example, in Eq. 65.6, F_v is the allowable shear load on the fasteners and C is a tabulated coefficient. The ability to use Eq. 65.6 depends on having tables of C values for the fastener configuration and eccentricity needed. The *AISC Manual* contains such tables in Part 4, "Connections."

$$P = CA_bF_v \qquad 65.6$$

9. TENSION CONNECTIONS

Figure 65.3 illustrates a basic *tension connection*. As the name implies, fasteners in this hanger-type connection are subjected to tensile stresses. The tendency of the flanges of the structural tee to act as cantilever beams under the downward load P and the upward force of the restraining bolt is called *prying action*, which must be considered for design of such connections. The effect of prying action is to increase the tension in the bolts. The *AISC Manual* Part 4 contains methods of design and analysis with examples for hanger-type connections.

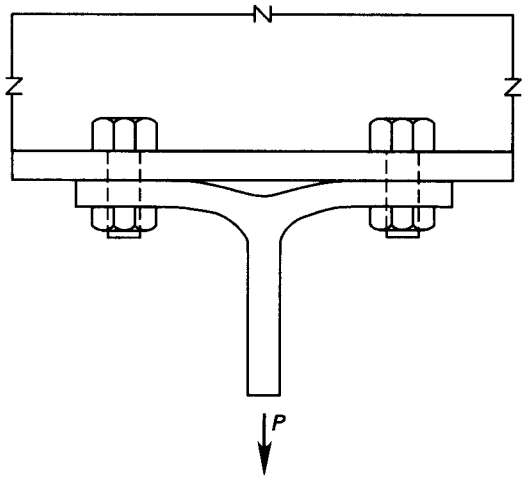

Figure 65.3 *Fasteners in Tension Connection*

10. COMBINED SHEAR AND TENSION CONNECTIONS

Consider the simple framing connection shown in Fig. 65.4. If the vertical shear is assumed to act along line A, the bolts in the column connection will be put into tension. The most highly stressed (in tension) will be the topmost fasteners.

By summing moments about the neutral axis (for tension) of the fastener group, it is possible to determine the maximum tensile stress. The neutral axis is located approximately one sixth or one seventh of the way up from the bottom of the connector group area, such that the area of bolts in tension equals the area of the support in compression. A few trials may be necessary to locate the neutral axis.

Once the neutral axis is located, the moment of inertia of the fastener group is found by use of the parallel axis theorem. The applied moment is $M = Pe$. The stress in the fasteners farthest from the neutral axis is

$$f_{t,\max} = \frac{Mc}{I} = \frac{Pec}{I} \qquad 65.7$$

The tensile force in the farthest fastener is

$$T_{\max} = f_{t,\max} A_b \qquad 65.8$$

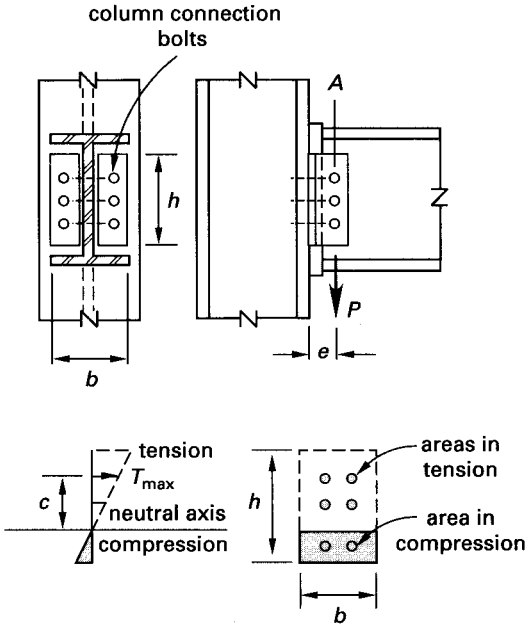

Figure 65.4 *Combined Shear and Tension Connection*

11. FRAMING CONNECTIONS

There are three basic types of framing connections used to connect beams to columns.

- *Type 1, rigid framing connections*: These connections are intended to transmit moments from one member to another. Type 1 connections can be designed by both working stress and plastic design methods. As was demonstrated in California's 1994 Northridge earthquake, moment-resisting connections (particularly those with welded portions) in seismically active areas must be designed with sufficient ductility to resist large amounts of quickly introduced strain energy.
- *Type 2, simple framing connections*: These connections transmit vertical loads, but essentially no (i.e., less than 20%) moment transfer occurs. Generally, only working stress methods are used to design type 2 connections.
- *Type 3, semi-rigid connections*: When the moment transfer across a connection is significant but not total (i.e., between 20% and 90%), the connection is semi-rigid.

Plastic design is not used for type 3 connections. Since it is difficult to determine the amount of moment transfer, type 3 connections are the most rare.

12. TYPE 2 (SIMPLE) FRAMING CONNECTIONS

Type 2 (simple) framing connections, also known as *flexible connections*, are designed to be as flexible as possible. Design is fairly predetermined by use of the standard tables of framed beam connections in the *AISC Manual*. Construction methods include beam seats and clips to beam webs.

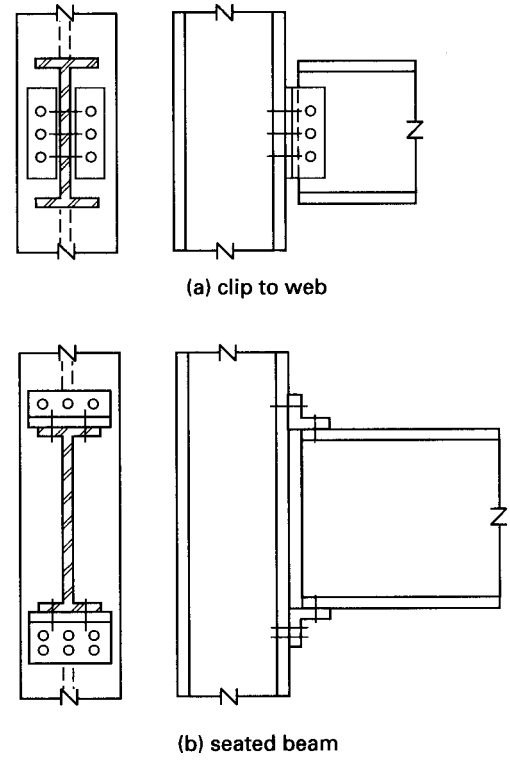

Figure 65.5 *Bolted Type 2 Framing Connections*

Connections to beams and columns can be by bolting and/or welding, and such fastening methods can be used on either the beams or the columns. Usually, the shop connection will be welded. The field connection, however, can be either welded or bolted. Welded connections, stiffened connections, and the use of top

seats do not necessarily imply a moment-resisting connection. When used moderately, coping does not reduce the shear capacity of members.

Direct shear determines the number of bolts required in the column connection. It is common to neglect the effect of eccentricity in determining shear stresses in riveted and bolted beam connections to webs. It is also common to neglect the effect of eccentricity in determining shear stresses in riveted and bolted column connections. However, the eccentricity can be considered, which will add tension stress to the shear stress on column fasteners.

Angle thickness must be checked for allowable bearing pressure. Angles should be checked for direct shear, as well. Since the connection is designed to rotate, the angle (for seated beams) should be checked for bending stress as its free lip bends.

13. TYPE 1 (MOMENT-RESISTING) FRAMING CONNECTIONS

Moment-resisting connections transmit their vertical (shearing) load through the same types of connections as type 2 connections, typically through connections at the beam web. However, the flanges of the beam are also rigidly connected to the column. These top and bottom flange connections are in tension and compression respectively, and serve to transmit the moment.

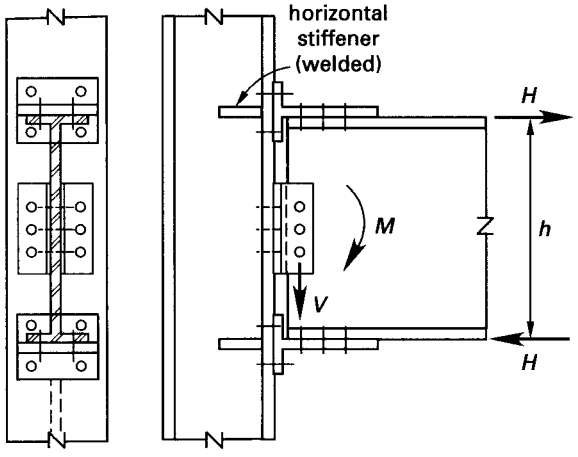

Figure 65.6 *Bolted Type 1 Framing Connections*

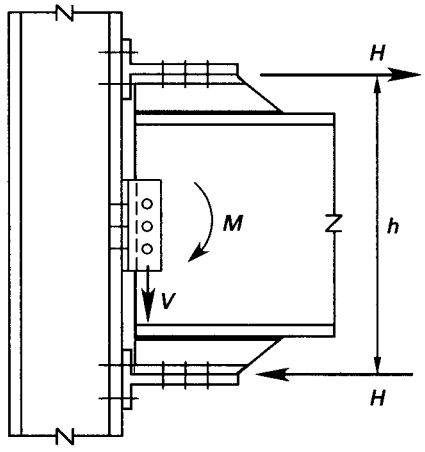
Since moment transfer is through the flanges by tension and compression connections, the design of such connections involves ensuring adequate strength in tension and compression. Design of the shear transfer mechanism (i.e., the web connections) is essentially the same as for type 2 connections. Also, in order to prevent localized buckling of the column flanges, horizontal stiffeners (between the column flanges) may be needed.

The moment-resisting ability of a type 2 connection can be increased to essentially any desired value by increasing the distance between the tension and compression connections. Figure 65.7 illustrates how this could be accomplished by using an intermediate plate between the beam flanges and the column. The horizontal tensile and compressive forces, H, can be calculated from Eq. 65.9.

$$H = \pm\frac{M}{h} \qquad 65.9$$



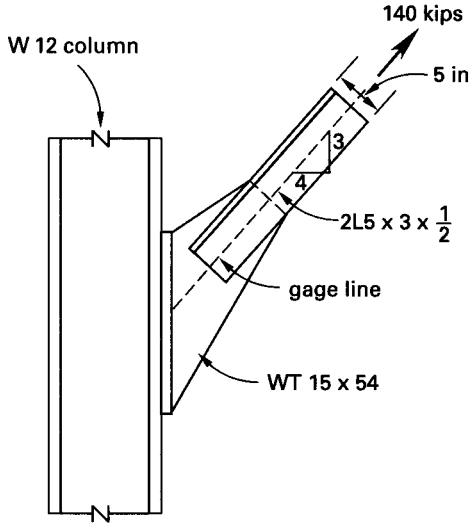


Figure 65.7 *Bolted Type 1 Connection with Increased Moment Resistance*

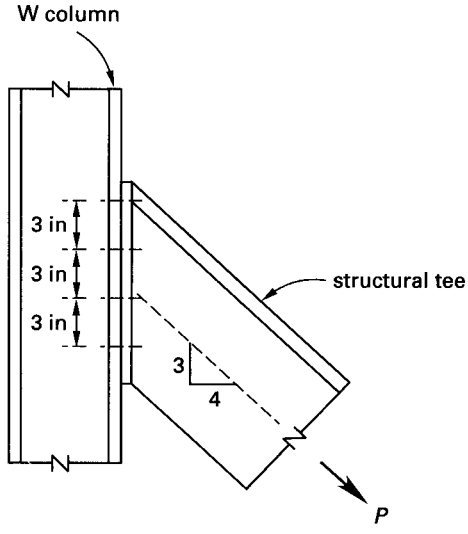
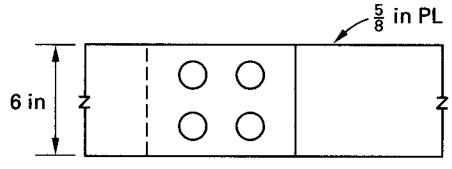


PRACTICE PROBLEMS

1. A bracing member made of a pair of $5 \times 3 \times 1/2$ angles to carry a service tensile load of 140 kips is attached to a W 12 column via a structural tee as shown. All connections are to be bearing-type and made with $^7/_8$ in diameter A325 bolts with threads in the plane of shear. A36 steel is used for all structural members. Neglecting block shear, determine the required number of bolts for (a) the connection between the bracing member and the structural tee and (b) the connection between the structural tee and the column.



Answers: (a) Use six bolts with a 3 in pitch. (b) Use eight bolts with four in each vertical row at 3 in pitch.

2. In the bracket-to-column connection shown, four 3/4 in diameter bolts are used in each of the two vertical rows at 3 in pitch (for a total of eight bolts), such that the load P passes through the center of gravity of the bolt group. Determine the maximum value of the load P (assuming the connected parts do not govern) for (a) a slip-critical connection and (b) a bearing-type connection with threads excluded from the shear plane. Assume standard holes.

Answers: (a) 59.2 kips; (b) 131 kips

3. *(Time limit: one hour)* Two 5/8 in plates are spliced as shown to form a member carrying an axial tensile force of unknown magnitude. Four 7/8 in diameter bolts are used at center-to-center spacing of 3 in in both longitudinal and transverse directions. All holes are punched. The plate steel is A588, grade 50. Neglect block shear.

(a) The allowable tensile load for the member, based on the yielding criterion alone, is most nearly

(A) 68 kips
(B) 80 kips
(C) 88 kips
(D) 110 kips

The answer is (D).

(b) The allowable tensile load for the member, based on the fracture criterion alone, is most nearly

(A) 68 kips
(B) 80 kips
(C) 88 kips
(D) 110 kips

The answer is (C).

(c) Assuming that deformation around bolt holes is not a design consideration, the allowable bearing stress in the member is most nearly

(A) 76 ksi
(B) 84 ksi
(C) 95 ksi
(D) 105 ksi

The answer is (D).

(d) Assuming an A325SC slip-critical connection, the shear capacity of the connection is most nearly

(A) 35 kips
(B) 41 kips
(C) 56 kips
(D) 68 kips

The answer is (B).

(e) Assuming an A325SC slip-critical connection, the allowable tensile load capacity of the member is most nearly

(A) 41 kips
(B) 68 kips
(C) 80 kips
(D) 87 kips

The answer is (A).

(f) Assuming an A325N bearing-type connection with threads in the shear plane, the shear capacity of the four bolts is most nearly

(A) 35 kips
(B) 50 kips
(C) 72 kips
(D) 90 kips

The answer is (B).

(g) Assuming an A325N bearing-type connection with threads in the shear plane, the allowable tensile load capacity of the member is most nearly

(A) 41 kips
(B) 50 kips
(C) 80 kips
(D) 87 kips

The answer is (B).

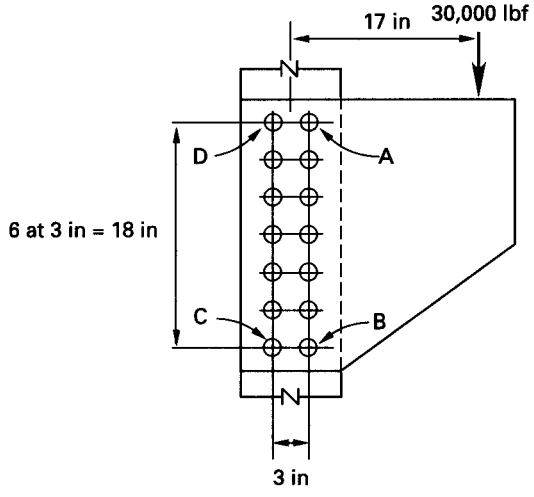
(h) Assuming an A325X bearing-type connection with threads excluded from the shear plane, the shear capacity of the four bolts is most nearly

(A) 35 kips
(B) 41 kips
(C) 72 kips
(D) 90 kips

The answer is (C).

(i) Assuming an A3255X bearing-type connection with threads excluded from the shear plane, the maximum service tensile load the member can carry is most nearly

(A) 41 kips
(B) 72 kips
(C) 87 kips
(D) 90 kips



The answer is (B).

(j) The actual bearing stress in the member corresponding to its tensile capacity with a slip-critical connection is most nearly

(A) 17.3 kips/in^2
(B) 18.7 kips/in^2
(C) 19.9 kips/in^2
(D) 21.3 kips/in^2

The answer is (B).

4. *(Time limit: one hour)* In the bracket connection shown, all fasteners are 3/4 in diameter bolts.

For parts (a) through (g), use a traditional elastic approach.

(a) The polar area moment of inertia of the bolt group is most nearly

(A) 190 in^4
(B) 240 in^4
(C) 290 in^4
(D) 300 in^4

The answer is (B).

(b) The torsional shear stress in bolts A, B, C, and D is most nearly

(A) 15,900 psi
(B) 18,700 psi
(C) 19,600 psi
(D) 20,300 psi

The answer is (C).

(c) The vertical component of the torsional shear stress in bolts A, B, C, and D is most nearly

(A) 2200 psi
(B) 2800 psi
(C) 3200 psi
(D) 3600 psi

The answer is (C).

(d) The horizontal component of the torsional shear stress in bolts A, B, C, and D is most nearly

(A) 12,500 psi
(B) 18,200 psi
(C) 18,900 psi
(D) 19,400 psi

The answer is (D).

(e) The direct vertical shear stress in the bolts is most nearly

(A) 4200 psi
(B) 4400 psi
(C) 4900 psi
(D) 5000 psi

The answer is (C).

(f) The total shear stress in bolts A and B is most nearly

(A) 16,200 psi
(B) 18,500 psi
(C) 21,000 psi
(D) 22,600 psi

The answer is (C).

(g) The total shear stress in bolts C and D is most nearly

(A) 15,200 psi
(B) 17,700 psi
(C) 18,900 psi
(D) 19,400 psi

The answer is (D).

For parts (h) through (j), use the *AISC* tables.

(h) Assuming A325SC bolts in standard holes, the allowable load for the bolt group is most nearly

(A) 20,800 lbf
(B) 25,600 lbf
(C) 26,900 lbf
(D) 30,400 lbf

The answer is (D).

Structural

(i) Assuming A325N bolts in standard holes, the allowable load for the bolt group is most nearly

(A) 22,900 lbf
(B) 27,300 lbf
(C) 37,700 lbf
(D) 38,400 lbf

The answer is (C).

(j) The connection is adequate for

(A) A325SC bolts only
(B) A325N bolts only
(C) both A325SC and A325N bolts
(D) neither A325SC nor A325N bolts

The answer is (C).

1. INTRODUCTION

Welding is a joining process in which the surfaces of two pieces of structural steel (the *base metal*) are heated to a fluid state, usually with the addition of other molten steel (called *weld metal* or *filler metal*) from the *electrodes*. The properties of the base metal and those of the deposited weld metal should be similar, but the weld metal should be stronger than the metals it connects.

The American Welding Society *Structural Welding Code—Steel* (AWS D1.1) is the governing standard for structural welding and it is incorporated by reference, with a few differences, into the *AISC Specifications*.

Two procedures are typically used for structural welding. The *shielded metal arc welding* (SMAW) process is used both in the shop and in the field. Electrodes available for SMAW welding are designated as E60XX, E70XX, E80XX, E90XX, E100XX, and E110XX. The letter "E" denotes an electrode. The first two digits indicate the ultimate tensile strength (F_u) in ksi; thus, the tensile strength of the weld metal ranges from 60 ksi to 110 ksi. The XX designations indicate how the electrodes are used.

The *submerged arc welding* (SAW) process is primarily used in the shop. The electrodes for the SAW process are specified somewhat differently. Each designation is a combination of flux (that shields the weld) and electrode classifications. For example, in the designation F7X-E7XX, F indicates a granular flux, the first digit following F represents the tensile strength requirement of the resulting weld (e.g., 7 means 70 ksi), E represents an electrode, the first digit following the E represents the minimum tensile strength of the weld metal (e.g., 7 means 70 ksi), and the XX represents numbers related to the use. The most commonly used electrode for structural work is E70 because it is compatible with all grades of steel having yield stresses (F_y) up to 60 ksi.

2. TYPES OF WELDS AND JOINTS

Figure 66.1 shows four common types of welds: fillet, groove, plug, and slot. Each type of weld has certain advantages that determine the extent of its use. The *fillet weld* is the most commonly used type in structural connections due to its overall economy and its ease of fabrication. The *groove weld* is primarily used to connect structural members aligned in the same plane. It is

more costly as it often requires extensive edge preparation and precise fabrication. The use of *slot welds* and *plug welds* is rather limited—they are used principally in combination with fillet welds, where the size of the connection limits the length available for fillet welds.

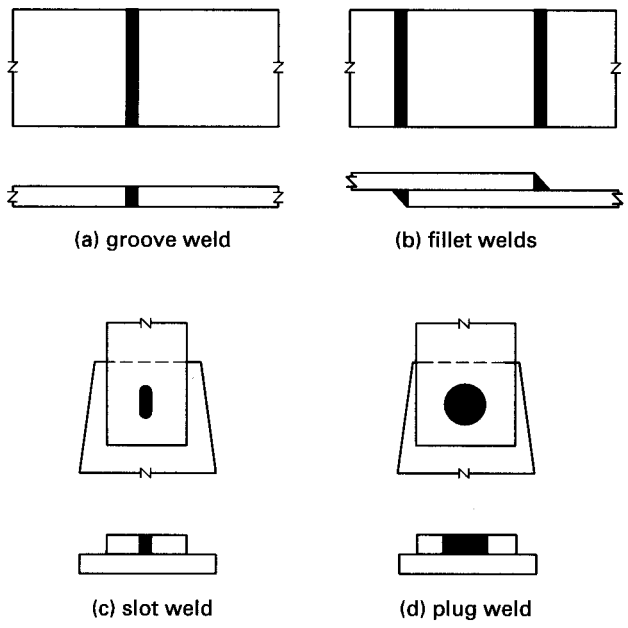

Figure 66.1 *Types of Welds*

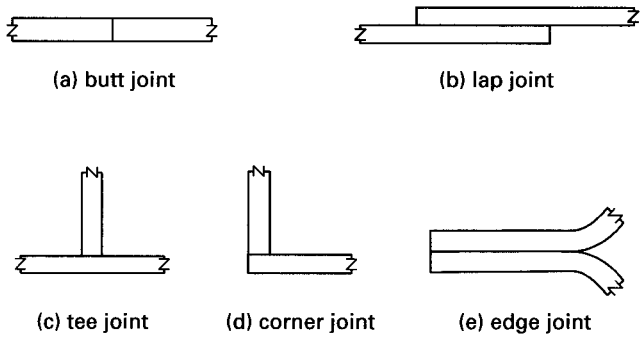
There are five basic types of joints: butt, lap, tee, corner, and edge, as shown in Fig. 66.2. The type of joint depends on factors such as type of loading, shape and size of members connected, joint area available, and relative costs of various types of welds. The *lap joint* is the most common type because of ease of fitting (i.e., there is no need for great precision in fabrication) and ease of joining (i.e., there is no need for special preparation of edges being joined).



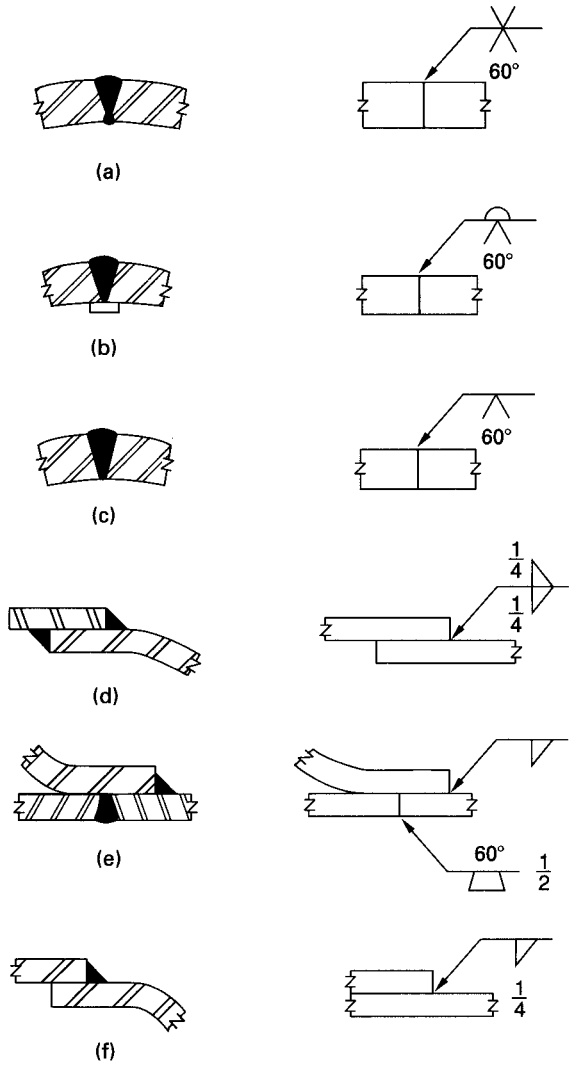


Figure 66.2 *Types of Welded Joints*

[a]Designations: (a) double-weld butt joint, (b) single-weld butt joint with integral backing strip, (c) single-weld butt joint without backing strip, (d) double-full fillet lap joint, (e) single-full fillet lap joint with plug welds, (f) single-full fillet lap joint without plug welds.

Figure 66.3 *Standard Weld Symbols*[a]

3. FILLET WELDS

An enlarged view of a fillet weld is shown in Fig. 66.4. The applied load is assumed to be carried by the weld throat, which has an effective dimension of t_e.

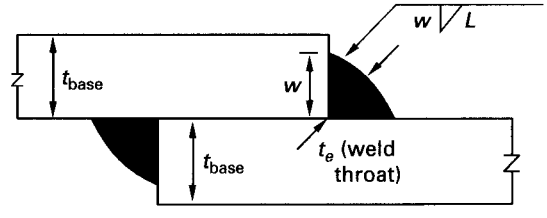

Figure 66.4 *Fillet Weld*

The effective weld throat thickness, t_e, depends on the type of welding used. For hand-held shielded metal arc welding (SMAW) processes,

$$t_e = 0.707w \qquad 66.1$$

If submerged arc welding (SAW) is used [*AISC Specification* J2.2a],

$$t_e = w \quad [w \leq \tfrac{3}{8} \text{ in}] \qquad 66.2$$

$$t_e = 0.707w + 0.11 \quad [w \geq \tfrac{3}{8} \text{ in}] \qquad 66.3$$

Weld sizes, w, of $^3/_{16}$ in, $^1/_4$ in, and $^5/_{16}$ in are desirable because they can be made in a single pass. ($^5/_{16}$ in is an appropriate limit for SMAW, especially when using hand-held rods. If SAW is used, up to $^1/_2$ in welds can be made in one pass.) However, fillet welds from $^3/_{16}$ in to $^1/_2$ in can be made in $^1/_{16}$ in increments. For welds larger than $^1/_2$ in, every $^1/_8$ in weld size can be made.

In almost all instances, loads carried by welds result in shear stresses, regardless of the weld group orientation. The allowable shear stress on the weld fillet throat is [AISC Table J2.5]

$$F_v = 0.30F_{u,\text{rod}} \qquad 66.4$$

Shear stress in the base material may not be greater than $0.40F_y$. For tensile or compressive loads, the allowable stress parallel to the weld axis is the same as for the base metal.

To simplify the analysis and design of certain types of welded connections, it is convenient to define the shear resistance per unit length of weld as Eq. 66.5. (When the base material thickness is small, the weld strength may be limited by the shear strength of the base metal. This should also be checked.)

$$R_w = 0.30t_eF_{u,\text{rod}} \qquad 66.5$$

Several special restrictions that apply to fillet welds are given as follows [*AISC Specifications* J2.2b].

- Minimum weld size depends on the thickness of the thicker of the two parts joined, except that the weld size need not exceed the thickness of the thinner part. (When weld size is increased to satisfy these minimums, the capacity is not increased. Weld strength is based on the theoretical weld size calculated.)
- For materials less than $^1/_4$ in thick, the maximum weld size along edges of connecting parts is equal to the material thickness. For materials thicker than $^1/_4$ in, the maximum size must be $^1/_{16}$ in less than the material thickness.
- The minimum-length weld for full strength analysis is four times the weld size. (If this criterion is not met, the weld size is downgraded to one fourth of the weld length.)
- If the strength required of a welded connection is less than would be obtained from a full-length weld of the smallest size, then an intermittent weld can be used. The minimum length of an intermittent weld is four times the weld size or $1^1/_2$ in, whichever is greater.
- The minimum weld length for lap joints (as illustrated in Fig. 66.4) is five times the thinner plate's thickness, but not less than 1 in.

Table 66.1 *Minimum Fillet Weld Size*

thickness of thicker part joined (in)	minimum w (in)
to $\frac{1}{4}$ inclusive	$\frac{1}{8}$
over $\frac{1}{4}$ to $\frac{1}{2}$ inclusive	$\frac{3}{16}$
over $\frac{1}{2}$ to $\frac{3}{4}$ inclusive	$\frac{1}{4}$
over $\frac{3}{4}$	$\frac{5}{16}$

From *AISC Specifications* Table J2.4.

4. CONCENTRIC TENSION CONNECTIONS

If the weld group centroid is in line with the applied load, the loading is concentric. Equation 66.6 can be used to design or evaluate the connection.

$$f_v = \frac{P}{A_{\text{weld}}} = \frac{P}{L_{\text{weld}}t_e} \qquad 66.6$$

Example 66.1

Two $^1/_2 \times 8$ A36 steel plates are lap-welded using E70 electrodes with a shielded metal arc process. Size the weld to carry a concentric tensile loading of 50 kips.

Solution

Good design will weld both joining ends to the base plate. The total weld length will be

$$L_{\text{weld}} = (2)(8 \text{ in}) = 16 \text{ in}$$

This length meets the minimum-length specification of five times the thinner plate's thickness. From Table 66.1, the minimum weld thickness for a $^1/_2$ in plate is $^3/_{16}$ in. Try $w = {}^3/_{16}$ in. From Eq. 66.1,

$$t_e = 0.707w = (0.707)\left(\tfrac{3}{16} \text{ in}\right)$$

The required strength per inch of weld is

$$R_w = \frac{P}{L_{\text{weld}}} = \frac{50 \text{ kips}}{16 \text{ in}} = 3.125 \text{ kips/in}$$

Structural

From Eq. 66.5, the actual shear resistance per unit length is

$$R_w = 0.30t_eF_{u,\text{rod}} = (0.30)(0.707)\left(\tfrac{3}{16}\text{ in}\right)(70\text{ ksi})$$
$$= 2.78\text{ kips/in}$$

Since 2.78 kips/in < 3.125 kips/in, a larger weld is needed. Try $w = {}^1/_4$ in.

$$R_w = (0.30)(0.707)\left(\tfrac{1}{4}\text{ in}\right)(70\text{ ksi})$$
$$= 3.71\text{ kips/in} > 3.125\text{ kips/in} \quad \text{[OK]}$$

The maximum weld size allowed is ${}^1/_2$ in $-$ ${}^1/_{16}$ in $=$ ${}^7/_{16}$ in. The ${}^1/_4$ in weld can be used.

5. NONCONCENTRIC TENSION CONNECTIONS

When tension is applied along an unsymmetrical member, the tensile force will act along a line passing through the centroid of the member. In that instance, it may be desirable or necessary to design a *balanced weld group* in order to have the force also pass through the centroid of the weld group. (*AISC Specifications* Sec. J1.9 exempts single and double angles from the need to balance welds when loading is static. All other static loading configurations, and angles subjected to fatigue loading, must have balanced welds.)

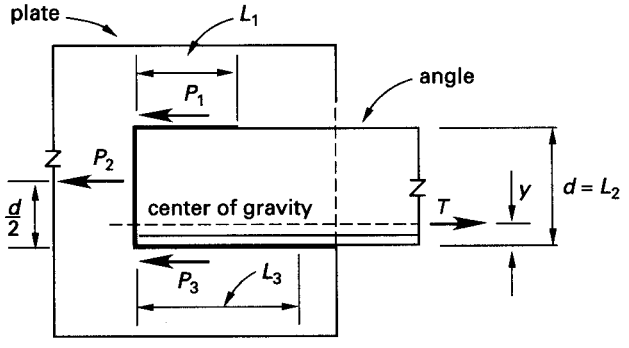

Figure 66.5 *Balanced Weld Group*

The procedure for designing the unequal weld lengths assumes that the end weld (if present) acts at full shear stress with a resultant passing through its mid-height (e.g., $d/2$ in Fig. 66.5). The forces in the other welds are assumed to act along the edges of the angle. Moments are taken about a point on the line of action of either longitudinal weld, resulting in Eq. 66.7.

$$P_3 = T\left(1 - \frac{y}{d}\right) - \frac{P_2}{2} \qquad 66.7$$

$$P_2 = R_wL_2 = R_wd \qquad 66.8$$

$$P_1 = T - P_2 - P_3 \qquad 66.9$$

$$L_1 = \frac{P_1}{R_w} \qquad 66.10$$

$$L_3 = \frac{P_3}{R_w} \qquad 66.11$$

6. ECCENTRICALLY LOADED WELDED CONNECTIONS

There are two possible loading conditions that will result in an eccentrically loaded weld group: (a) loading in the plane of the weld group (as shown in Fig. 66.6) causing combined shear and torsion, and (b) loading out of the plane of the weld group causing combined shear and bending (as shown in Fig. 66.7).

The complexity of the stress distribution in shear/torsion connections makes accurate analysis and design based on pure mechanics principles impossible. Therefore, simplifications are made and the assumed shear stress in the most critical location is calculated. This type of problem can be dealt with in two ways: the elastic method and the ultimate strength method.

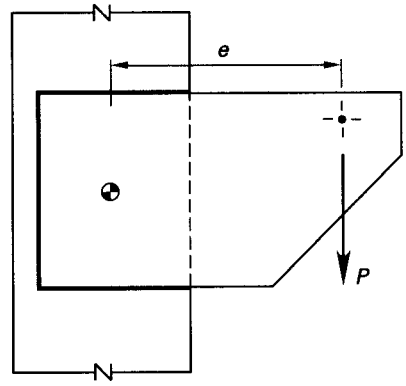

Figure 66.6 *Welded Connection in Combined Shear and Torsion*

7. ELASTIC METHOD FOR ECCENTRIC SHEAR/TORSION CONNECTIONS

The elastic method starts by finding the centroid of the weld group. The centroid can be located by weighting the weld areas (calculated from the weld throat size and length) by their distances from an assumed axis, or the welds can be treated as lines and their lengths used in place of their areas. Appendix 66.A is useful in this latter case. (In an analysis of a weld group, the throat size will be known and welds can be treated as areas. In design, the throat size will be unknown, and it is common to treat the welds as lines. Alternatively, a variable weld size can be used and carried along in a design problem. However, the results will be essentially identical.)

Once the centroid is located, the polar area moment of inertia is calculated. This is usually accomplished by calculating and adding the moments of inertia with respect to the horizontal and vertical axes. For the purpose of calculating the moment of inertia, the welds may also be treated as either areas or lines.

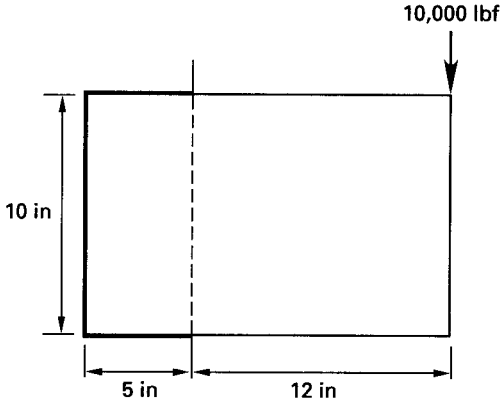
$$J = I_x + I_y \qquad 66.12$$

The distance from the weld group centroid to the critical location in the weld group is next determined, usually by inspection. This distance is used to calculate the torsional shear.

$$f_{v,t} = \frac{Mr}{J} = \frac{Per}{J} \qquad 66.13$$

The direct shear is easily calculated from the total weld area (or length, if the throat size is not known).

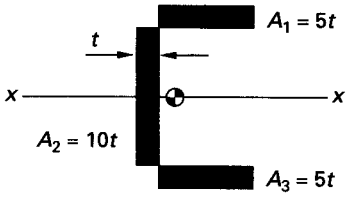
$$f_{v,d} = \frac{P}{A} \qquad 66.14$$



Vector addition is used to combine the torsional and direct shear stresses.

$$f_v = \sqrt{(f_{v,t,y} + f_{v,d})^2 + (f_{v,t,x})^2} \qquad 66.15$$

Although the elastic method is simple, it does not result in a consistent factor of safety and may result in an excessively conservative design of connections.



Example 66.2

A 50 ksi plate bracket is attached using shielded metal arc welding with E70 electrodes to the face of a 50 ksi column as shown. Buckling and bending of the plate and column can be neglected. What size fillet weld is required?

Solution

step 1: Assume the weld has an effective throat thickness, t.

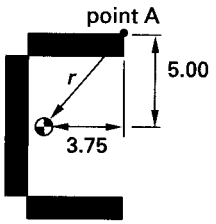
step 2: Find the centroid of the weld group. By inspection, $y_c = 0$. For the three welds,

$$A_1 = 5t$$
$$\overline{x}_1 = 2.5 \text{ in}$$
$$A_2 = 10t$$
$$\overline{x}_2 = 0$$
$$A_3 = 5t$$
$$\overline{x}_3 = 2.5 \text{ in}$$
$$\overline{x}_c = \frac{(5t)(2.5 \text{ in}) + (10t)(0) + (5t)(2.5 \text{ in})}{5t + 10t + 5t}$$
$$= 1.5 \text{ in}$$

step 3: Determine the centroidal moment of inertia of the weld group about the x-axis. Use the parallel axis theorem for areas 1 and 3.

$$I_x = \frac{t(10 \text{ in})^3}{12} + (2)\left(\frac{(5 \text{ in})t^3}{12} + (5 \text{ in})t(5 \text{ in})^2\right)$$
$$= 333.33t + 0.833t^3$$

Since t will be small (probably less than 0.5 in), the t^3 term can be neglected. So, $I_x = 333.33t$.



step 4: Determine the centroidal moment of inertia of the weld group about the y-axis.

$$I_y = \frac{(10 \text{ in})t^3}{12} + (10 \text{ in})t(1.25 \text{ in})^2 + (2)\left(\frac{t(5 \text{ in})^3}{12} + (5 \text{ in})t(1.25 \text{ in})^2\right)$$
$$= 52.08t + 0.833t^3 \approx 52.08t$$

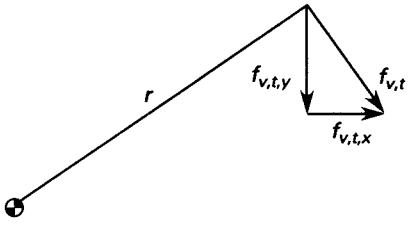
step 5: The polar moment of inertia is

$$J = I_x + I_y = 333.33t + 52.08t = 385.4t$$

step 6: By inspection, the maximum shear stress will occur at point A.

$$r = \sqrt{(3.75 \text{ in})^2 + (5 \text{ in})^2} = 6.25 \text{ in}$$

Structural



step 7: The applied moment is

$$M = Pe = (10{,}000 \text{ lbf})(12 \text{ in} + 3.75 \text{ in})$$
$$= 157{,}500 \text{ in-lbf}$$

step 8: The torsional shear stress is given by Eq. 66.13.

$$f_{v,t} = \frac{Mr}{J} = \frac{(157{,}000 \text{ in-lbf})(6.25 \text{ in})}{385.4t}$$
$$= 2554.2/t$$

This shear stress is directed at right angles to the line r. The x- and y-components of the stress can be determined from geometry.

$$f_{v,t,y} = \left(\frac{3.75 \text{ in}}{6.25 \text{ in}}\right)\left(\frac{2554.2}{t}\right) = 1532.5/t$$

$$f_{v,t,x} = \left(\frac{5.00 \text{ in}}{6.25 \text{ in}}\right)\left(\frac{2554.2}{t}\right) = 2043.4/t$$

step 9: The direct shear stress is

$$f_{v,d} = \frac{P}{A} = \frac{10{,}000 \text{ lbf}}{t(5 \text{ in} + 10 \text{ in} + 5 \text{ in})}$$
$$= 500/t$$

step 10: The resultant shear stress at point A is

$$f_v = \sqrt{\left(\frac{1532.5 + 500}{t}\right)^2 + \left(\frac{2043.4}{t}\right)^2}$$
$$= 2882.1/t$$

step 11: For a 50 ksi base metal, the weld strength controls the allowable stress. From Eq. 66.4, the allowable stress is

$$F_v = 0.30F_u = (0.30)\left(70 \frac{\text{kips}}{\text{in}^2}\right)\left(1000 \frac{\text{lbf}}{\text{kip}}\right)$$
$$= 21{,}000 \text{ psi}$$

The weld throat size is

$$t = \frac{2882.1 \frac{\text{lbf}}{\text{in}}}{21{,}000 \frac{\text{lbf}}{\text{in}^2}} = 0.137 \text{ in}$$

step 12: The weld size is given by Eq. 66.1.

$$w = \frac{t}{0.707} = \frac{0.137 \text{ in}}{0.707}$$
$$= 0.194 \text{ in} \quad [\text{say } 1/4 \text{ in}]$$

Example 66.3

Use App. 66.A to calculate the polar moment of inertia of the weld group in Ex. 66.2.

Solution

From App. 66.A with $b = 5$ in and $d = 10$ in,

$$J = \left(\frac{(8)(5 \text{ in})^3 + (6)(5 \text{ in})(10 \text{ in})^2 + (10 \text{ in})^3}{12} - \frac{(5 \text{ in})^4}{(2)(5 \text{ in}) + (10 \text{ in})}\right)t$$
$$= 385.42t$$

(Note that this is the same result as was calculated in Ex. 66.2.)

8. AISC ULTIMATE STRENGTH METHOD FOR ECCENTRIC SHEAR/TORSION CONNECTIONS

An eccentrically loaded weld group has a tendency to rotate about a point called the *instantaneous center of rotation*. The location of this point depends on the eccentricity, the geometry of the weld group, and the deformation of weld elements. The ultimate shear strength of a weld group is obtained by linking the load-deformation relationship of individual weld elements to the correct location of the instantaneous center. The AISC ultimate strength method calculates the capacity of an eccentrically loaded welded connection as Eq. 66.16.

$$P = CC_1Dl \qquad 66.16$$

C and C_1 are coefficients from the Eccentric Loads on Weld Groups tables XIX-XXVI of Part 4 of the *AISC Manual*. These coefficients depend on the load configuration and electrode type. D is the number of multiples of $1/16$ in in the weld size. l is the weld length.

Example 66.4

Use the *AISC Manual* to calculate the capacity of the weld group designed in Ex. 66.2.

Solution

Referring to AISC Table XXIII,

$$l = 10 \text{ in}$$
$$kl = 5 \text{ in}$$
$$al = 12 \text{ in} + 3.75 \text{ in} = 15.75 \text{ in}$$

For a 1/4 in weld and E70 electrodes, the following coefficients are needed.

$$k = \frac{5 \text{ in}}{10 \text{ in}} = 0.5$$

$$a = \frac{15.75 \text{ in}}{10 \text{ in}} = 1.575$$

$$C = 0.419 \quad \text{[interpolated]}$$

$$C_1 = 1 \quad \text{[for E70 electrodes]}$$

$$D = \frac{\frac{1}{4}}{\frac{1}{16}} = 4$$

From Eq. 66.16, the capacity of the connection is

$$P = CC_1Dl = (0.419)(1)(4)(10) = 16.76 \text{ kips}$$

9. CONNECTIONS WITH SHEAR AND BENDING STRESSES

Figure 66.7 illustrates a welded connection that must support both direct shear and a bending moment. Even though the maximum shear and maximum bending moment do not actually occur at the same place, simplifying assumptions are made to combine the nominal stresses as vectors.

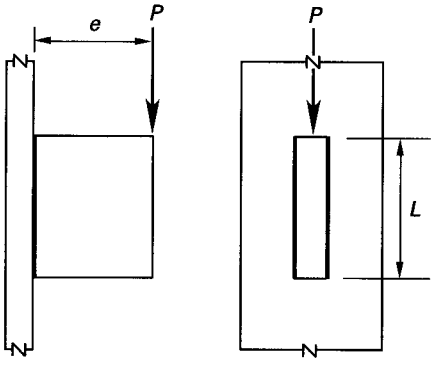


Figure 66.7 *Welded Connection in Combined Shear and Bending*

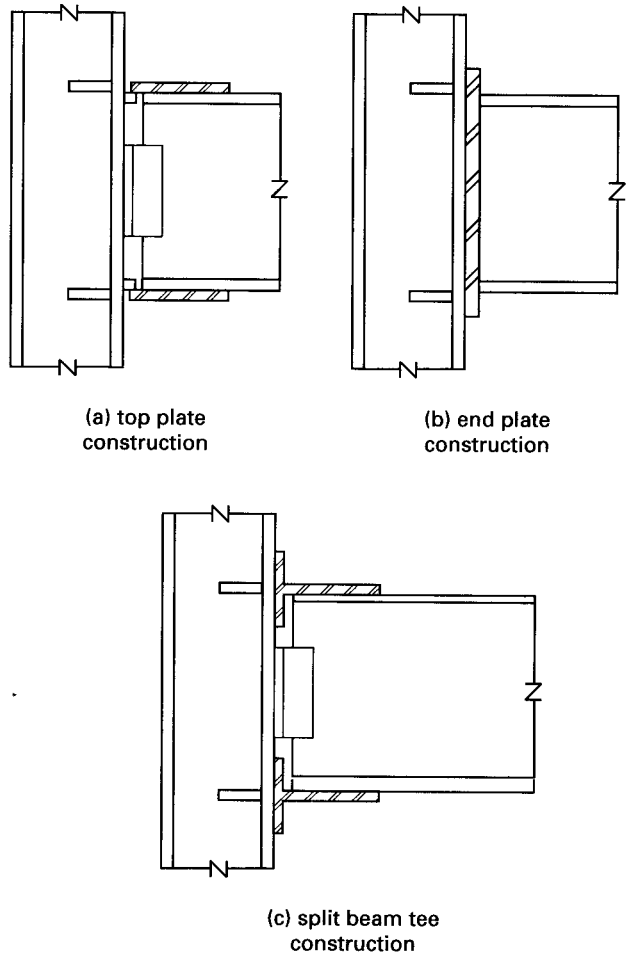
The nominal shear stress is

$$f_v = \frac{P}{A_{\text{weld}}} = \frac{P}{2Lt_e} \qquad 66.17$$

The nominal bending stress is easily calculated if the section modulus, S, of the weld group can be obtained from App. 66.A.

$$f_b = \frac{Mc}{I} = \frac{M}{S} = \frac{Pe}{S} \qquad 66.18$$

The resultant stress is



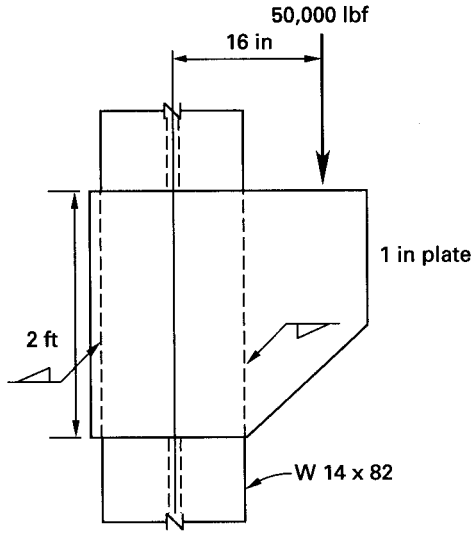
$$f = \sqrt{f_v^2 + f_b^2} \qquad 66.19$$

The resultant stress must be less than the allowable stress, as calculated from Eq. 66.4.

10. WELDED CONNECTIONS IN BUILDING FRAMES

Part 4 of the *AISC Manual* contains tables listing capacities of various welded (E70XX electrodes) shear connections (type 2): framed beam connections, seated beam connections, stiffened seated beam connections, and end plate shear connections. The *AISC Manual* also contains several procedures for designing moment connections (both type 1 and type 3). These procedures specifically assume top plate or end plate construction (as in Fig. 66.8) in order to transmit moments. Construction with split beam tees and the accompanying *prying action* are not addressed.

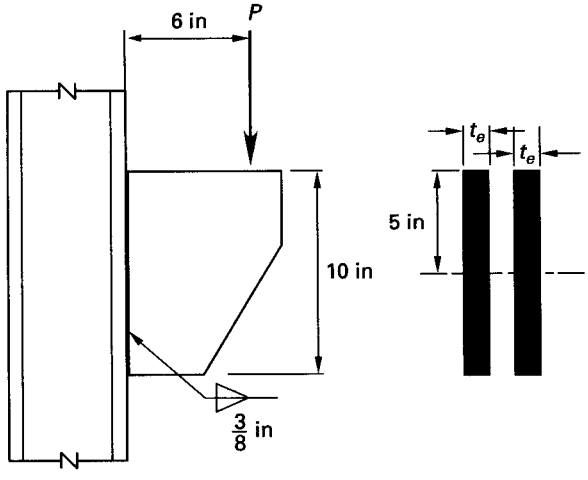
Welded beam-column connections intended to transfer moment in seismically active areas require special consideration to ensure that the connection behaves in a ductile manner.



[a]Not intended to transmit seismically induced loading without special detailing.

Figure 66.8 *Welded Moment-Resisting Connections*[a]

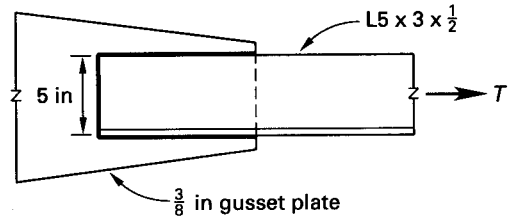
Structural



PRACTICE PROBLEMS

1. Determine the size of the fillet weld required to connect the 1 in thick plate bracket to the column flange as shown. A36 steel is used for both the bracket and the column. Assume SMAW process with E70XX electrodes.

Answer: 5/16 in



2. The connection between the column flange and plate is made with a 3/8 in size fillet weld using E70 electrodes. Determine the capacity, P, of the connection if the process is (a) SMAW and (b) SAW.

(a) bracket (b) weld cross-section

Answers: (a) 29.8 kips; (b) 42.2 kips

3. *(Time limit: one hour)* The fillet-welded lap joint shown is to be designed as a connection between the long leg of an L 5 × 3 × 1/2 tension member of A36 steel and a 3/8 in thick gusset plate. The full strength of the angle is to be developed, minimizing the effect of eccentricity. E70 electrodes will be used. The gusset plate does not govern the design.

(a) The axial tensile capacity of the angle member is most nearly

(A) 72 kips
(B) 81 kips
(C) 89 kips
(D) 110 kips

The answer is (B).

(b) The minimum and maximum sizes of fillet weld that can be used are most nearly

(A) 1/8 in and 3/8 in
(B) 3/16 in and 7/16 in
(C) 1/4 in and 1/2 in
(D) 5/16 in and 5/8 in

The answer is (B).

For parts (c) through (g), assume an SMAW process with the minimum permissible weld size is used.

(c) The strength of the fillet weld per unit length is most nearly

(A) 2.0 kips/in
(B) 2.3 kips/in
(C) 2.8 kips/in
(D) 3.0 kips/in

The answer is (C).

(d) The load carried by the end (transverse) weld, P_2, is most nearly

(A) 11.4 kips
(B) 12.7 kips
(C) 13.9 kips
(D) 14.3 kips

The answer is (C).

(e) The load P_3 carried by the bottom longitudinal weld is most nearly

(A) 33 kips
(B) 40 kips
(C) 46 kips
(D) 51 kips

The answer is (C).

(f) The load P_1 carried by the top longitudinal weld is most nearly

(A) 17 kips
(B) 21 kips
(C) 26 kips
(D) 31 kips

The answer is (B).

(g) The required lengths of the top and bottom longitudinal welds are, respectively, most nearly

(A) 7 in and 17 in
(B) 8 in and 17 in
(C) 7 in and 18 in
(D) 8 in and 18 in

The answer is (B).

For parts (h) through (j), assume an SAW process with the minimum permissible weld size is used.

(h) The load, P_3, carried by the bottom longitudinal weld is most nearly

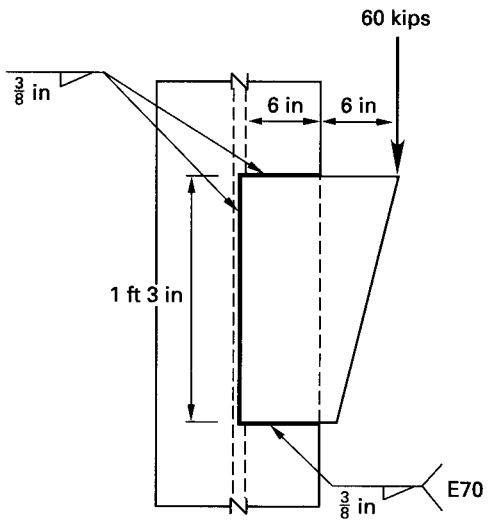
(A) 33 kips
(B) 38 kips
(C) 40 kips
(D) 43 kips

The answer is (D).

(i) The load, P_1, carried by the top longitudinal weld is most nearly

(A) 19 kips
(B) 21 kips
(C) 26 kips
(D) 31 kips

The answer is (A).



(j) The required lengths of the top and bottom longitudinal welds are, respectively, most nearly

(A) 5 in and 11 in
(B) 6 in and 11 in
(C) 5 in and 12 in
(D) 6 in and 12 in

The answer is (A).

4. *(Time limit: one hour)* The adequacy of a $\frac{3}{8}$ in fillet welded connection between a bracket and a column is to be checked. E70 electrodes are used. The column and the bracket do not control the design.

For parts (a) through (g), assume an effective throat thickness, t_e, of 1 in.

(a) The distance measured from the left end of the bracket plate to the centroid of the weld group is most nearly

(A) 1.1 in
(B) 1.3 in
(C) 1.9 in
(D) 2.1 in

The answer is (B).

(b) The polar moment of inertia of the weld group is most nearly

(A) 830 in^4
(B) 970 in^4
(C) 1100 in^4
(D) 1300 in^4

The answer is (C).

(c) The torsional moment acting on the weld group is most nearly

(A) 410 in-kip
(B) 470 in-kip
(C) 520 in-kip
(D) 640 in-kip

The answer is (D).

(d) The maximum stress in weld due to the torsional moment is most nearly

(A) 3.5 ksi
(B) 4.2 ksi
(C) 5.4 ksi
(D) 6.8 ksi

The answer is (C).

(e) The horizontal and vertical components of the maximum stress in weld due to the torsional moment are, respectively, most nearly

(A) 3.9 ksi and 3.4 ksi
(B) 4.6 ksi and 2.8 ksi
(C) 5.0 ksi and 2.1 ksi
(D) 5.7 ksi and 1.9 ksi

The answer is (B).

(f) The stress in weld due to direct shear is most nearly

(A) 1.7 ksi
(B) 2.2 ksi
(C) 2.9 ksi
(D) 3.2 ksi

The answer is (B).

(g) The resultant maximum stress (combination of torsional and direct shear stresses) in the weld group is most nearly

(A) 3.5 ksi
(B) 4.8 ksi
(C) 5.8 ksi
(D) 6.8 ksi

The answer is (D).

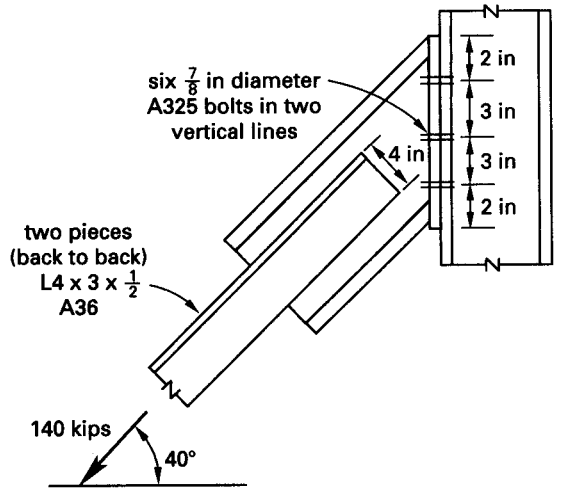
(h) Assuming that the SMAW process is used, the actual resistance per unit length of weld is most nearly

(A) 3.8 kips/in
(B) 4.7 kips/in
(C) 5.6 kips/in
(D) 6.8 kips/in

The answer is (C).

(i) Assuming that the SAW process is used, the shear resistance per unit length of weld is most nearly

(A) 3.8 kips/in
(B) 4.9 kips/in
(C) 6.3 kips/in
(D) 7.9 kips/in



The answer is (D).

(j) The connection is adequate for

(A) both SMAW and SAW processes
(B) neither SMAW nor SAW processes
(C) an SMAW process only
(D) an SAW process only

The answer is (D).

5. *(Time limit: one hour)* Two $4 \times 3 \times 1/2$ angles are welded back to back to an intermediate wide-flange section that is bolted to a column as shown. All pieces are A36 steel. E70 electrodes are used to form the maximum weld size permitted. No threads are in the shear plane. (a) Specify the lengths and locations of the welds used to connect the angles to the intermediate section using a balanced configuration. (b) Determine if the bolts are adequate for a slip-critical-type connection. (c) Determine if the bolts are adequate for a bearing-type connection.

Answer: (a) $L_1 = 1.58$ in, $L_3 = 5.18$ in; (b) not adequate; (c) not adequate

1. INTRODUCTION

The main goal of the *Load and Resistance Factor Design* (LRFD) is to provide a uniform reliability (margin of safety) for steel structures under various loading conditions. This uniform reliability is not normally achieved with the *Allowable Stress Design* (ASD) method.

The ASD method uses a deterministic approach in that both loads and member resistances are considered to be known quantities without any variability. The basic premise of the ASD method is that the computed stress in a structural component under applied loads must not exceed an allowable stress that is a fraction of some specified strength such as the yield strength, F_y. The stress can be of any type—axial, flexural, shear, etc.—depending on the type of member.

In general, loads on a structure are any combination of service (working) dead loads, live loads, wind loads, snow loads, earthquake loads, and so on. But a distinction between the various load types is never a part of the design process in the ASD method. By keeping the actual (computed) stress within the allowable limit, the ASD method typically provides conservative results and an adequate margin of safety.

The *margin of safety*, MS, of a structural component (tension member, beam, etc.) is expressed in terms of the factor of safety, FS—a number greater than 1.0—which is incorporated into the allowable stress. For example, in the design of a tension member based on the yielding criterion, the allowable stress is $0.6F_y$ or $F_y/1.67$, where the number 1.67 is the factor of safety.

$$\text{MS} = \text{FS} - 1 \qquad 67.1$$

From a design perspective, the major weakness of the ASD method is that the factors of safety for various elements (tension, bending, etc.) have different values. These values are judgmental in that they were adopted based on years of practical design experience. As a result, identical members under different load types designed by the ASD method would have nonuniform safety margins.

The LRFD method uses a probabilistic approach in which the member resistances are incorporated. Of the various types of loads, dead loads can be estimated more accurately than live loads or wind loads. Thus, the degree of variability is different for different types of loads. A set of load factors that accounts for possible overloading for each type of load is used in the design.

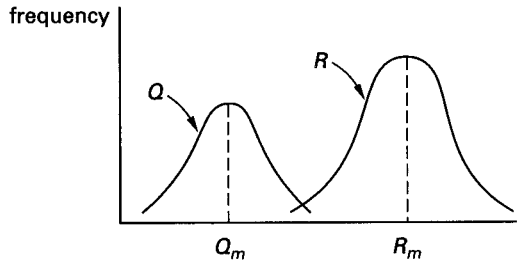
Also, the resistance (strength) of a member in tension, compression, or bending, for example, is a variable quantity based on factors such as dimensions and material properties. A set of resistance factors is incorporated in the design procedure to account for possible understrength of members. Load factors and resistance factors are the results of a statistical study of the variabilities of the subject quantities.

Since the different factors reflect the degrees of uncertainty in the various loads and resistances, a uniform reliability is possible with LRFD. This approach leads to a more rational and, perhaps, more cost-effective design. In some special cases, LRFD also provides a greater degree of flexibility.

2. PHILOSOPHY OF LRFD

The Load and Resistance Factor Design (LRFD) concept is based on limit states. A *limit state* is defined as a condition that represents the limit of structural usefulness. There are two types of limit states: (a) strength limit states, which define safety against extreme loads during the lifetime of a structure, and (b) serviceability limit states, which define the functional performance of a structure or its components under normal service conditions.

Strength limit states relate to maximum load-carrying abilities (moment capacity, shear capacity, etc.), and they vary from member to member. Several strength limit states may apply to a given member. A strength limit state may be conceptual, such as plastic hinge or mechanism formation, or it may represent actual collapse of the whole or part of the structure, such as fracture or instability. The following limit states of strength are most common: onset of yielding, formation of a plastic hinge, formation of a plastic mechanism, overall frame or member instability, lateral torsional buckling, local buckling, tensile fracture, development of fatigue cracks, deflection instability, alternating plasticity, and excessive deformation.

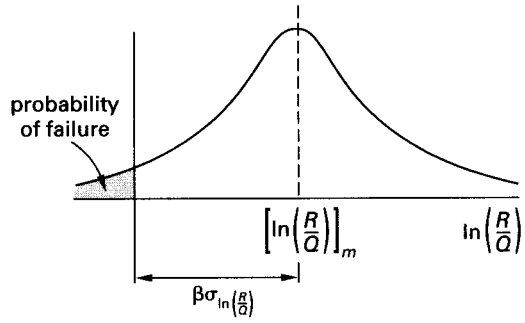


Serviceability limit states include unacceptable elastic deflections and drift, unacceptable vibrations, and permanent deformations.

For any structural design, public safety is the primary concern, and minimum considerations for it are not matters of individual judgment. On the other hand, functional aspects of a structure permit more exercise of judgment on the part of designers. For this reason, LRFD specifications focus on the strength limit states. This does not imply that serviceability limit states are less important, however, and designers must equally ensure functional performance and economy of design.

3. PROBABILISTIC BASIS OF LRFD

When the structural resistance of a member is exceeded by the load on that member, the limit state is exceeded and failure is said to have occurred. For a given strength limit state (moment, shear, etc.), the nominal load effect, Q, and the nominal resistance, R, are assumed to be statistically independent random variables. The frequency distribution curves for Q and R can be plotted on the same graph, as shown in Fig. 67.1. A margin of safety exists as long as the resistance, R, is greater than the load effect, Q.



But since both Q and R are random variables, there always exists some probability (however small) that R is smaller than Q, and this implies possible failure. Thus, the overlap region corresponding to $R < Q$ represents the failure zone. The area of the failure zone depends on two characteristics of the frequency distribution curves: (a) the mean values R_m and Q_m, representing the relative positioning, and (b) the standard deviations, σ_R and σ_Q, representing the dispersions or spreads.

Source: AISC LRFD Commentary, Fig. C-A5.1

Figure 67.1 *Frequency Distribution of Load Effect Q and Resistance R*

As a matter of convenience, an equivalent situation representing only one variable, ln R/Q, is obtained by dividing the inequality $R < Q$ by Q and expressing the results logarithmically. The probability of ln $R/Q < 0$, as shown by the shaded area in Fig. 67.2, is an equivalent representation of the failure event.

Source: AISC LRFD Commentary, Fig. C-A5.2

Figure 67.2 *Reliability Index, β*

The shaded area (i.e., the probability of failure) can be reduced, and thus the reliability can be increased, by either moving the mean $(\ln R/Q)_m$ to the right or by reducing the spread of the curve for a given position of the mean relative to the origin. These two approaches can be combined by defining the position of the mean $(\ln R/Q)_m$ using the standard deviation $\sigma_{\ln(R/Q)}$ as the unit of measure. Thus, the reliability (or margin of safety) is the distance from the origin to the mean, expressed as $\beta\sigma_{\ln(R/Q)}$ (as shown in Fig. 67.2), in which the multiplier β is called the *reliability index*.

The larger this distance, the greater the reliability (or, equivalently, the smaller the probability of the limit state being exceeded). Usually, the actual distributions of R and Q are not known, but their mean values and standard deviations can be estimated. From these estimated values, the mean and the standard deviation of the variable ln R/Q can be approximated as

$$\left(\ln\left(\frac{R}{Q}\right)\right)_m \approx \ln\left(\frac{R_m}{Q_m}\right) \qquad 67.2$$

$$\sigma_{\ln\left(\frac{R}{Q}\right)} \approx \sqrt{V_R^2 + V_Q^2} \qquad 67.3$$

The *coefficients of variation* in Eq. 67.3 are

$$V_R = \frac{\sigma_R}{R_m} \qquad 67.4$$

$$V_Q = \frac{\sigma_Q}{Q_m} \qquad 67.5$$

The distance representing the margin of safety can be expressed by Eq. 67.6 [AISC LRFD C-A-2].

$$\beta\sigma_{\ln\left(\frac{R}{Q}\right)} \approx \beta\sqrt{V_R^2 + V_Q^2} = \ln\left(\frac{R_m}{Q_m}\right) \qquad 67.6$$

The reliability index, β, is obtained From Eq. 67.7 [AISC C-A-5-3].

$$\beta = \frac{\ln\left(\frac{R_m}{Q_m}\right)}{\sqrt{V_R^2 + V_Q^2}} \qquad 67.7$$

Since there is less likelihood (because of shorter duration) of wind or even lesser likelihood of an earthquake occurring with full gravity load, smaller values of β can be used for those two cases. Using a higher value for connections is consistent with the traditional practice of making connections stronger than the members they connect. The *AISC LRFD Specifications* are based upon the following values of β.

- $\beta =$ 3.0 for members subject to gravity loads (dead, snow, and live loads)
- $\beta =$ 2.5 for members subject to gravity loads combined with wind loads
- $\beta =$ 1.75 for members subject to gravity loads combined with earthquake loads
- $\beta =$ 4.5 for connections

4. AISC LRFD SPECIFICATIONS

The *AISC LRFD Specifications* are based on (a) probabilistic models of loads and resistances, (b) calibration to the 1978 *AISC ASD Specifications* for selected members, (c) evaluation of the resulting criteria by judgment and past experience, and (d) comparative design office studies of representative structures.

The general format of the *AISC LRFD Specifications* is given by Eq. 67.7 [C-A5-1]. In Eq. 67.8, i is an index over the type of load (i.e., dead load, live load, wind load, etc.), Q_i is the nominal load effect (shear, moment, etc.), and γ_i is the load factor corresponding to Q_i. R_n is the nominal resistance (strength), and ϕ is the resistance factor corresponding to R_n.

$$\sum \gamma_i Q_i \leq \phi R_n \qquad 67.8$$

The left side of Eq. 67.8 represents the required resistance (strength) of a structural member computed by structural analysis based upon code-specified nominal loads. The right side of Eq. 67.8 is the design strength, which represents a limiting structural capacity provided by the member. The nominal resistance, R_n, of a structural member is calculated based on the standard techniques given in Chaps. D through K of *AISC LRFD Specifications*. (Member capacities utilize full material strengths, such as yield strength, rather than using allowable stress values.)

5. LOAD FACTORS AND LOAD COMBINATIONS

The *load factors*, γ_i, account for possible overloading of the structure beyond the code-specified nominal loads. These factors also account for underestimation of load effects due to oversimplification in structural analysis or changes in the use for which a particular structure was designed. Not only can each load effect have a different load factor, but the value of the load factor for a particular load effect will also depend on the combination of loads under consideration.

The most critical effect may occur when one or more loads are not acting. The required strength, $\sum \gamma_i Q_i$, of a structure or its components is determined as the maximum (absolute value) of the factored load combinations given in the *AISC LRFD Specifications* Sec. A4.1. Exceptions are made for garages, areas occupied as places of public assembly, and all areas where the live load is greater than 100 psf. In those cases, the load factor for L in combinations A4-3, A4-4, and A4-5 equals 1.0.

$1.4D$	[A4-1]
$1.2D + 1.6L + 0.5(L_r \text{ or } S \text{ or } R)$	[A4-2]
$1.2D + 1.6(L_r \text{ or } S \text{ or } R) + (0.5L \text{ or } 0.8W)$	[A4-3]
$1.2D + 1.3W + 0.5L + 0.5(L_r \text{ or S or R})$	[A4-4]
$1.2D \pm 1.0E + 0.5L + 0.2S$	[A4-5]
$0.9D \pm (1.3W \text{ or } 1.0E)$	[A4-6]

The nominal service loads are usually taken from the governing building code. In the absence of a code, ASCE 7, Minimum Design Loads for Buildings and Other Structures can be used. Earthquake loads can be determined from the AISC Seismic Provisions for Structural Steel Buildings, Part 6 of the *AISC LRFD Manual*, Vol. I.

In the load combinations, the value of the load factor for dead loads is smaller than that used for live loads because the magnitudes of the dead loads can be estimated more accurately than those of live loads. Also, the load factor for a given load effect is not the same in all load combinations. For example, in combination [A4-2], the load factor for live load L is 1.6, whereas in [A4-3], it is 0.5. This is because the live load is considered to be the dominant load in [A4-2], whereas one of the three loads L_r, S, or R is the principal load in [A4-3]. The use of multiple load factors for the same load effect arises from the logic that when several loads act in combination with the dead load (e.g., dead plus

live plus wind), only one assumes its maximum lifetime value, while the others are at their *arbitrary-point-in-time (APT) values*. Each combination represents the total design loading, when a different load is at its maximum.

Table 67.1 *Assumed Dominant Loads*

load combination	load at lifetime (50-year) maximum
[A4-1]	D^a
[A4-2]	L
[A4-3]	L_r, S, or R (a roof load)
[A4-4]	W (acting in direction of D)
[A4-5]	E (acting in direction of D)
[A4-6]	W or E (opposing D)

[a]For use during construction; other loads not present.

Whether the loads themselves or the load effects are combined, the results are the same, provided the principle of superposition is valid. This is usually true because deflections are small and the stress-strain behavior is linear elastic. Therefore, second-order effects can usually be neglected. Although the linear elastic assumption is not correct at strength limit states, it is valid under normal service load conditions and is permissible as a design assumption under the *AISC LRFD Specifications*. (Sec. A.5.1 allows the designer to use elastic or plastic analysis with factored loads.)

6. RESISTANCE FACTORS

Resistance factors, ϕ, are used to account for the uncertainties in material strengths, workmanship, and dimensions. The resistance factor varies with the type of member and with the limit state being considered. The theoretical or nominal capacity (strength or serviceability) is multiplied by a resistance factor that is almost always less than 1.0. The *AISC LRFD Specifications* gives the following values.

tension members	
yielding limit state	$\phi_t = 0.90$
fracture limit state	$\phi_t = 0.75$
compression members	
buckling limit state	$\phi_c = 0.85$
bending members	
flexure limit state	$\phi_b = 0.90$
shear limit state	$\phi_v = 0.90$

1. INTRODUCTION

Masonry units used in the United States include concrete, clay (brick as well as structural clay tile), glass block, and stone. Concrete and clay masonry are used for the majority of structural masonry construction.

The relevant structural properties of clay and concrete masonry are similar, although test methods and requirements can vary significantly between the two materials. Requirements listed in this chapter are those of ACI 530, *Building Code Requirements for Masonry Structures*, referred to as the *MSJC Code*, *Specification for Masonry Structures*, and *MSJC Specification*.

2. UNIT SIZES AND SHAPES OF CONCRETE MASONRY

Concrete masonry units (CMUs) are manufactured in different sizes, shapes, colors, and textures to achieve a number of finishes and functions. The most common shapes are shown in Fig. 68.1. Typical concrete masonry unit nominal face dimensions are 8 in × 16 in (203 mm × 406 mm), with nominal thicknesses of 4, 6, 8, 10, and 12 in (102, 152, 203, 254, and 305 mm).

The shapes shown in Fig. 68.2 have been developed specifically for reinforced construction. Open-ended units can be placed around reinforcing bars.

In addition to the units shown, special unit shapes have been developed to maximize certain performance characteristics such as insulation, sound absorption, and resistance to water penetration.

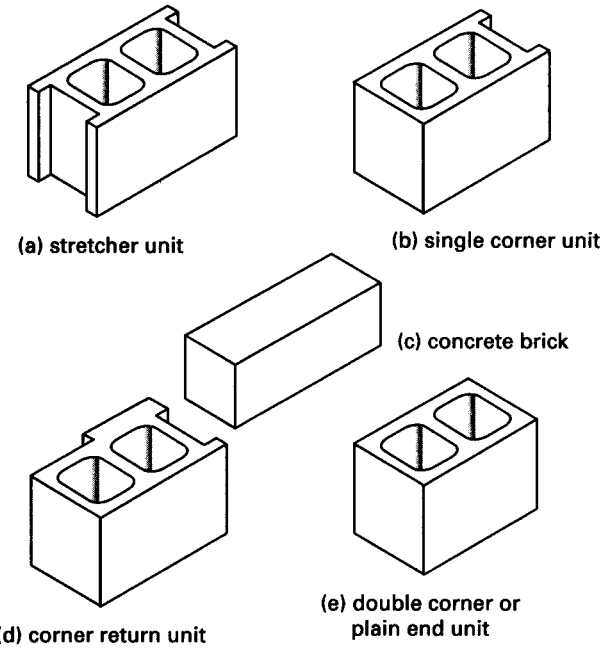

Figure 68.1 *Typical Concrete Masonry Units*

Structural

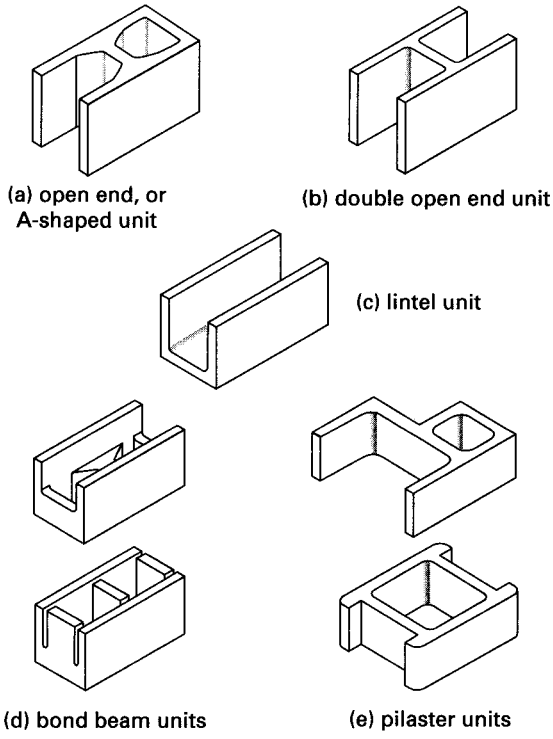

Figure 68.2 *Concrete Masonry Units Accommodating Reinforcement*

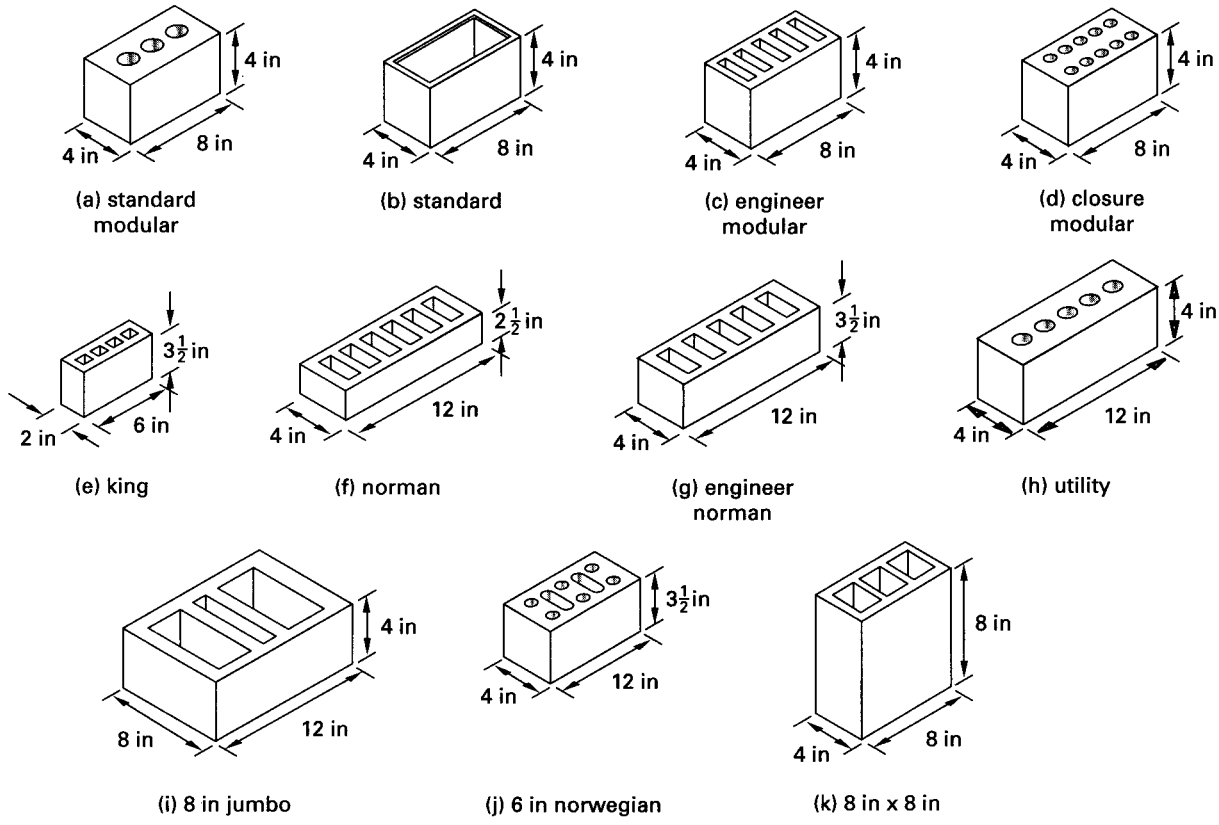

3. UNIT SIZES AND SHAPES OF CLAY MASONRY

Brick (i.e., clay masonry) is manufactured by either extrusion or molding; both processes make it easy to produce unique features. (Very large shapes can be difficult to manufacture because of problems with proper drying and firing.) Clay brick is available in many sizes, most of which are based on a 4 in × 4 in (102 mm × 102 mm) module. Typical clay brick sizes are shown in Fig. 68.3.

Brick types used in structural applications include building brick, face brick, and hollow brick. *Building brick* is typically used as a backing material or in other applications where appearance is not an issue. *Face brick* is used in both structural and nonstructural masonry where an appealing appearance is a requirement. *Hollow brick* is identical to face brick but has a larger core area, which allows hollow brick to be reinforced.

4. COMPRESSIVE STRENGTH

Compressive strength of a masonry assembly varies with time, unit properties, mortar type, and grout, if used. Strength is typically tested at 28 days. The specified compressive strength of masonry, f'_m, is noted in the project documents and is used to establish allowable stresses for masonry elements.

[a]Actual dimensions are typically 3/8 in (9.5 mm) less than nominal dimensions.

Figure 68.3 *Typical Brick Sizes (Nominal Dimensions[a])*

Compliance with specified compressive strength is verified by either the unit strength method or the prism test method. The *unit strength method* involves testing the net area compressive strength of the units and using this value and the mortar type to establish the compressive strength of the masonry. Criteria from the *MSJC Specification* are listed in Tables 68.1 and 68.2.

Table 68.1 *Compressive Strength of Clay Masonry*

net area compressive strength of clay masonry units, lbf/in^2 (MPa)		net area compressive strength of masonry, lbf/in^2 (MPa)
type M or S mortar	type N mortar	
1700 (11.7)	2100 (14.5)	1000 (6.9)
3350 (23.1)	4150 (28.6)	1500 (10.3)
4950 (34.1)	6200 (42.7)	2000 (13.8)
6600 (45.5)	8250 (56.9)	2500 (17.2)
8250 (56.9)	10,300 (71.0)	3000 (20.1)
9900 (68.3)	–	3500 (24.1)
13,200 (91.0)	–	4000 (27.6)

Table 68.2 *Compressive Strength of Concrete Masonry*

net area compressive strength of concrete masonry units, lbf/in^2 (MPa)		net area compressive strength of masonry[a] lbf/in^2 (MPa)
type M or S mortar	type N mortar	
1250 (8.6)	1300 (9.0)	1000 (6.9)
1900 (13.1)	2150 (14.8)	1500 (10.3)
2800 (19.3)	3050 (21.0)	2000 (13.8)
3750 (25.8)	4050 (27.9)	2500 (17.2)
4800 (33.1)	5250 (36.2)	3000 (20.1)

[a]For units of less than 4 in (102 mm) height, use 85% of the values listed.

Source: *MSJC Specification* 1.4B2b. Based on the compressive strength of concrete masonry units and the type of mortar used in construction.

Concrete masonry units are required by ASTM C90 to have an average net area compressive strength of 1900 lbf/in^2 (13.1 MPa). This corresponds to f'_m values of 1500 lbf/in^2 and 1350 lbf/in^2 (10.3 and 9.3 MPa) for mortar types M or S and type N, respectively. f'_m values up to 4000 lbf/in^2 (27.6 MPa) are attainable using high-strength concrete masonry units.

Clay units typically have strengths ranging from 3000 lbf/in^2 (20.7 MPa) to over 20,000 lbf/in^2 (138 MPa), averaging between 6000 lbf/in^2 and 10,000 lbf/in^2 (41.3 and 68.9 MPa) in North America. The required minimum average compressive strength of clay brick is 3000 lbf/in^2 (20.7 MPa) for brick grade SW.

The *prism test method* determines the compressive strength of masonry at 28 days or at the designated test age. Prisms are constructed from materials representative of those to be used in the construction. Typical concrete masonry prisms are two units high, where brick prisms are five units high. A set of three prisms is tested in compression until failure. The individual prism strengths are then corrected to account for the aspect ratio of the prism and averaged together.

5. DENSITY

Density, or unit weight, of a masonry unit is described in terms of dry weight per cubic foot. Larger densities result in increased wall and building weight, heat capacity, sound transmission loss, and thermal conductivity (resulting in lower R-values and decreased fire resistance).

6. MODULUS OF ELASTICITY

The *MSJC Code* defines the modulus of elasticity (elastic modulus) in compression as the *chord modulus* (defined as the slope of a line intersecting the stress-strain curve at two points, neither of which is the origin of the curve) from a stress value of 5 to 33% of the compressive strength of masonry. Moduli of elasticity are determined from *MSJC Code* Sec. 5.5.2.2.

$$E_m = 700 f'_m \quad \text{[clay masonry]} \qquad 68.1$$

$$E_m = 900 f'_m \quad \text{[concrete masonry]} \qquad 68.2$$

7. BOND STRENGTH

Bond describes both the amount of unit/mortar contact and the strength of adhesion. Bond varies with mortar properties (air and water content, water retention), unit surface characteristics (texture and suction), workmanship (pressure applied to joint during tooling, time between spreading mortar and placing units), and curing. In unreinforced masonry design, relative bond strengths are reflected in allowable flexural tension values.

8. DIMENSIONS

Masonry unit dimensions are listed in the following order: thickness × height × length. Nominal dimensions are used for planning bond patterns and modular layout with respect to door and window openings. Actual dimensions of masonry units are typically 3/8 in (9.5 mm) less than nominal dimensions, so that the 4 or 8 in (102 or 203 mm) module size is maintained with 3/8 in (9.5 mm) mortar joints.

9. ABSORPTION

Absorption describes the amount of water a masonry unit can hold when it is saturated. For concrete masonry, absorption is determined either in terms of weight

of water per cubic foot of concrete, or as a percent by dry weight of concrete. For a given aggregate type and gradation, absorption is an indication of how well the concrete was compacted during manufacture. This, in turn, influences compressive strength, tensile strength, and durability.

The maximum permissible absorption per ASTM C90 for concrete masonry ranges from 13 to 18 lbm/ft^3 (208 to 288 kg/m^3), depending on the concrete density.

For brick, there are two categories of absorption: water absorption and *initial rate of absorption* (IRA). *Water absorption* tests are used to calculate a *saturation coefficient* for brick, which is an indicator of durability.

The IRA indicates how much water a brick draws in during the first minute of contact with water. Typical IRA values range between 5 and 40 g/min-30 in^2 (0.2 and 2.05 kg/min·m^2). IRA affects mortar and grout bond. If the IRA is too high, the brick absorption can impair the strength and extent of the bond with mortar and grout. High-suction brick should be wetted prior to laying to reduce suction (although the brick should be surface dry when laid). Very low-suction brick should be covered and kept dry on the jobsite.

In the laboratory, IRA is measured using oven-dried brick, which results in a higher measured IRA than if a moist brick were tested. The field test for IRA, on the other hand, is performed without drying the units. The laboratory test will indicate the order of magnitude of the IRA, where the field test indicates if additional wetting is necessary to lay the units.

10. DURABILITY

Clay brick *durability* may be predicted from either (a) the compressive strength, absorption, and saturation coefficient or (b) the compressive strength and ability to pass 50 freeze-thaw cycles.

Brick durability is reflected in *weathering grades* (severe, moderate, or negligible weathering), defined in ASTM standards. These standards also indicate weather conditions in the United States and define where each grade is required. Brick that meets the severe weathering (SW) grade is commonly available.

11. MORTAR

Mortar structurally bonds units together, seals joints against air and moisture penetration, accommodates small wall movements, and bonds to joint reinforcement, ties, and anchors.

Mortar types are defined in ASTM C270. Four mortar types—M, S, N, and O—are included and vary by the proportions of ingredients. Types M, S, and N are the most commonly used.

Type N mortar is a medium-strength mortar suitable for exposed masonry above grade. It is typically recommended for exterior walls subject to severe exposure, for chimneys, and for parapet walls.

Type S mortar has a relatively high compressive strength and will typically develop the highest flexural bond strength (all other variables being equal). Type M mortar has high compressive strength and excellent durability. Both type M and type S mortar are recommended for below-grade construction and reinforced masonry.

Type O mortar is a relatively low compressive strength mortar suitable for limited exterior use and interior use. It should not be used in freezing or moist environments.

Mortar type is one factor used to determine f'_m, if the unit strength method is used. Mortar type is also used to determine allowable compressive strengths for empirically designed masonry and allowable flexural tension for unreinforced masonry.

The *MSJC Code* restricts the use of some mortars for particular applications. In seismic performance categories C, D, and E, as well as for the empirical design of foundation walls, for example, mortar types S or M are required. Glass unit masonry requires type N or S mortar.

12. MORTAR COMPRESSIVE STRENGTH

Laboratory tests are for preconstruction evaluation of mortars and use low water content mortars. Results establish the general strength characteristics of the mortar mix. Field tests, on the other hand, establish quality control of mortar production and use mortars with high water contents, typical of those used in the work. Field test results are not required to meet the minimum compressive strength values contained in the property specification of ASTM C270.

Field test results should not be compared to lab test results, since the higher water content adversely affects the compressive strength of mortar, but also enhances the bond strength.

13. GROUT

Grout is a fluid cementitious mixture used to fill masonry cores or cavities to increase structural performance. Grout is most commonly used in reinforced construction to bond steel reinforcement to the masonry. The collar joint of a double wythe masonry wall is sometimes grouted to allow composite action.

Grout modulus of elasticity is calculated as $500f_g$.

14. GROUT SLUMP

Grout slump is determined using the same procedure that is used to measure concrete slump. Grout slump should be between 8 and 11 in (203 and 279 mm) to

facilitate complete filling of the grout space and proper performance [*MSJC Specification* 2.6B2]. When relatively quick water loss is expected due to high temperatures and/or highly absorptive masonry units, a higher slump should be maintained. The high initial water content of grout compensates for water absorption by the masonry units after placement. Thus, grout gains high strength despite the high initial water-to-cement ratios.

15. GROUT COMPRESSIVE STRENGTH

When grout compressive strength testing is required, ASTM Test Method C1019 is used. Grout specimens are formed in a mold made up of masonry units with the same absorption and moisture content characteristics as those being used on the job. The masonry units remove excess water from the grout to more closely replicate grout strength in the wall. Concrete test methods should not be used for grout, as grout cubes or cylinders formed in nonabsorptive molds will produce unreliable results.

After curing, the grout specimens are capped and tested. Although a lower aggregate-to-cement ratio generally produces higher grout strengths, there is no direct relationship between the two.

Grout compressive strength is required to equal the specified compressive strength of masonry, but cannot be less than 2000 lbf/in^2 (13.8 MPa).

16. STEEL REINFORCING BARS

Reinforcement increases masonry strength and ductility, providing increased resistance to applied loads and (in the case of horizontal reinforcement) to shrinkage cracking. The two principal types of reinforcement used in masonry are reinforcing bars and cold-drawn wire products.

Reinforcing bars are placed vertically and/or horizontally in the masonry and are grouted into position.

MSJC Specification 3.4E includes installation requirements to ensure elements are placed as assumed in the design. The *MSJC Code*, Sec. 8.4, provides for a minimum masonry and grout cover around reinforcing bars to reduce corrosion and ensure sufficient clearance for grout and mortar to surround reinforcement and accessories, so that stresses can be properly transferred. Bar positioners are often used to hold reinforcement in place during grouting.

Reinforcing bars for masonry are the same as those used in concrete construction, although for masonry, bars larger than no. 11 are not permitted and bars larger than no. 9 are seldom used. Core size and masonry cover requirements may further restrict the maximum bar size that can be used. For bar reinforcement, $F_s = 24{,}000$ lbf/in^2 (165 MPa) for grade-60 steel.

17. DEVELOPMENT LENGTH

Development length (*anchorage* or *embedment length*) ensures that forces can be transferred. Reinforcing bars can be anchored by embedment length, hooks, or mechanical devices. Reinforcing bars anchored by embedment length rely on interlock of the bar deformations with grout and on the masonry cover being sufficient to prevent splitting from the reinforcing bar to the free surface.

The required embedment length for reinforcement in tension is given by Eq. 68.3, but it cannot be less than 12 in (305 mm) for bars and 6 in (152 mm) for wire.

$$l_d = 0.22 d_b F_s \quad \text{[SI]} \quad \textit{68.3(a)}$$

$$l_d = 0.0015 d_b F_s \quad \text{[U.S.]} \quad \textit{68.3(b)}$$

Equation 68.3 assumes that the bond strength will be at least 160 lbf/in^2 (1.1 MPa). When *epoxy-coated bars* are used, the development length above must be increased by 50%. In addition, Sec. 8.5.3 of the *MSJC Code* requires increased embedment lengths for flexural reinforcement in some cases.

Figure 68.4 illustrates the requirements for standard hooks, when reinforcement is anchored by hooks. Table 68.3 summarizes equivalent embedment lengths for *standard hooks* of various sizes.

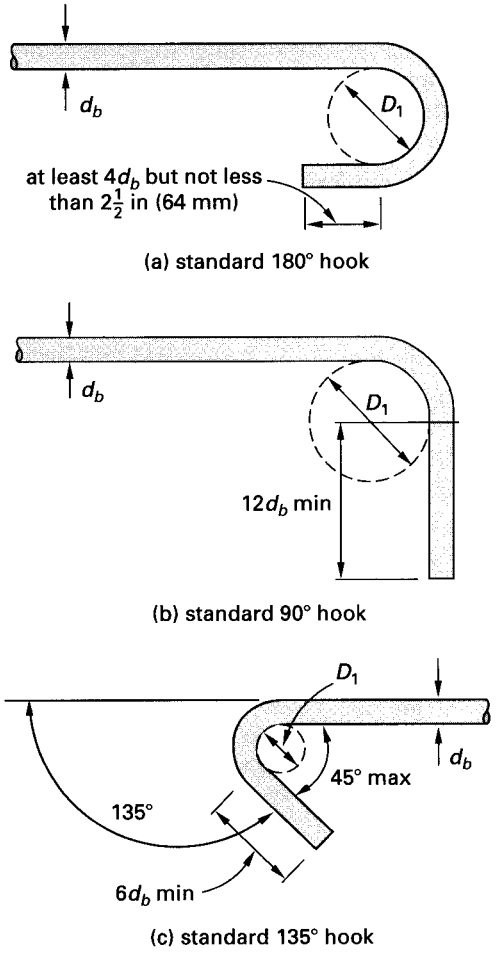

Figure 68.4 *Standard Hooks*

Structural

Table 68.3 *Standard Hook Dimensions and Equivalent Development Lengths*

bar size no.	bar diameter d_b, in (mm)	inside diameter of bend[a] D_i, in (mm)	outside diameter of bend D_o, in (mm)	$4d_b$ extension in (mm)	$6d_b$ extension in (mm)	hook equivalent development length[b] l_{dh}, in (mm)
3	0.375 (9.5)	2.25 (57)	2.63 (67)	1.50[c] (38)	2.25 (57)	4.22 (107)
4	0.5 (13)	3.00 (76)	3.50 (89)	2.00[c] (51)	3.00 (76)	5.63 (143)
5	0.625 (16)	3.75 (95)	4.38 (111)	2.50 (64)	3.75 (95)	7.03 (178)
6	0.75 (19)	4.50 (114)	5.25 (133)	3.00 (76)	4.50 (114)	8.44 (214)
7	0.875 (22)	5.25 (133)	6.13 (156)	3.50 (89)	5.25 (133)	9.85 (250)
8	1.0 (25)	6.00 (152)	7.00 (178)	4.00 (102)	6.00 (152)	11.25 (286)
9	1.128 (29)	9.02 (229)	10.15 (258)	4.51 (115)	6.77 (172)	12.69 (322)

[a]Based on requirements for grade-60 reinforcing steel as follows: for bar size nos. 3 through 8, D_i must equal or exceed $6d_b$; for no. 9 bars, D_i must equal or exceed $8d_b$. Diameters of bend may be decreased to $5d_b$ for grade-40 reinforcement.
[b]Equivalent development length, l_{dh}, is $11.25d_b$.
[c]For 180° standard hooks, bar extensions may not be less than 2½ in (64 mm).

18. HORIZONTAL JOINT REINFORCEMENT

Joint reinforcement is a welded wire assembly consisting of two or more longitudinal wires connected with cross wires. It is placed in horizontal mortar bed joints, most commonly to control wall cracking associated with thermal or moisture shrinkage or expansion. Secondary functions include (a) metal tie system for bonding adjacent masonry wythes and (b) structural steel reinforcement.

For wire joint reinforcement, $F_s = 30{,}000$ lbf/in^2 (207 MPa).

19. BOND PATTERNS

Allowable design stresses, lateral support criteria, and minimum thickness requirements for masonry are based primarily on structural testing and research on wall panels laid in running bond. *Running bond* is defined as construction where the head joints in successive courses are horizontally offset at least one-quarter the unit length (typical offset is half the unit length). When a different bond pattern is used, its influence on the compressive and flexural strength of the wall should be considered.

1. METHODS OF DESIGN

Building Code Requirements for Masonry Structures (the *MSJC Code*) defines a wall as a vertical element with a horizontal length-to-thickness ratio greater than three, and used to enclose space. This differentiates walls from columns, which are subject to additional design limitations. Masonry walls can serve as veneer facings subject to out-of-plane flexure; loadbearing walls subject to axial compression, flexure, or both; and shear walls. While walls are typically designed to span vertically (between floors) or horizontally (between intersecting walls or pilasters), they can also be designed for two-way bending to limit deflection and increase stability.

Masonry structures are currently designed using one of several methods, including empirical procedures, allowable stress design, and strength design. Allowable stress design (ASD) is currently the most widely used of the three methods.

2. EMPIRICAL WALL DESIGN

Empirical design is a procedure of proportioning and sizing masonry elements. The criteria are based on historical experience rather than analytical methods. This method is conservative for most masonry construction. It is an expedient method for typical loadbearing structures, exterior curtain walls, and interior partitions.

Prescriptive criteria in Ch. 9 of the *MSJC Code* govern vertical and lateral load resistance of walls. Certain limitations (such as maximum wind velocity, maximum building height, and seismic performance category) apply to empirical designs, helping to ensure the construction and design loads are consistent with the experience used to establish the empirical criteria. This *MSJC Code* chapter includes requirements for wall lateral support, allowable stresses, anchorage for lateral support, and shear wall spacing.

3. ALLOWABLE STRESS WALL DESIGN

The allowable stress design (ASD) method compares expected or calculated design stresses due to expected loads to allowable design stresses. Loads are unfactored; that is, the service loads are such that they may be expected to occur during the structure's life. When calculated design stresses are less than allowable stresses, the design is acceptable.

Allowable stresses are determined by reducing expected material strengths by appropriate factors of safety. In addition, Sec. 5.3 of the *MSJC Code* permits allowable stresses to be increased by one third for load combinations including wind or seismic loads. Masonry allowable stresses may vary with unit type, mortar type, compressive strength, and other factors. Stronger masonry will have higher allowable stresses.

The following assumptions form the basis of ASD for masonry. (a) Stress is linearly proportional to strain for stresses within the allowable stress (elastic) range. Therefore, sections that are plane before bending remain plane after bending. (b) Masonry materials combine to form a homogeneous, isotropic material. (c) Reinforcement, when used, is perfectly bonded to masonry.

The tensile strength of masonry units, mortar, and grout is neglected, as is the compressive resistance of steel reinforcement, unless confined by lateral ties to prevent buckling in accordance with provisions in the *MSJC Code*. (These confinement provisions are virtually impossible to meet for walls.) Axial tension and flexural tension are resisted entirely by steel reinforcement.

ASD of *plain (unreinforced) masonry* is covered in Ch. 6 of the *MSJC Code*. When unreinforced, masonry is designed to resist tensile and compressive loads; the tensile strength of any steel in the wall is neglected. Tension due to axial loads, such as wind uplift, is not permitted in unreinforced masonry. Compressive stress from dead loads can be used to offset axial tension, although if axial tension develops, the wall must be reinforced to resist the tension.

MSJC Code Ch. 7 includes ASD criteria for axial compression and flexure, axial tension, and shear for reinforced masonry walls.

4. STRENGTH DESIGN

The strength design method compares factored loads to the design strength of the material. Expected loads are multiplied by load factors to provide a factor of safety. The ultimate strength of the wall section is reduced by a strength reduction factor, ϕ, that accounts for variations in material properties and workmanship.

Although this same method is typically used to design reinforced concrete elements, different design parameters apply to masonry.

In strength design, compressive stress is assumed to be rectangular and uniformly distributed over an equivalent compression zone, bounded by the compression face of the masonry, with a depth of $0.85c$. The maximum usable strain at the extreme compression fiber of the masonry is limited to 0.003.

The amount of reinforcement is limited to half of the reinforcing ratio at balanced conditions, ρ_{bal}, to ensure ductility. Balanced conditions exist when the strain in the reinforcement reaches its specified yield strength, f_y, just as the masonry reaches its assumed maximum usable strain of 0.003.

Strength design provisions for masonry are currently included in the Uniform Building Code.

5. PROPERTIES OF BUILT-UP SECTIONS

Wall design is greatly assisted by using tabulated properties of various built-up sections. Appendices 69.A through D are convenient tabulations of useful properties.

In Apps. 69.A through D, the net cross-sectional area of masonry, A_n, and the section modulus, S, are based on the minimum cross-sectional area (i.e., the mortared and grouted areas) of the wall [*MSJC Code* 5.13.1]. Moment of inertia, I, and radius of gyration, r, are based on the average cross-sectional area, which is taken through the masonry unit [*MSJC Code* 5.13.2 and 5.13.3].

On horizontal bed joints, masonry units are typically mortared on the face shells only. Webs are not typically mortared unless they are adjacent to a grouted core, in which case, they are mortared to confine the grout. Section properties listed reflect these practices.

6. ASD WALL DESIGN: FLEXURE—UNREINFORCED

Examples of walls subjected to out-of-plane flexure are exterior nonloadbearing walls subjected to wind or seismic loads, along with retaining walls. The self-weight of the wall can be neglected where the wall design will be governed by tension, such as for a one-story wall. In this case, the wall weight will offset tension in the wall, so the assumption is conservative.

In ASD, the actual wall stress is calculated as $f_b = M/S$ and compared to the allowable stress, F_b, obtained from Table 69.1.

Example 69.1

Evaluate the tensile stresses in a one-story masonry wall for a wind load of 20 lbf/ft^2. The wall is 12 ft high and simply supported at the top and bottom. 12 in concrete masonry and portland cement-lime type S mortar are used.

Solution

From Table 69.1, $F_b = 25$ lbf/in^2, which can be increased by one third for wind loads. Therefore,

$$F_b = \left(\tfrac{4}{3}\right)\left(25.0\ \frac{\text{lbf}}{\text{in}^2}\right) = 33.3\ \text{lbf/in}^2$$

Structural

Table 69.1 *Allowable Flexural Tensile Stress for Clay and Concrete Masonry in lbf/in^2 (MPa)*

	mortar types			
	portland cement/lime or mortar cement		masonry cement or air entrained portland cement/lime	
masonry type	M or S	N	M or S	N
normal to bed joints				
solid units	40 (0.28)	30 (0.21)	24 (0.17)	15 (0.10)
hollow units[a]				
ungrouted	25 (0.17)	19 (0.13)	15 (0.10)	9 (0.06)
fully grouted	68 (0.47)	58 (0.40)	41 (0.28)	26 (0.18)
parallel to bed joints in running bond				
solid units	80 (0.55)	60 (0.41)	48 (0.33)	30 (0.21)
hollow units				
ungrouted and partially grouted	50 (0.35)	38 (0.26)	30 (0.21)	19 (0.13)
fully grouted	80 (0.55)	60 (0.41)	48 (0.33)	30 (0.21)

[a]For partially grouted masonry, allowable stresses shall be determined on the basis of linear interpolation between hollow units that are fully grouted or ungrouted and hollow units based on the amount of grouting.

Source: *MSJC Code* Table 6.3.1.1

From App. 69.A, $S = 159.9 \text{ in}^3/\text{ft}$.

Determine the maximum moment.

$$M = \frac{wl^2}{8} = \frac{\left(20 \frac{\text{lbf}}{\text{ft}^2}\right)(12 \text{ ft})^2 \left(12 \frac{\text{in}}{\text{ft}}\right)}{8}$$
$$= 4320 \text{ in-lbf/ft}$$

Calculate the stress and compare to the allowable stress.

$$f_b = \frac{M}{S} = \frac{4320 \frac{\text{in-lbf}}{\text{ft}}}{159.9 \frac{\text{in}^3}{\text{ft}}}$$
$$= 27.0 \text{ lbf/in}^2 < 33.3 \text{ lbf/in}^2 \quad \text{[OK]}$$

7. ASD WALL DESIGN: FLEXURE—REINFORCED

The structural model for allowable stress design of fully grouted flexural members is shown in Fig. 69.1. The allowable stress for grade-60 steel is $F_s = 24{,}000 \text{ lbf/in}^2$ (165 MPa).

The allowable bending stress for masonry flexural members is

$$F_b = \tfrac{1}{3} f'_m \qquad 69.1$$

The allowable shear stress for masonry flexural members is given by Eq. 69.2, although shear due to out-of-plane bending seldom governs the design.

$$F_v = \sqrt{f'_m} \qquad 69.2$$

Fully grouted masonry walls respond in bending similar to reinforced concrete beams. Analysis of these walls is based on the straight-line theory for beams subjected to bending. The equations governing the analysis follow the traditional ASD equations for reinforced concrete.

$$\rho = \frac{A_s}{bd} \qquad 69.3$$

$$k = \sqrt{2\rho n + (\rho n)^2} - \rho n \qquad 69.4$$

$$j = 1 - \frac{k}{3} \qquad 69.5$$

$$M_m = F_b b d^2 \left(\frac{jk}{2}\right) \qquad 69.6$$

$$M_s = A_s F_s j d \qquad 69.7$$

$$M_R = \text{the lesser of } M_m \text{ and } M_s \qquad 69.8$$

$$V_R = F_v b d \qquad 69.9$$

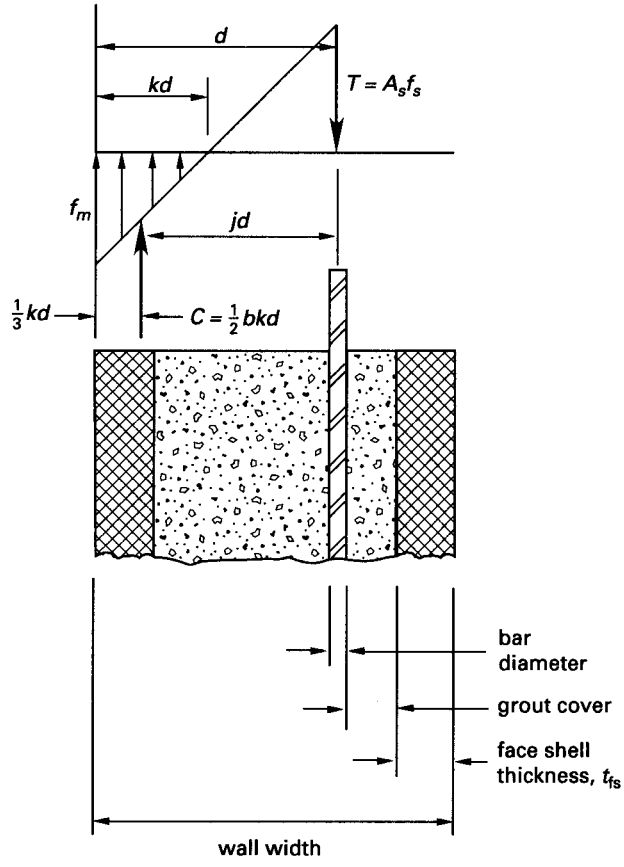

Figure 69.1 *Stress Distribution for Fully Grouted Masonry*

Section 7.3.3.1 of the *MSJC Code* limits the width of the compression area, b, used in stress calculations to the smallest of: the center-to-center bar spacing, six times the wall thickness, or 72 in (1829 mm) for running bond masonry.

Determining the balanced condition allows the designer to know whether reinforcement stress or masonry stress governs the design. A *balanced condition* occurs when both the steel and masonry reach their respective allowable stresses at the same time (i.e., $f_m = F_b$ and $f_s = F_s$), although the balanced design is not necessarily the most cost-effective. If there is less reinforcement than that required for a balanced condition, moment capacity is governed by F_s. The balanced condition is determined by setting masonry compressive stress, C, equal to reinforcement tensile stress, T.

$$\rho_{\text{bal}} = \frac{nF_b}{2F_s\left(n + \frac{F_s}{F_b}\right)} \quad \text{[balanced]} \qquad 69.10$$

When analyzing *partially grouted masonry* (i.e., where some core voids are filled and others are not), there are two cases to consider: (a) neutral axis falling within the face shell of the masonry, and (b) neutral axis falling within the core area. When the neutral axis falls within

the face shell (i.e., when kd is less than the face shell thickness), the analysis is identical to the analysis of the fully grouted masonry wall.

When the neutral axis falls within the core area of the masonry, the masonry wall responds to bending similar to a reinforced concrete T-beam. The grouted area and the face shell react to forces as a single unit, rather than as two separate beams. (T-beam performance seldom occurs in walls less than 10 in thick.) The analysis of partially grouted walls is summarized in Eqs. 69.11 through 69.16.

$$k = \frac{-A_s n - t_{fs}(b - b_w)}{db_w} + \frac{\sqrt{\left(A_s n + t_{fs}(b - b_w)\right)^2 + t_{fs}^2 b_w (b - b_w) + 2db_w A_s n}}{db_w} \qquad 69.11$$

$$j = \left(\frac{1}{kdb_w + t_{fs}(b - b_w)\left(2 - \frac{t_{fs}}{kd}\right)}\right) \times \left(kb_w\left(d - \frac{kd}{3}\right) + \left(\frac{2t_{fs}(b - b_w)}{kd^2}\right) \times \left((kd - t_{fs})\left(d - \frac{t_{fs}}{2}\right) + \left(\frac{t_{fs}}{2}\right)\left(d - \frac{t_{fs}}{3}\right)\right)\right) \qquad 69.12$$

$$M_m = \tfrac{1}{2}F_b kdb_w\left(d - \frac{kd}{3}\right) + F_b t_{fs}(b - b_w) \times \left(\left(1 - \frac{t_{fs}}{kd}\right)\left(d - \frac{t_{fs}}{2}\right) + \left(\frac{t_{fs}}{2kd}\right)\left(d - \frac{t_{fs}}{3}\right)\right) \qquad 69.13$$

$$M_s = A_s F_s jd \qquad 69.14$$

$$M_R = \text{the lesser of } M_m \text{ and } M_s \qquad 69.15$$

$$V_R = F_v\left(bt_{fs} + b_w(d - t_{fs})\right) \qquad 69.16$$

Table 69.2 *Reinforcing Steel Areas, A_s, in in^2/ft*

bar spacing (in)	reinforcing bar size						
	no. 3	no. 4	no. 5	no. 6	no. 7	no. 8	no. 9

72	0.018	0.033	0.051	0.074	0.100	0.131	0.166

Example 69.2

Design a cantilever concrete masonry retaining wall for a maximum design moment of 12,960 in-lbf/ft. The wall is 6 ft high. Use 8 in units with $f'_m = 1500$ lbf/in^2.

Solution

Work on a per unit width basis.

Place steel on the tension (nonsoil) side of the wall. Choose $d = 4.75$ in. Use fully grouted masonry.

For an initial steel estimate, assume $j = 0.9$.

$$\begin{aligned} E_m &= 900f'_m \\ &= (900)\left(1500\ \frac{\text{lbf}}{\text{in}^2}\right) \\ &= 1{,}350{,}000\ \text{lbf/in}^2 \end{aligned}$$

$$n = \frac{E_s}{E_m} = \frac{29{,}000{,}000\ \frac{\text{lbf}}{\text{in}^2}}{1{,}350{,}000\ \frac{\text{lbf}}{\text{in}^2}} = 21.5$$

From Eq. 69.1,

$$\begin{aligned} F_b &= \tfrac{1}{3}f'_m \\ &= \left(\tfrac{1}{3}\right)\left(1500\ \frac{\text{lbf}}{\text{in}^2}\right) \\ &= 500\ \text{lbf/in}^2 \end{aligned}$$

Obtain an initial estimate of the steel required. From Eq. 69.7,

$$\begin{aligned} A_s &= \frac{M}{F_s jd} \\ &= \frac{12{,}960\ \frac{\text{in-lbf}}{\text{ft}}}{\left(24{,}000\ \frac{\text{lbf}}{\text{in}^2}\right)(0.9)(4.75\ \text{in})} \\ &= 0.126\ \text{in}^2/\text{ft} \end{aligned}$$

From Table 69.2, try no. 6 bars at 32 in on center, giving $A_s = 0.166$ in^2/ft.

$$\rho = \frac{A_s}{bd} \quad \text{[Eq. 69.3]} = \frac{0.166\ \frac{\text{in}^2}{\text{ft}}}{\left(12\ \frac{\text{in}}{\text{ft}}\right)(4.75\ \text{in})} = 0.0029$$

$$\begin{aligned} k &= \sqrt{2\rho n + (\rho n)^2} - \rho n \quad \text{[Eq. 69.4]} \\ &= \sqrt{(2)(0.0029)(21.5) + (0.0029)^2(21.5)^2} - (0.0029)(21.5) \\ &= 0.296 \end{aligned}$$

Structural

$$j = 1 - \frac{k}{3} \quad \text{[Eq. 69.5]}$$

$$= 1 - \frac{0.296}{3} = 0.901$$

$$M_m = F_b b d^2 \left(\frac{jk}{2}\right) \quad \text{[Eq. 69.6]}$$

$$= \left(500 \frac{\text{lbf}}{\text{in}^2}\right)\left(12 \frac{\text{in}}{\text{ft}}\right)(4.75 \text{ in})^2\left(\frac{(0.901)(0.296)}{2}\right)$$

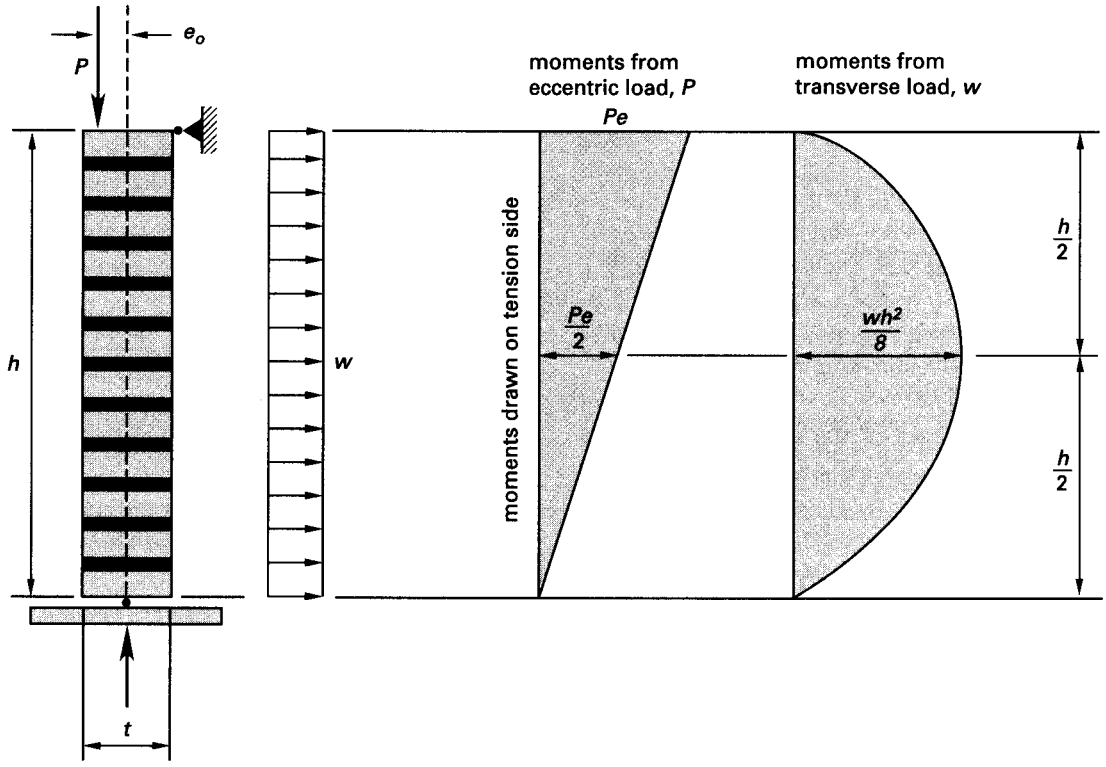
$$= 18{,}052 \text{ in-lbf/ft}$$

$$M_s = A_s F_s j d \quad \text{[Eq. 69.7]}$$

$$= \left(0.166 \frac{\text{in}^2}{\text{ft}}\right)\left(24{,}000 \frac{\text{lbf}}{\text{in}^2}\right)(0.901)(4.75 \text{ in})$$

$$= 17{,}051 \text{ in-lbf/ft}$$

$$M_R = 17{,}051 \text{ in-lbf/ft} > 12{,}960 \text{ in-lbf/ft} \quad \text{[OK]}$$



8. ASD WALL DESIGN: AXIAL COMPRESSION AND FLEXURE—UNREINFORCED

Many masonry walls are designed for both axial compression and flexure. Examples include: loadbearing exterior walls (subject to wind and/or seismic loads), tall nonloadbearing exterior walls (where the self-weight of the wall decreases wall capacity), and walls with an eccentric vertical load.

Axial capacity decreases with increasing wall height. For very tall slender walls, elastic buckling is the limiting factor. For most masonry walls, however, the main effect of slenderness is the development of additional bending due to deflection (known as the P-Δ effect). In previous masonry design codes, slenderness effects were indicated by the h/t ratio. The *MSJC Code* now uses h/r to more accurately reflect the response of hollow and partially grouted masonry.

Walls subject to compressive loads only may be in pure compression or may be subject to flexure. For unreinforced walls where the compressive load is within a distance S/A_n (i.e., $t/6$ for solid sections) from the centroid of the wall, there will be no net tensile stress due to load eccentricity.

The critical section for walls subject to eccentric load and out-of-plane loads (such as wind or seismic) may be either at the top of the wall or at midheight, depending on the magnitudes of the loads. Both locations should be checked.

Note: For large *P* and small *w*, the critical location is at the top of the wall.

$$M = Pe$$

For small *P* and large *w*, the critical location is near the midheight.

$$M = \frac{Pe}{2} + \frac{wh^2}{8}$$

Figure 69.2 *Unreinforced Walls Subject to Axial Compression and Flexure*

Unreinforced walls subjected to axial compression, flexure, or both must satisfy Eqs. 69.17 through 69.22. In Eq. 69.19, e should be the actual or estimated eccentricity. It should not include virtual eccentricity due to lateral load.

$$\frac{f_a}{F_a} + \frac{f_b}{F_b} \leq 1 \qquad 69.17$$

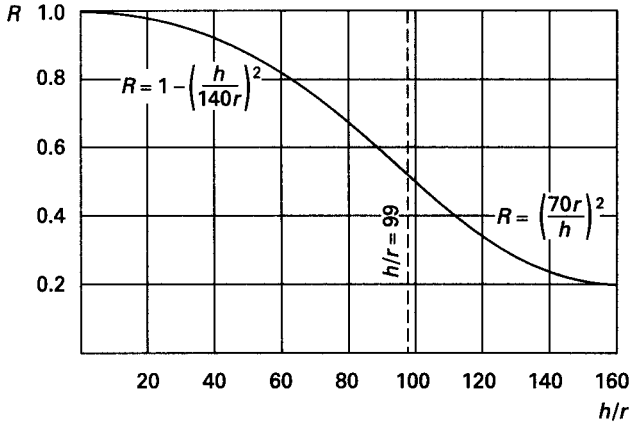
$$P \leq \tfrac{1}{4}P_e \qquad 69.18$$

$$P_e = \left(\frac{\pi^2 E_m I}{h^2}\right)\left(1 - 0.577\left(\frac{e}{r}\right)\right)^3 \qquad 69.19$$

$$F_a = \tfrac{1}{4}f'_m\left(1 - \left(\frac{h}{140r}\right)^2\right) \quad [h/r < 99] \qquad 69.20$$

$$F_a = \tfrac{1}{4}f'_m\left(\frac{70r}{h}\right)^2 \quad [\text{with } h/r > 99] \qquad 69.21$$

$$F_b = \tfrac{1}{3}f'_m \qquad 69.22$$



In addition, Sec. 6.3.1.1 requires tensile stresses due to out-of-plane flexure to be less than the allowable values in Table 69.1. This limiting tensile stress may control for large eccentricities.

Equation 69.17 recognizes that compressive stresses due to both axial load and bending may occur simultaneously, and it assumes a straight-line interaction between axial and flexural compression stresses. Equation 69.18 is intended to safeguard against buckling due to an eccentric axial load. This replaces arbitrary slenderness limits used in previous codes.

The effect of slenderness can be characterized by defining a *slenderness reduction factor*, R. Figure 69.3 illustrates the variation of R over a wide range of h/r values.

$$R = 1 - \left(\frac{h}{140r}\right)^2 \quad [h/r < 99] \qquad 69.23$$

$$R = \left(\frac{70r}{h}\right)^2 \quad [h/r > 99] \qquad 69.24$$

Reprinted by permission of the American Concrete Institute from *Masonry Designer's Guide*, copyright © 1993.

Figure 69.3 *Slenderness Reduction Factor*

Example 69.3

Determine the maximum allowable concentric axial load on an 8 in hollow unreinforced concrete masonry wall rising vertically 12 ft. $f'_m = 2000$ psi.

Solution

From App. 69.A,

$$r = 2.84 \text{ in}$$
$$A_n = 30 \text{ in}^2/\text{ft}$$
$$I = 334 \text{ in}^4/\text{ft}$$
$$S = 81.0 \text{ in}^3/\text{ft}$$
$$\frac{h}{r} = \frac{(12 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}{2.84 \text{ in}} = 50.7 \quad [< 99]$$

From Eq. 69.20,

$$F_a = \left(\tfrac{1}{4}\right)\left(2000 \frac{\text{lbf}}{\text{in}^2}\right)\left(1 - \left(\frac{50.7}{140}\right)^2\right) = 434 \text{ lbf/in}^2$$

For concentric loading,

$$P = A_n F_a$$
$$= \left(30 \frac{\text{in}^2}{\text{ft}}\right)\left(434 \frac{\text{lbf}}{\text{in}^2}\right)$$
$$= 13{,}020 \text{ lbf/ft}$$

Check buckling. From Eq. 68.2,

$$E_m = 900f'_m$$
$$= (900)\left(2000 \frac{\text{lbf}}{\text{in}^2}\right)$$
$$= 1{,}800{,}000 \text{ lbf/in}^2$$
$$e = 0$$
$$P_e = \left(\frac{\pi^2 E_m I}{h^2}\right)\left(1 - 0.577\left(\frac{e}{r}\right)\right)^3$$
$$= \left(\frac{\pi^2\left(1.8 \times 10^6 \frac{\text{lbf}}{\text{in}^2}\right)\left(334 \frac{\text{in}^4}{\text{ft}}\right)}{(144 \text{ in})^2}\right)(1)^3$$
$$= 286{,}150 \text{ lbf/ft}$$
$$P \leq \tfrac{1}{4}P_e$$
$$\leq \left(\tfrac{1}{4}\right)\left(286{,}150 \frac{\text{lbf}}{\text{ft}}\right)$$
$$\leq 71{,}540 \text{ lbf/ft} \quad [\text{OK}]$$

Structural

Example 69.4

Repeat Ex. 69.3 assuming an eccentricity of 1.5 in.

$$F_a = 434 \text{ lbf/in}^2$$

$$f_a = \frac{P}{A_n}$$

$$f_b = \frac{M}{S} = \frac{Pe}{S}$$

$$F_b = \tfrac{1}{3} f'_m \quad \text{[Eq. 69.1]}$$

$$= \left(\tfrac{1}{3}\right)\left(2000 \frac{\text{lbf}}{\text{in}^2}\right)$$

$$= 667 \text{ lbf/in}^2$$

$$\frac{\frac{P}{A}}{F_a} + \frac{\frac{Pe}{S}}{F_b} = 1 \quad \text{[Eq. 69.17]}$$

$$\frac{\frac{P}{30 \frac{\text{in}^2}{\text{ft}}}}{434 \frac{\text{lbf}}{\text{in}^2}} + \frac{\frac{P(1.5 \text{ in})}{81 \frac{\text{in}^3}{\text{ft}}}}{667 \frac{\text{lbf}}{\text{in}^2}} = 1$$

$$P = 9563 \text{ lbf/ft}$$

Check buckling.

$$P_e = \left(\frac{\pi^2 \left(1.8 \times 10^6 \frac{\text{lbf}}{\text{in}^2}\right)\left(334 \frac{\text{in}^4}{\text{ft}}\right)}{(144 \text{ in})^2}\right) \times \left(1 - (0.577)\left(\frac{1.5 \text{ in}}{2.84 \text{ in}}\right)\right)^3$$

$$= 96{,}160 \text{ lbf/ft}$$

$$P \le \tfrac{1}{4} P_e = \left(\tfrac{1}{4}\right)\left(96{,}160 \frac{\text{lbf}}{\text{ft}}\right) = 24{,}041 \text{ lbf/ft} \quad \text{[OK]}$$

Check tension.

$$-f_a + f_b < F_t$$

$$-\frac{P}{A_n} + \frac{Pe}{S} < F_t$$

$$-\frac{9563 \frac{\text{lbf}}{\text{ft}}}{30 \frac{\text{in}^2}{\text{ft}}} + \frac{\left(9563 \frac{\text{lbf}}{\text{ft}}\right)(1.5 \text{ in})}{81 \frac{\text{in}^3}{\text{ft}}} = -142 \text{ lbf/in}^2$$

The section is in compression.

9. ASD WALL DESIGN: AXIAL COMPRESSION AND FLEXURE—REINFORCED

Reinforced walls subjected to axial compression and/or flexure are designed according to the following requirements.

$$F_b = \tfrac{1}{3} f'_m \qquad 69.25$$

The compressive force due to axial loading is limited to

$$P_a = (0.25 f'_m A_n + 0.65 A_{st} F_s)\left(1 - \left(\frac{h}{140r}\right)^2\right) \quad [h/r < 99] \qquad 69.26$$

$$P_a = \left(0.25 f'_m A_n + 0.65 A_{st} F_s\right)\left(\frac{70r}{h}\right)^2 \quad [h/r > 99] \qquad 69.27$$

Many design approaches are used to design reinforced masonry walls for combined axial compression and flexure, typically using iterative procedures (usually by means of computer programs) or graphic methods (i.e., interaction diagrams).

Figures 69.4 and 69.5 show interaction diagrams for cases where compression controls and where tension controls, respectively. The controlling condition is determined by comparing k to k_b, where

$$k_b = \frac{F_b}{F_b + \frac{F_s}{n}} \qquad 69.28$$

These diagrams are applicable to fully grouted masonry and to partially grouted masonry where the neutral axis falls within the face shell. Therefore, the designer must verify that $k_d < t_{fs}$ before using these diagrams.

Example 69.5

Determine the amount of steel needed to adequately reinforce an 8 in fully grouted concrete masonry wall subjected to a compressive load of 1000 lbf/ft with an eccentricity at the midheight of the wall of 6 in. Use the following values.

$$f'_m = 1500 \text{ lbf/in}^2$$

$$F_b = 500 \text{ lbf/in}^2$$

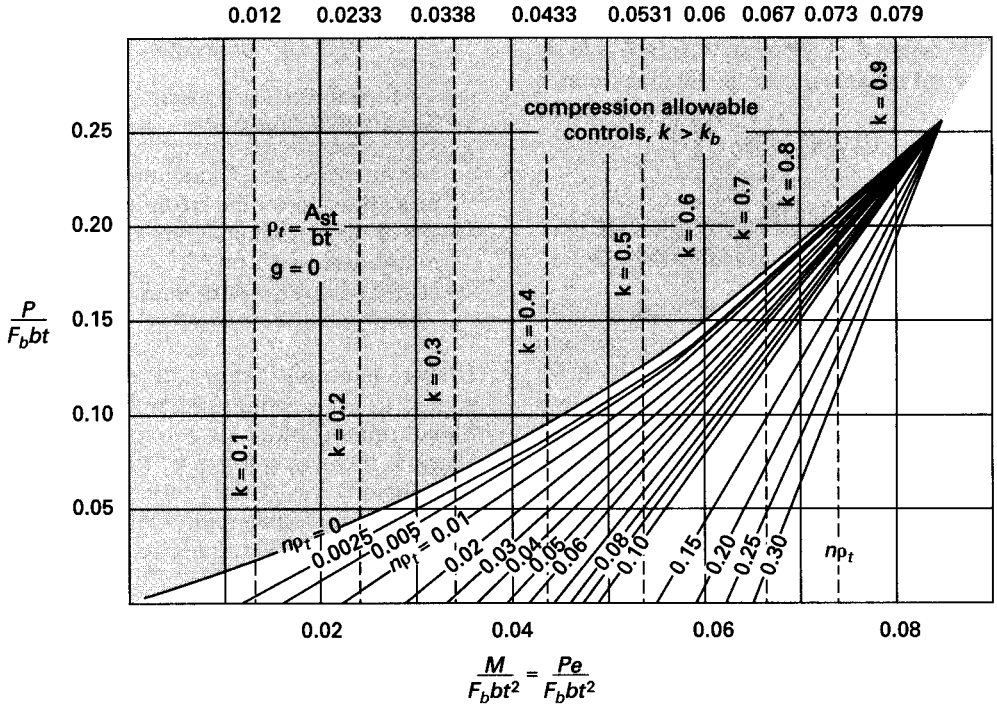
$$n = 21.5$$

$$\frac{h}{r} = 68$$

$$A_n = 91.5 \text{ in}^2\text{/ft}$$

$$F_s = 24{,}000 \text{ lbf/in}^2$$

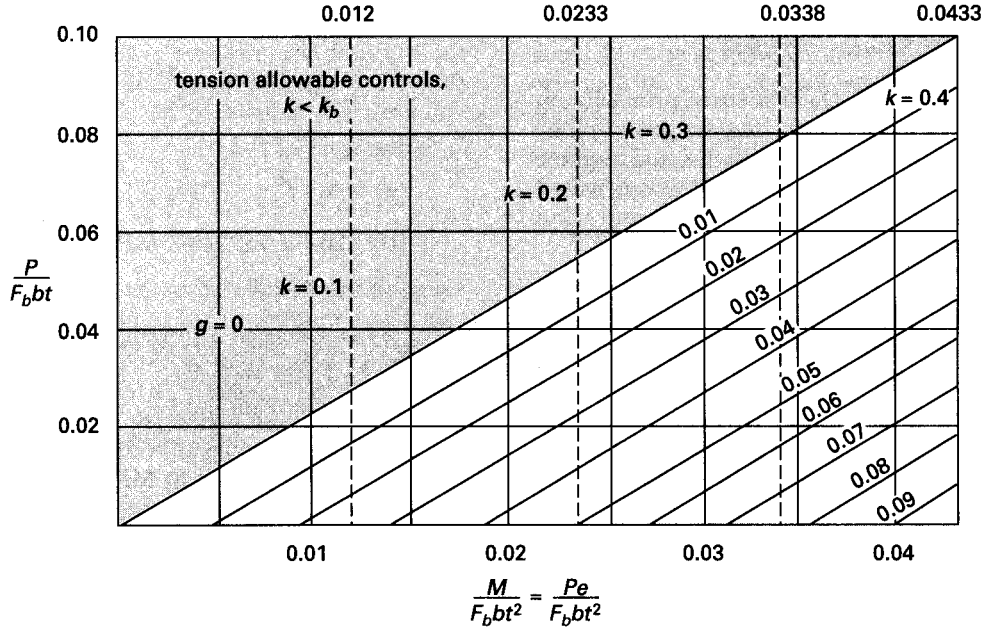
Solution



$$\frac{P}{F_b b t} = \frac{1000 \frac{\text{lbf}}{\text{ft}}}{\left(500 \frac{\text{lbf}}{\text{in}^2}\right)(12 \text{ in})(7.625 \text{ in})} = 0.022$$

$$\frac{Pe}{F_b b t^2} = \frac{\left(1000 \frac{\text{lbf}}{\text{ft}}\right)(6 \text{ in})}{\left(500 \frac{\text{lbf}}{\text{in}^2}\right)(12 \text{ in})(7.625 \text{ in})^2} = 0.017$$

$$k_b = \frac{F_b}{F_b + \frac{F_s}{n}} \quad \text{[Eq. 69.28]}$$



$$= \frac{500 \frac{\text{lbf}}{\text{in}^2}}{500 \frac{\text{lbf}}{\text{in}^2} + \frac{24{,}000 \frac{\text{lbf}}{\text{in}^2}}{21.5}}$$

$$= 0.309$$

Figure 69.4 *Interaction Diagram for Reinforced Wall (compression controls)*

Reprinted by permission of the American Concrete Institute from *Masonry Designer's Guide*, copyright © 1993.

Figure 69.5 *Interaction Diagram for Reinforced Wall (tension controls)*

Structural

From Fig. 69.4, $k = 0.14$. Since $k < k_b$, tension governs and Fig. 69.5 should be used. From Fig. 69.5, $\rho_t F_s / F_b = 0.014$.

$$\rho_t = \frac{0.014F_b}{F_s} = \frac{(0.014)\left(500\ \frac{\text{lbf}}{\text{in}^2}\right)}{24{,}000\ \frac{\text{lbf}}{\text{in}^2}}$$

$$= 0.00029$$

$$A_s = \rho_t bt = (0.00029)(12\text{ in})(7.625\text{ in})$$

$$= 0.027\text{ in}^2/\text{ft}$$

From Table 69.2, choose no. 3 bars at 48 in on center for a steel area of $A_s = 0.028\text{ in}^2/\text{ft}$.

Check the allowable compressive force. For $h/r < 99$, use Eq. 69.26.

$$P_a = (0.25f'_m A_n + 0.65A_{st}F_s)\left(1 - \left(\frac{h}{140r}\right)^2\right)$$

$$= \left((0.25)\left(1500\ \frac{\text{lbf}}{\text{in}^2}\right)\left(91.5\ \frac{\text{in}^2}{\text{ft}}\right)\right.$$

$$\left. + (0.65)\left(0.028\ \frac{\text{in}^2}{\text{ft}}\right)\left(24{,}000\ \frac{\text{lbf}}{\text{in}^2}\right)\right)$$

$$\times \left(1 - \left(\frac{68}{140}\right)^2\right)$$

$$= 26{,}551\text{ lbf/ft} \quad \text{[OK]}$$

10. ASD WALL DESIGN: SHEAR

Design of masonry walls for shear focuses primarily on shear walls, since flexural shear due to out-of-plane bending seldom governs the design (whereas in-plane shear often controls). Shear walls must be oriented along both axes of the building, since seismic and wind lateral loads can occur in any direction.

Small openings in shear walls do not impact intended performance to a great degree. Shear walls with large openings can be thought of as smaller shear panels connected by panels subject to shear and flexure.

Loads distributed to shear walls depend on the relative rigidities of the floor diaphragms and shear walls. *Flexible diaphragms* transfer loads in proportion to the distance between the load and shear wall, whereas *rigid diaphragms* transfer loads in proportion to the relative stiffness of the walls. To design walls as rigid diaphragms, the proportions must meet the ratios in Table 69.3.

Shear wall design depends on the wall axial load for two reasons. First, walls in compression have greater shear resistance. Second, compression offsets flexural tension from lateral loads, which may eliminate the need for shear reinforcement.

Table 69.3 *Maximum Span-to-Width Ratios for Rigid Floor Diaphragms*

floor construction	span-to-width
cast-in-place solid concrete slab	5:1
precast concrete interconnected	4:1
metal deck with concrete fill	3:1
metal deck with no fill	2:1
cast-in-place gypsum deck (roof)	3:1

If there is no net flexural tension, the shear wall is designed as an unreinforced wall [*MSJC Code* Sec. 6.5]. Shear reinforcement is required only if $f_v > F_v$. If there is flexural tension in the wall, the wall must be reinforced to resist that tension. The design is checked to determine if that reinforcement is sufficient to resist shear as well. F_v is calculated according to *MSJC Code* Sec. 7.5.2.2.

If $f_v > F_v$, shear reinforcement must be provided. F_v is recalculated according to *MSJC Code* Sec. 7.5.2.3. If f_v still exceeds F_v, a larger wall must be used to resist the shear.

11. ASD WALL DESIGN: SHEAR WALLS WITH NO NET TENSION

If the compressive stress, P/A_n, exceeds flexural stress, M/S, the wall has no net flexural tension. In this case, f_v and F_v are determined according to the following procedure [*MSJC Code* Sec. 6.5].

$$f_v = \frac{VQ}{Ib} = \frac{3V}{2A_n} \quad \text{[rectangular sections]} \qquad 69.29$$

F_v is the least of

(a) $1.5\sqrt{f'_m}$

(b) 120 lbf/in^2 (0.83 MPa)

(c) $v + 0.45N_v/A_n$

In (c), v has values of 37 lbf/in^2 (0.26 MPa) for masonry in running bond that is not grouted solid, 37 lbf/in^2 (0.26 MPa) for masonry in other than running bond with open end units that are grouted solid, 60 lbf/in^2 (0.41 MPa) for masonry in running bond that is grouted solid, and 15 lbf/in^2 (0.10 MPa) for masonry in other than running bond with other than open end units that are grouted solid.

As for other stress conditions in ASD, the calculated stress, f_v, may not exceed the allowable F_v. If $f_v > F_v$, the wall may be reinforced or increased in size. If reinforced, F_v is calculated from *MSJC Code* Sec. 7.5.2.3 (corresponding to Eqs. 69.33 and 69.34) and the amount of reinforcement is calculated from *MSJC Code* Sec. 7.5.3 (corresponding to Eq. 69.35) and related requirements.

12. ASD WALL DESIGN: SHEAR WALLS WITH NET TENSION

Walls subjected to flexural tension are reinforced to resist the tension. In this case, calculated shear stress in the masonry is determined by Eq. 69.32 [*MSJC Code* Sec. 7.5.2.1].

$$f_v = \frac{V}{bd} \qquad 69.30$$

F_v is determined from *MSJC Code* Sec. 7.5.2.2. The quantity M/Vd is always taken as a positive value.

$$F_v = \tfrac{1}{3}\left(4 - \frac{M}{Vd}\right)\sqrt{f'_m}$$
$$< 80 - 45\left(\frac{M}{Vd}\right) \quad [M/Vd < 1] \qquad 69.31$$

$$F_v = \sqrt{f'_m}$$
$$< 35 \text{ lbf/in}^2 \quad (0.24 \text{ MPa}) \quad [M/Vd \geq 1] \qquad 69.32$$

If $f_v < F_v$, the section is satisfactory. If $f_v > F_v$, shear reinforcement is required, and F_v is recalculated using *MSJC Code* Sec. 7.5.2.3.

$$F_v = \tfrac{1}{2}\left(4 - \frac{M}{Vd}\right)\sqrt{f'_m}$$
$$< 120 - 45\left(\frac{M}{Vd}\right) \quad [M/Vd < 1] \qquad 69.33$$

$$F_v = 1.5\sqrt{f'_m}$$
$$< 75 \text{ lbf/in}^2 \quad (0.52 \text{ MPa}) \quad [M/Vd \geq 1] \qquad 69.34$$

If f_v still exceeds F_v, the wall size must be increased.

When shear reinforcement is required, the *MSJC Code* contains the following requirements. The minimum area of shear reinforcement placed parallel to the direction of applied shear force is

$$A_v = \frac{Vs}{F_s d} \qquad 69.35$$

Maximum spacing of shear reinforcement is the lesser of $d/2$ or 48 in (1219 mm). Reinforcement must also be provided perpendicular to the shear reinforcement. This reinforcement must be uniformly distributed, have a maximum spacing of 8 ft (2.4 m), and have a minimum reinforcement area of at least $\frac{1}{3}A_v$.

13. MULTI-WYTHE CONSTRUCTION

Multiple-wythe masonry walls are analyzed using the same procedures outlined in previous sections. In some cases, however, determination of wall thickness or other parameters may vary, depending on the type of wall and how it is loaded.

Multi-wythe walls can be designed for *composite action* (i.e., where the two wythes act as one unit to resist loads) or for *noncomposite action*. Masonry veneer is a nonstructural facing that transfers the out-of-plane load to the backing (structural wythe). The *MSJC Code* contains empirical requirements for both anchored and adhered veneer.

14. MULTI-WYTHE CONSTRUCTION—COMPOSITE ACTION

Multi-wythe walls designed for composite action are tied together by either wall ties or masonry headers. (Wall ties are more common and provide more ductility than headers.) The ties or headers ensure adequate shear transfer across the collar joint. When wall ties are used, the space between the wythes (collar joint) must be filled with mortar or grout. To help ensure shear transfer, specific requirements govern the size and spacing of the headers and ties, and shear stresses are limited.

For composite action, stresses are calculated using section properties based on the minimum transformed net cross-sectional area of the composite member. Areas of dissimilar materials are transformed in accordance with relative elastic moduli ratios.

Shear stresses at the interfaces between wythes and collar joints or within headers are limited to the following: mortared collar joints, 5 lbf/in^2 (0.034 MPa); grouted collar joints, 10 lbf/in^2 (0.069 MPa); headers, $\sqrt{(\text{unit compressive strength of header})}$, in lbf/in^2 (MPa), over net area of header.

When bonded by headers, the headers must be uniformly distributed. The sum of their cross-sectional areas must be at least 4% of the wall surface area. Headers must be embedded at least 3 in (76 mm) into each wythe.

Wythes bonded using wall ties are subject to the following restrictions.

- Maximum spacing between ties is 36 in (914 mm) horizontally and 24 in (610 mm) vertically.
- With a W1.7 wire, one wall tie is needed for every $2\frac{2}{3}$ ft^2 (0.25 m^2) of wall. With W2.8 wire, one wall tie is needed for every $4\frac{1}{2}$ ft^2 (0.42 m^2) of wall.

Cross wires of joint reinforcement or rectangular wall ties may be used as wall ties. "Z" wall ties can be used only on walls constructed of solid masonry units.

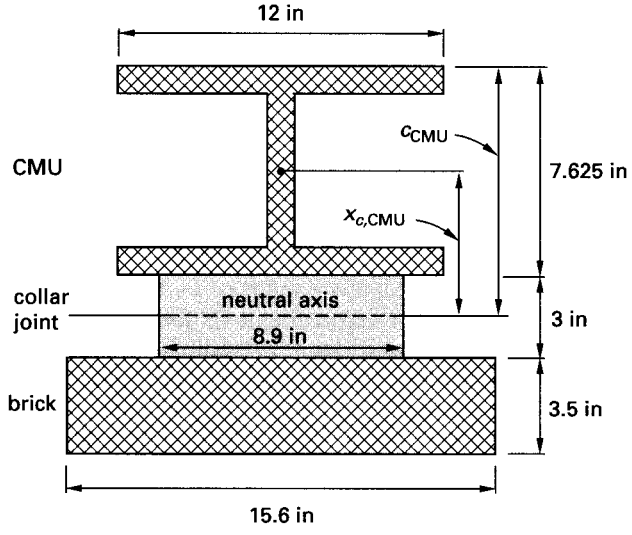
Example 69.6

Determine the maximum lateral wind load that can be sustained by a nonloadbearing multi-wythe composite wall constructed of 8 in concrete masonry units (CMUs), a 3 in grouted collar joint, and 4 in face brick. Both wythes are constructed with type-S portland cement-lime mortar. The wall spans vertically 20 ft and can

be assumed to be simply supported laterally at the top and bottom. Neglect the self-weight of the wall. The following properties are to be used.

	CMU	brick	grout
f'_m or f_g (in lbf/in^2)	1500	2500	2000
E_m (in lbf/in^2)	1,350,000	1,750,000	1,000,000

Solution



$$n_{\text{br}} = \frac{E_{m,\text{br}}}{E_{m,\text{CMU}}} = \frac{1{,}750{,}000\ \frac{\text{lbf}}{\text{in}^2}}{1{,}350{,}000\ \frac{\text{lbf}}{\text{in}^2}} = 1.3$$

$$n_g = \frac{E_{m,\text{g}}}{E_{m,\text{CMU}}} = \frac{1{,}000{,}000\ \frac{\text{lbf}}{\text{in}^2}}{1{,}350{,}000\ \frac{\text{lbf}}{\text{in}^2}} = 0.74$$

The widths of the transformed areas (relative to a 12 in long CMU) are

brick: $(1.3)(12\text{ in}) = 15.6$ in

grout: $(0.74)(12\text{ in}) = 8.9$ in

Determine the distance from the centroid of the transformed area to the centroid of the CMU.

From App. 69.A, $A_{n,\text{CMU}} = 30$ in^2/ft.

$$x_{c,\text{CMU}} = \frac{\sum Ax_i}{\sum A}$$

$$= \frac{\begin{array}{l}(30\text{ in}^2)(0\text{ in}) \\ \quad + (15.6\text{ in})(3.5\text{ in})\left(\frac{7.625\text{ in}}{2} + 3\text{ in} + \frac{3.5\text{ in}}{2}\right) \\ \quad + (8.9\text{ in})(3\text{ in})\left(\frac{7.625\text{ in}}{2} + \frac{3.0\text{ in}}{2}\right)\end{array}}{30\text{ in}^2 + (15.6\text{ in})(3.5\text{ in}) + (8.9\text{ in})(3\text{ in})}$$

$= 5.47$ in [below the centroid of the CMU]

Determine the transformed moment of inertia.

From App. 69.A, $I_{\text{CMU}} = 308.7$ in^4/ft.

From App. 69.B, $I_{\text{br}} = 42.9$ in^4/ft.

$$\begin{aligned} I_{\text{tr}} &= \sum (I + Ax_c^2) \\ &= 308.7\text{ in}^4 + (30\text{ in}^2)(5.47\text{ in})^2 \\ &\quad + \frac{(8.9\text{ in})(3\text{ in})^3}{12} \\ &\quad + (8.9\text{ in})(3\text{ in})(0.16\text{ in})^2 \\ &\quad + (42.9\text{ in}^4)\left(\frac{15.6\text{ in}}{12\text{ in}}\right) \\ &\quad + (15.6\text{ in})(3.5\text{ in})(3.09\text{ in})^2 \\ &= 1804\text{ in}^4 \quad \text{[per foot of wall]} \end{aligned}$$

Determine the allowable flexural tension from Table 69.1.

$$F_{b,\text{CMU}} = \left(25\ \frac{\text{lbf}}{\text{in}^2}\right)(1.33) = 33.3\text{ lbf/in}^2$$

$$F_{b,\text{br}} = \left(40\ \frac{\text{lbf}}{\text{in}^2}\right)(1.33) = 53.2\text{ lbf/in}^2$$

Determine the maximum allowable moment for each wythe.

$$\text{CMU: } M = \frac{F_b I_{\text{tr}}}{c} = \frac{\left(33.3\ \frac{\text{lbf}}{\text{in}^2}\right)(1804\text{ in}^4)}{9.32\text{ in}} = 6446\text{ in-lbf}$$

$$\text{brick: } M = \frac{F_b I_{\text{tr}}}{c} = \frac{\left(53.2\ \frac{\text{lbf}}{\text{in}^2}\right)(1804\text{ in}^4)}{4.81\text{ in}} = 19{,}953\text{ in-lbf}$$

This design is limited by stresses in the CMU wythe: $M_{\text{max}} = 6446$ in-lbf.

Since the wall is simply supported laterally at its top and bottom, $M_{max} = wl^2/8$.

$$w = \frac{8M_{max}}{l^2}$$
$$= \frac{(8)\left(6446\ \frac{\text{in-lbf}}{\text{ft}}\right)}{(20\ \text{ft})^2\left(12\ \frac{\text{in}}{\text{ft}}\right)}$$
$$= 10.7\ \text{lbf/ft}^2$$

Check the shear at the collar joint. For simply supported walls,

$$V = \frac{wl}{2} = \frac{\left(10.7\ \frac{\text{lbf}}{\text{ft}^2}\right)(20\ \text{ft})}{2}$$
$$= 107\ \text{lbf/ft}$$

The statical moment at the CMU/collar joint interface is

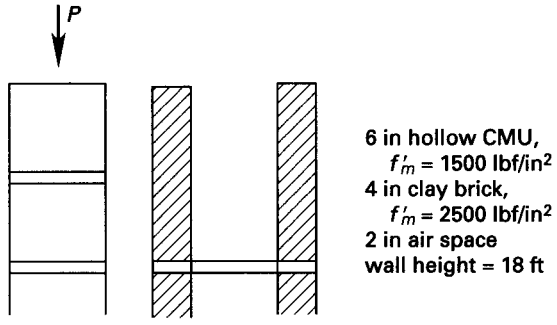
$$Q = (15.6\ \text{in})(3.5\ \text{in})(3.09\ \text{in}) + (8.9\ \text{in})(3\ \text{in})(0.16\ \text{in})$$
$$= 173.0\ \text{in}^3$$

Use Eq. 69.29.

$$f_v = \frac{VQ}{I_{tr}b}$$
$$= \frac{(107\ \text{lbf})(173.0\ \text{in}^3)}{(1804\ \text{in}^4)(8.9\ \text{in})}$$
$$= 1.2\ \frac{\text{lbf}}{\text{in}^2} < 10\ \frac{\text{lbf}}{\text{in}^2} \quad \text{[OK]}$$

15. MULTI-WYTHE CONSTRUCTION—NONCOMPOSITE ACTION

For noncomposite design, each wythe is designed to individually resist the applied loads. Unless a more detailed analysis is performed, the following guidelines and restrictions apply.



- Collar joints may not contain headers, grout, or mortar.
- Gravity loads from supported horizontal members are resisted by the wythe nearest to the center of the span of the supported member. Any resulting bending moment about the weak axis of the wall is distributed to each wythe in proportion to its relative stiffness.
- In-plane loads are carried only by the wythe subjected to the load.
- Out-of-plane loads are resisted by all wythes in proportion to their relative flexural stiffness.
- Stresses are determined using the net cross-sectional area of the member or part of member under consideration and, where applicable, using the transformed area concept described previously.
- Collar joint width is limited to 4.5 in (114 mm) unless a detailed wall tie analysis is performed.

Wythes can be connected using wall ties or adjustable ties. If wall ties are used, the spacings described previously under composite action are applicable. Adjustable ties are subject to the following restrictions.

- One tie must be provided for each 1.77 ft^2 (0.16 m^2) of wall area.
- The maximum horizontal and vertical spacing is 16 in (406 mm).
- Adjustable ties may not be used when the misalignment of bed joints from one wythe to the other exceeds 1¼ in (32 mm).
- Maximum clearance between connecting parts of the tie is 1/16 in (1.6 mm).
- Pintle ties shall have at least two pintle legs of wire size W2.8.

PRACTICE PROBLEMS

1. Determine the allowable vertical load of the masonry wall shown.

Answer: 4092 lbf/ft

2. A 25 ft high, 10 in CMU wall is partially grouted and reinforced. The wall is nonloadbearing and is subjected to wind only. The wall is simply supported at top and bottom, and reinforcement is placed in the center of the wall.

$$f'_m = 2000\ \text{lbf/in}^2$$
$$n = 16.1$$

Structural

(a) With reinforcement spaced at 24 in, determine the largest reinforcing bars that can be used such that the neutral axis falls within the face shell of the unit.

(A) no. 4 bars
(B) no. 5 bars
(C) no. 6 bars
(D) no. 7 bars

The answer is (B).

For parts (b) through (f), assume the wall has no. 6 bars spaced at 32 in vertically.

(b) Determine the location of the neutral axis.

(A) 1.0 in
(B) 1.2 in
(C) 1.7 in
(D) 2.0 in

The answer is (B).

(c) Determine the resisting moment assuming steel governs.

(A) 17,500 in-lbf/ft
(B) 20,000 in-lbf/ft
(C) 23,000 in-lbf/ft
(D) 24,500 in-lbf/ft

The answer is (C).

(d) Determine the allowable compressive stress.

(A) 670 lbf/in^2
(B) 890 lbf/in^2
(C) 1000 lbf/in^2
(D) 1140 lbf/in^2

The answer is (B).

(e) Determine the resisting moment of the wall.

(A) 17,000 in-lbf/ft
(B) 22,000 in-lbf/ft
(C) 23,000 in-lbf/ft
(D) 29,000 in-lbf/ft

The answer is (C).

(f) Determine the shear capacity.

(A) 2600 lbf/ft
(B) 3400 lbf/ft
(C) 3900 lbf/ft
(D) 4300 lbf/ft

The answer is (B).

(g) Determine the area of steel required to produce a balanced design condition.

(A) 0.15 in^2/ft
(B) 0.18 in^2/ft
(C) 0.21 in^2/ft
(D) 0.25 in^2/ft

The answer is (D).

(h) Determine the maximum moment on the wall if it is subjected to a 25 lbf/ft^2 wind load.

(A) 23,400 in-lbf/ft
(B) 24,200 in-lbf/ft
(C) 24,800 in-lbf/ft
(D) 25,100 in-lbf/ft

The answer is (A).

For parts (i) and (j), the wall must resist a moment of 20,000 in-lbf/ft. Assume fully grouted masonry.

(i) Using $\rho = 0.004$ and $d = 4.81$ in, determine the amount of steel required.

(A) 0.12 in^2/ft
(B) 0.15 in^2/ft
(C) 0.18 in^2/ft
(D) 0.20 in^2/ft

The answer is (B).

(j) With no. 5 bars spaced at 16 in, determine the steel stress.

(A) 14,000 lbf/in^2
(B) 16,000 lbf/in^2
(C) 18,000 lbf/in^2
(D) 20,000 lbf/in^2

The answer is (D).

3. An 8 in hollow unreinforced concrete masonry wall, 12 ft high, is simply supported at top and bottom.

For parts (a) through (e), $f'_m = 1800$ lbf/in^2.

(a) Determine the allowable stresses.

(A) $F_a = 390$ lbf/in^2, $F_b = 600$ lbf/in^2
(B) $F_a = 320$ lbf/in^2, $F_b = 800$ lbf/in^2
(C) $F_a = 520$ lbf/in^2, $F_b = 600$ lbf/in^2
(D) $F_a = 390$ lbf/in^2, $F_b = 800$ lbf/in^2

The answer is (A).

(b) Determine the maximum vertical load the wall can be designed for, with a 2 in eccentricity.

(A) 6700 lbf/ft
(B) 7900 lbf/ft
(C) 10,000 lbf/ft
(D) 14,000 lbf/ft

The answer is (B).

(c) Determine the maximum wind load if the wall carries no vertical load. Neglect the self-weight of the wall.

(A) 9.4 lbf/ft^2
(B) 12 lbf/ft^2
(C) 16 lbf/ft^2
(D) 18 lbf/ft^2

The answer is (B).

For parts (d) and (e), the wall is subjected to an axial load of 5000 lbf/ft. There is no lateral load.

(d) Determine the allowable shear stress.

(A) 64 lbf/in^2
(B) 110 lbf/in^2
(C) 120 lbf/in^2
(D) 130 lbf/in^2

The answer is (A).

(e) Assuming the wall has no net tension, determine the maximum shear force the wall can be designed for.

(A) 900 lbf/ft
(B) 1000 lbf/ft
(C) 1100 lbf/ft
(D) 1300 lbf/ft

The answer is (D).

For parts (f) through (j), assume the wall is subjected to a vertical dead load, D, of 4500 lbf/ft ($e = 2.5$ in) and a lateral wind load, w, of 35 lbf/ft^2.

(f) Considering both wind and dead loads, determine the flexural compressive stress in the masonry.

(A) 120 lbf/in^2
(B) 140 lbf/in^2
(C) 160 lbf/in^2
(D) 180 lbf/in^2

The answer is (C).

(g) Considering both wind and dead loads, determine the masonry strength, f'_m, required.

(A) 890 lbf/in^2
(B) 950 lbf/in^2
(C) 1100 lbf/in^2
(D) 1500 lbf/in^2

The answer is (A).

(h) Determine the flexural tension capacity required.

(A) 6 lbf/in^2
(B) 10 lbf/in^2
(C) 14 lbf/in^2
(D) 15 lbf/in^2

The answer is (B).

(i) Determine the minimum required masonry strength, f'_m.

(A) 890 lbf/in^2
(B) 950 lbf/in^2
(C) 1100 lbf/in^2
(D) 1500 lbf/in^2

The answer is (C).

(j) Determine the minimum net area required to sustain an 18,000 lbf/ft axial load.

(A) 30 in^2/ft
(B) 39 in^2/ft
(C) 46 in^2/ft
(D) 52 in^2/ft

The answer is (C).

4. Design the joint reinforcement for a concrete masonry wall to carry a 20 lbf/ft^2 wind load. The wall spans 10 ft horizontally and is simply supported at both ends. Use allowable stress design. Assume the following.

- $f'_m = 1500$ lbf/in^2
- 8 in hollow units, laid with face shell mortar bedding, type-S mortar
- The wall will be built using horizontal joint reinforcement every other course (spaced at 16 in).
- The wall carries no axial loads.
- The masonry modulus of elasticity is $E_m = 2.08 \times 10^6$ lbf/in^2.
- The modulus of elasticity of steel is $E_s = 29{,}000{,}000$ lbf/in^2.
- Steel stress governs the design.

Answer: Use W2.1 (8 ga) horizontal joint reinforcement every other course.

1. MASONRY COLUMNS

Columns are isolated structural elements subject to axial loads and often to flexure. To distinguish columns from short walls, *Building Code Requirements for Masonry Structures* (the "*MSJC Code*") defines a column as an isolated vertical member whose length-to-thickness ratio does not exceed three and whose height-to-hickness ratio is greater than four.

Pilasters are sometimes confused with columns. Whereas columns are isolated elements, pilasters are integral parts of masonry walls. A pilaster is a thickened wall section that typically projects beyond one or both faces. It provides lateral stability to the masonry wall and may carry axial loads as well.

Concrete masonry columns are most often constructed of hollow masonry units, with grout and reinforcement in the masonry cores. Brick columns are typically constructed of solid units laid with an open center, as shown in Fig. 70.1. In both cases, units in successive courses should be laid in a running bond (i.e., overlapping) pattern to avoid a continuous vertical mortar joint up the side of the column.

Columns are designed for axial compression, flexure, and shear as needed. Design methods and assumptions are essentially the same as those presented for masonry walls. However, three significant differences may exist. (a) Due to the structural importance of columns, the *MSJC Code* imposes additional criteria for minimum size, slenderness, and reinforcement. (b) Biaxial bending may be significant in columns. (c) Compression reinforcement may be necessary.

2. SLENDERNESS

Whereas slenderness effects are not a major consideration with most walls, they can be significant for columns. Load-carrying capacity can be reduced due to either buckling or to additional bending moments caused by deflection (P-Δ effects). In the *MSJC Code*, slenderness effects are included in the calculation of allowable compressive stress for reinforced masonry. For columns, the *MSJC Code* also limits the ratio between the effective height and the least nominal dimension to a maximum of 25. Additionally, columns are required to have a side dimension of at least 8 in (203 mm) nominal.

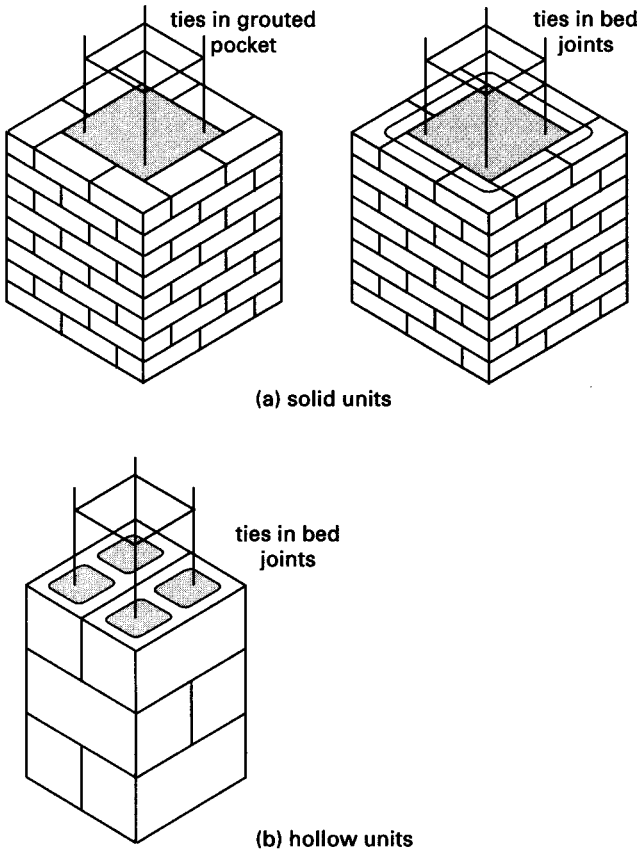

Figure 70.1 *Column Reinforcement*

The effective height of a column varies with end conditions. *Effective height* is equal to the distance between points of inflection for the member. If the restraint conditions are unknown, the clear height between supports should be used.

3. REINFORCEMENT

The *MSJC Code* requires a minimum amount of reinforcement to prevent brittle collapse of columns. The general design provisions for reinforced masonry described in Ch. 69 are used to analyze masonry columns, as well.

The area of vertical column reinforcement must be between $0.0025A_n$ and $0.04A_n$ [*MSJC Code* 5.9.1.4]. A minimum of four reinforcement bars is required, which allows ties to provide a confined core of masonry. Vertical bars must have a clear distance between bars of least $1\frac{1}{2}$ times the nominal bar diameter, but not less than $1\frac{1}{2}$ in (38 mm).

Lateral ties in columns enclose the vertical bars and provide support to prevent buckling of column reinforcement acting in compression and resistance to diagonal tension for columns subjected to shear. Requirements are based on those for concrete columns and are summarized as follows [*MSJC Code* 5.9.1.6].

- Lateral ties must be at least $\frac{1}{4}$ in (6.4 mm) in diameter, with maximum vertical spacing of 16 longitudinal bar diameters, 48 lateral tie bar or wire diameters, or the least cross-sectional dimension of the member.
- Every corner and alternate longitudinal bar must be supported by a tie corner. Tie corners may not have an included angle of more than 135°. No vertical bar can be more than 6 in (152 mm) away from such a laterally supported bar.
- Lateral ties may be placed in either a mortar joint or in grout, although placement in grout is preferable. Ties in contact with the vertical reinforcing bars are more effective in preventing buckling and result in more ductile behavior. In Seismic Performance Categories (SPC) D and E, the *MSJC Code* requires the ties to be embedded in grout for this reason.
- Where longitudinal bars are located around the perimeter of a circle, a complete circular lateral tie is permitted. (The lap length for circular ties is 48 tie diameters.)
- Lateral ties must be located within one-half the lateral tie spacing at the top and bottom of the column.
- Where beams or brackets frame into a column from four directions, lateral ties may be terminated within 3 in (76 mm) below the lowest reinforcement.

When designing devices used to transfer lateral support to columns, a minimum force of 1000 lbf (4448 N) must be used. In SPC C, D, and E, the *MSJC Code* mandates further prescriptive requirements, including ties around anchor bolts and size and spacing of column ties.

4. DESIGNING FOR AXIAL LOAD AND BENDING

The eccentricity of column loads is an important consideration because of slenderness effects. Eccentricity can be due to eccentric axial loads, lateral loads, or a column that is out of plumb. For column design, the *MSJC Code* [Sec. 5.9.1.3] requires a minimum eccentricity equal to 0.1 times each side dimension. This requirement is intended to account for construction imperfections that may introduce eccentricities. If the actual eccentricity exceeds the code minimum, the actual eccentricity is used in the design. Stresses about each principal axis must be checked independently.

The method used to design the column depends on the magnitude of the axial load relative to the bending moment. There are three possibilities: (a) the column is in pure compression and the allowable axial load is governed by the allowable axial compressive force, P_a; (b) the allowable moment and axial force are governed

by the allowable flexural compressive stress, F_b; (c) the allowable moment and axial force are governed by the allowable tensile stress in the reinforcement, F_s.

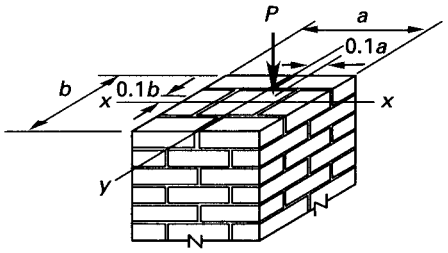

Figure 70.2 *Minimum Design Eccentricity*

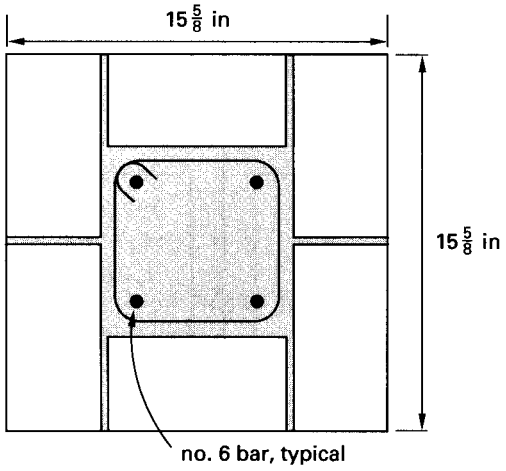
5. DESIGNING FOR PURE COMPRESSION



When the eccentricity falls within the *kern* of the section, the entire section will be in compression. Transformed longitudinal column steel can be included using a transformation factor of n, although neglecting the steel is conservative. Equations for walls in compression are used to determine capacity.

$$P_a = (0.25f'_m A_n + 0.65A_{st}F_s)\left(1 - \left(\frac{h}{140r}\right)^2\right) \quad [h/r < 99] \qquad 70.1$$

$$P_a = (0.25f'_m A_n + 0.65A_{st}F_s)\left(\frac{70r}{h}\right)^2 \quad [h/r > 99] \qquad 70.2$$

Example 70.1

Determine the maximum column height for the clay brick column shown. The column carries a concentric axial load of 100,000 lbf. $f'_m = 2500$ lbf/in^2, $A_n = 244$ in^2, $S = 636$ in^3, and $r = 4.51$ in.

Solution

The *MSJC Code* allows a maximum height of

$$(25)(15.625 \text{ in}) = 390.6 \text{ in}$$

Check the load capacity. The minimum required eccentricity is

$$e = (0.1)(15.625 \text{ in}) = 1.56 \text{ in}$$

$$e_k = \frac{t}{6} = \frac{15.625 \text{ in}}{6} = 2.6 \text{ in}$$

Since $e < e_k$, the section is in pure compression.

Neglecting the steel and assuming $h/r < 99$, Eq. 70.1 becomes

$$P_a = 0.25f'_m A_n \left(1 - \left(\frac{h}{140r}\right)^2\right)$$

$$100{,}000 \text{ lbf} = (0.25)\left(2500 \frac{\text{lbf}}{\text{in}^2}\right)(244 \text{ in}^2) \times \left(1 - \left(\frac{h}{(140)(4.51 \text{ in})}\right)^2\right)$$

$$h = 370 \text{ in} < 390.6 \text{ in}$$

Check the h/r ratio.

$$h/r = \frac{370 \text{ in}}{4.51 \text{ in}} = 82 \quad \text{[OK]}$$

The maximum column height is 370 in.

6. DESIGNING FOR COMPRESSION AND BENDING

For large eccentricities, the section is subject to axial compression and flexure, and the interaction of vertical load and bending moment must be checked as for reinforced masonry walls, typically using interaction diagrams or computer solutions.

The interaction diagrams shown in Apps. 70.A through F were developed for rectangular columns with equal areas of top and bottom steel, symmetrically placed and adequately tied. Three cases are presented representing three values of the steel spacing ratio, g. Apps. 70.A through C assume the allowable masonry compressive stress controls the design. Apps. 70.D through F assume allowable steel tensile stress governs. If it is unknown whether masonry or steel stress governs, the required value of r_t should be calculated from both interaction diagrams, and the larger steel area should be used.

Example 70.2

For the column in Ex. 70.1, assume a compressive load occurs at an eccentricity of 4.7 in. Determine the

Structural

maximum load if the effective column height is 18 ft. The modular ratio, n, is 12. Use interaction curves for $g = 0.6$.

Solution

Use Eq. 70.1 as in Ex. 70.1.

$$P_a = 0.25 f'_m A_n \left(1 - \left(\frac{h}{140r}\right)^2\right)$$

$$= (0.25)\left(2500\ \frac{\text{lbf}}{\text{in}^2}\right)(244\ \text{in}^2) \times \left(1 - \left(\frac{(18\ \text{ft})\left(12\ \frac{\text{in}}{\text{ft}}\right)}{(140)(4.51\ \text{in})}\right)^2\right)$$

$$= 134{,}653\ \text{lbf}$$

$$\frac{e}{t} = \frac{4.7\ \text{in}}{15.625\ \text{in}} = 0.30$$

$$n\rho_t = \frac{nA_s}{bt} = \frac{(12)(1.76\ \text{in}^2)}{(15.625\ \text{in})(15.625\ \text{in})} = 0.087$$

From App. 70.B, $P/F_b bt = 0.31$. The allowable bending stress is limited to one-third of the compressive strength.

$$P = 0.31 F_b bt$$

$$= (0.31)\left(\tfrac{1}{3}\right)\left(2500\ \frac{\text{lbf}}{\text{in}^2}\right)(15.625\ \text{in})(15.625\ \text{in})$$

$$= 63{,}070\ \text{lbf} < P_a \quad \text{[OK]}$$

7. BIAXIAL BENDING

Biaxial bending is due to the eccentricity of the vertical load about both principal axes of the column. Corner columns are particularly subject to biaxial bending. In this case, the neutral axis is not parallel to either principal axis. This requires an iterative process to determine the depth and angle of the neutral axis that satisfies the equilibrium of the axial force and bending moments about both principal axes.

The following interaction relationship may be used to determine an approximate allowable axial load under biaxial bending of columns. This equation applies to columns with significant axial load (i.e., $P > 0.1P_o$).

$$\frac{1}{P_{\text{biaxial}}} = \frac{1}{P_x} + \frac{1}{P_y} - \frac{1}{P_o} \qquad 70.3$$

Example 70.3

Assume the compressive load on the column in Ex. 70.2 has an additional eccentricity of 7.8 in along the y-axis. Determine the maximum compressive load.

Solution

From Ex. 70.2, $P_x = 63{,}070$ lbf (281 kN) and $P_o = 134{,}653$ lbf (599 kN).

$$\frac{e}{t} = \frac{7.8\ \text{in}}{15.625\ \text{in}} = 0.5$$

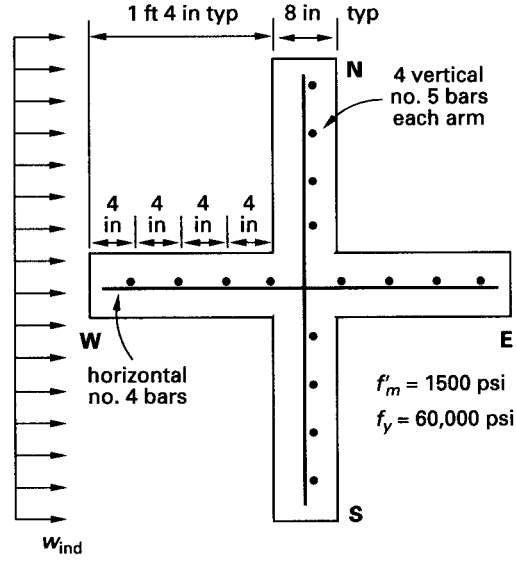
$$n\rho_t = 0.087$$

From App. 70.B, $P/F_b bt = 0.19$.

$$P_y = (0.19)\left(\tfrac{1}{3}\right)\left(2500\ \frac{\text{lbf}}{\text{in}^2}\right)(15.625\ \text{in})(15.625\ \text{in})$$

$$= 38{,}656\ \text{lbf}$$

Use Eq. 70.3.



$$\frac{1}{P_{\text{biaxial}}} = \frac{1}{P_x} + \frac{1}{P_y} - \frac{1}{P_o}$$

$$= \frac{1}{63{,}070\ \text{lbf}} + \frac{1}{38{,}656\ \text{lbf}} - \frac{1}{134{,}653\ \text{lbf}}$$

$$P_{\text{biaxial}} = 29{,}156\ \text{lbf}$$

PRACTICE PROBLEMS

1. *(Time limit: one hour)* A 36 ft tall vertical concrete masonry column with the cross section shown is firmly connected to its foundation at the base but is unsupported at the top. A 30 lbf/ft^2 wind acts perpendicular to the column face uniformly over the entire length. $f'_m = 1500$ lbf/in^2, $f_y = 60{,}000$ lbf/in^2, and $n = 20$. Neglecting the axial stresses due to the dead load, determine if the stresses in the steel and masonry are acceptable.

Answer: masonry unacceptable; steel acceptable

2. A 16 in square concrete masonry column with four vertical no. 6 bars and an effective height of 18 ft supports an axial load of 75,000 lbf. Determine the required masonry strength.

$r = 4.53$ in

$S = 635.8$ in^3

$A_n = 244.1$ in^2

Answer: 1940 lbf/in^2

3. A 32 in by 16 in clay brick column supports a compressive load of 350,000 lbf.

$e = 4$ in

$f'_m = 3000$ lbf/in^2

effective height = 10 ft

$r = 4.6$ in

$g = 0.8$

Determine the required steel area.

Answer: 5.6 in^2

4. A brick column, 24 in by 24 in, is reinforced with four no. 5 bars. Its effective height is 16 ft, and $f'_m = 3000$ lbf/in^2. It has a compressive load with 6 in eccentricity in the x-direction. Assume $g = 0.6$.

(a) Determine the radius of gyration, r.

(A) 5.9 in
(B) 6.2 in
(C) 6.8 in
(D) 7.0 in

The answer is (C).

(b) Determine the reinforcement ratio, ρ_t.

(A) 0.002
(B) 0.003
(C) 0.004
(D) 0.005

The answer is (A).

(c) Determine the axial capacity.

(A) 120,000 lbf
(B) 150,000 lbf
(C) 180,000 lbf
(D) 212,000 lbf

The answer is (D).

(d) Determine the moment capacity in the x-direction.

(A) 870,000 in-lbf
(B) 930,000 in-lbf
(C) 1,270,000 in-lbf
(D) 1,520,000 in-lbf

The answer is (C).

(e) Determine the axial stress.

(A) 320 lbf/in^2
(B) 380 lbf/in^2
(C) 420 lbf/in^2
(D) 500 lbf/in^2

The answer is (B).

(f) Determine the allowable compressive force.

(A) 300,000 lbf
(B) 400,000 lbf
(C) 500,000 lbf
(D) 600,000 lbf

The answer is (B).

For parts (g) through (j), assume an additional eccentricity of 4 in in the y-direction.

(g) Determine P_y.

(A) 160,000 lbf
(B) 190,000 lbf
(C) 230,000 lbf
(D) 280,000 lbf

The answer is (D).

(h) Determine P_a.

(A) 300,000 lbf
(B) 330,000 lbf
(C) 390,000 lbf
(D) 420,000 lbf

The answer is (D).

(i) Determine the maximum biaxial load.

(A) 140,000 lbf
(B) 170,000 lbf
(C) 200,000 lbf
(D) 230,000 lbf

The answer is (B).

(j) Determine the moment capacity in the y-direction.

(A) 980,000 in-lbf
(B) 1,030,000 in-lbf
(C) 1,120,000 in-lbf
(D) 1,200,000 in-lbf

The answer is (C).

5. A 32 in square concrete masonry column is subjected to the following: a dead load, D, of 180,000 lbf; a live load, L, of 140,000 lbf; and design shear force of 30,000 lbf. The forces due to earthquake, E, are as follows.

bending moment = 140,000 ft-lbf

axial compressive force = 45,000 lbf

Use $f'_m = 1500$ lbf/in^2, $h = 10$ ft, $r = 9.1$ in, $g = 0.4$, $n = 14$, and $d = 23$ in.

Structural

(a) Determine the design eccentricity for dead and live loads.

(A) 2.7 in
(B) 3.2 in
(C) 3.8 in
(D) 4.6 in

The answer is (B).

(b) Determine the design eccentricity for dead and live loads and earthquake forces.

(A) 2.5 in
(B) 3.7 in
(C) 4.6 in
(D) 6.9 in

The answer is (C).

(c) Determine the design eccentricity for $0.9D + E$.

(A) 4.3 in
(B) 5.2 in
(C) 6.9 in
(D) 8.1 in

The answer is (D).

(d) Determine the maximum axial stress on the column.

(A) 180 lbf/in^2
(B) 250 lbf/in^2
(C) 320 lbf/in^2
(D) 365 lbf/in^2

The answer is (C).

(e) Determine the maximum allowable axial load on the column. Neglect the steel's contribution.

(A) 370,000 lbf
(B) 420,000 lbf
(C) 460,000 lbf
(D) 510,000 lbf

The answer is (A).

(f) Considering the three load combinations ($D + L$, $D + L + E$, and $0.9D + E$), determine the minimum steel area required.

(A) none
(B) 2 in^2
(C) 3 in^2
(D) 4 in^2

The answer is (D).

(g) Determine the design shear stress on the column.

(A) 35 lbf/in^2
(B) 41 lbf/in^2
(C) 50 lbf/in^2
(D) 57 lbf/in^2

The answer is (B).

(h) Determine the allowable shear stress.

(A) 39 lbf/in^2
(B) 48 lbf/in^2
(C) 52 lbf/in^2
(D) 57 lbf/in^2

The answer is (C).

(i) Determine the area of shear reinforcement required.

(A) none
(B) 0.11 in^2/ft
(C) 0.20 in^2/ft
(D) 0.27 in^2/ft

The answer is (A).

(j) For shear reinforcement of no. 5 ties, determine the required tie spacing.

(A) 4 in o.c.
(B) 8 in o.c.
(C) 16 in o.c.
(D) 24 in o.c.

The answer is (B).

1. CENTER OF GRAVITY

A solid body will have both a center of gravity and a centroid, but the locations of these two points will not necessarily coincide. The earth's attractive force, called *weight*, can be assumed to act through the *center of gravity* (also known as the *center of mass*). Only when the body is homogeneous will the *centroid of the volume* coincide with the center of gravity.[1]

For simple objects and regular polyhedrons, the location of the center of gravity can be determined by inspection. It will always be located on an axis of symmetry. The location of the center of gravity can also be determined mathematically if the object can be described mathematically.

$$x_c = \frac{\int x\,dm}{m} \qquad 71.1$$

$$y_c = \frac{\int y\,dm}{m} \qquad 71.2$$

$$z_c = \frac{\int z\,dm}{m} \qquad 71.3$$

If the object can be divided into several smaller constituent objects, the location of the composite center of gravity can be calculated from the centers of gravity of each of the constituent objects.

$$x_c = \frac{\sum m_i x_{ci}}{\sum m_i} \qquad 71.4$$

$$y_c = \frac{\sum m_i y_{ci}}{\sum m_i} \qquad 71.5$$

$$z_c = \frac{\sum m_i z_{ci}}{\sum m_i} \qquad 71.6$$

2. MASS AND WEIGHT

The mass, m, of a homogeneous solid object is calculated from its mass density and volume. Mass is independent of the strength of the gravitational field.

$$m = \rho V \qquad 71.7$$

The weight, w, of an object depends on the strength of the gravitational field, g.

$$w = mg \qquad \text{[SI]} \qquad 71.8(a)$$

$$w = \frac{mg}{g_c} \qquad \text{[U.S.]} \qquad 71.8(b)$$

3. INERTIA

Inertia (the *inertial force* or *inertia vector*), $m\mathbf{a}$, is the resistance the object offers to attempts to accelerate it (i.e., change its velocity) in a linear direction. Although the mass, m, is a scalar quantity, the acceleration, $\mathbf{a}$, is a vector.

[1]The study of nonhomogeneous bodies is beyond the scope of this book. Homogeneity is assumed for all solid objects.

4. MASS MOMENT OF INERTIA

The *mass moment of inertia* measures a solid object's resistance to changes in rotational speed about a specific axis. I_x, I_y, and I_z are the mass moments of inertia with respect to the x-, y-, and z-axes. They are not components of a resultant value.[2]

The *centroidal mass moment of inertia*, I_c, is obtained when the origin of the axes coincides with the object's center of gravity. Although it can be found mathematically from Eqs. 71.9 through 71.11, it is easier to use App. 71.A for simple objects.

$$I_x = \int (y^2 + z^2)\, dm \qquad 71.9$$

$$I_y = \int (x^2 + z^2)\, dm \qquad 71.10$$

$$I_z = \int (x^2 + y^2)\, dm \qquad 71.11$$

5. PARALLEL AXIS THEOREM

Once the centroidal mass moment of inertia is known, the *parallel axis theorem* is used to find the mass moment of inertia about any parallel axis.

$$I_{\text{any parallel axis}} = I_c + md^2 \qquad 71.12$$

For a composite object, the parallel axis theorem must be applied for each of the constituent objects.

$$I = I_{c,1} + m_1 d_1^2 + I_{c,2} + m_2 d_2^2 + \cdots \qquad 71.13$$

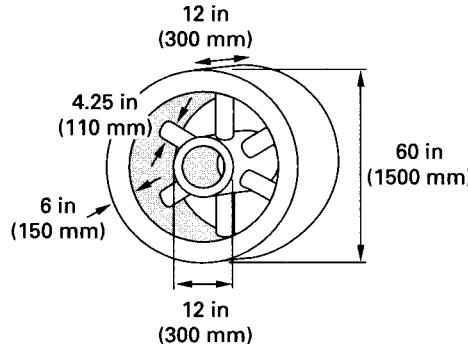
6. RADIUS OF GYRATION

The *radius of gyration*, k, of a solid object represents the distance from the rotational axis at which the object's entire mass could be located without changing the mass moment of inertia.

$$k = \sqrt{\frac{I}{m}} \qquad 71.14$$

$$I = k^2 m \qquad 71.15$$

[2]At first, it may be confusing to use the same symbol, I, for area and mass moments of inertia. However, the problem types are distinctly dissimilar, and both moments of inertia are seldom used simultaneously.



7. PRINCIPAL AXES

An object's mass moment of inertia depends on the orientation of axes chosen. The *principal axes* are the axes for which the *products of inertia* are zero. Equipment rotating about a principal axis will draw minimum power during speed changes.

Finding the principal axes through calculation is too difficult and time consuming to be used with most rotating equipment. Furthermore, the rotating axis is generally fixed. Therefore, *balancing operations* are used to change the distribution of mass about the rotational axis. A device, such as a rotating shaft, flywheel, or crank, is said to be *statically balanced* if its center of mass lies on the axis of rotation. It is said to be *dynamically balanced* if the center of mass lies on the axis of rotation and the products of inertia are zero.

PRACTICE PROBLEMS

1. A spoked flywheel has an outside diameter of 60 in (1500 mm). The rim thickness is 6 in (150 mm) and the width is 12 in (300 mm). The cylindrical hub has an outside diameter of 12 in (300 mm), a thickness of 3 in (75 mm), and a width of 12 in (300 mm). The rim and hub are connected by six equally spaced cylindrical radial spokes, each with a diameter of 4.25 in (110 mm). All parts of the flywheel are ductile cast iron with a density of 0.256 lbm/in^3 (7080 kg/m^3). What is the rotational mass moment of inertia of the entire flywheel?

Answer: 16,800 lbm-ft^2 (654 kg·m^2)

1. INTRODUCTION TO KINEMATICS

Dynamics is the study of moving objects. The subject is divided into kinematics and kinetics. *Kinematics* is the study of a body's motion independent of the forces on the body. It is a study of the geometry of motion without consideration of the causes of motion. Kinematics deals only with relationships among position, velocity, acceleration, and time. (Kinetics is covered in Chap. 73.)

2. PARTICLES AND RIGID BODIES

Bodies in motion can be considered *particles* if rotation is absent or insignificant. Particles do not possess rotational kinetic energy. All parts of a particle have the same instantaneous displacement, velocity, and acceleration.

A *rigid body* does not deform when loaded and can be considered a combination of two or more particles that remain at a fixed, finite distance from each other. At any given instant, the parts (particles) of a rigid body can have different displacements, velocities, and accelerations.

3. COORDINATE SYSTEMS

The position of a particle is specified with reference to a *coordinate system.* The description takes the form of an ordered sequence $(q_1, q_2, q_3, \ldots)$ of numbers called *coordinates*. A coordinate can represent a position along an axis, as in the rectangular coordinate system, or it can represent an angle, as in the polar, cylindrical, and spherical coordinate systems.

In general, the number of *degrees of freedom* is equal to the number of coordinates required to completely specify the state of an object. If each of the coordinates is independent of the others, the coordinates are known as *holonomic coordinates*.

The state of a particle is completely determined by the particle's location. In three-dimensional space, the locations of particles in a system of m particles must be specified by $3m$ coordinates. However, the number of required coordinates can be reduced in certain cases. The position of each particle constrained to motion on a surface (i.e., on a two-dimensional system) can be specified by only two coordinates. A particle constrained to moving on a curved path requires only one coordinate.[1]

The state of a rigid body is a function of orientation as well as position. Six coordinates are required to specify the state: three for orientation and three for location.

4. CONVENTIONS OF REPRESENTATION

Consider the particle shown in Fig. 72.1. Its position (as well as its velocity and acceleration) can be specified in three primary forms: vector form, rectangular coordinate form, and unit vector form.

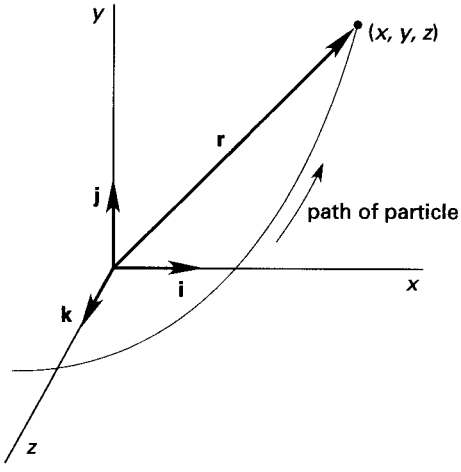

Figure 72.1 *Position of a Particle*

The vector form of the particle's position is $\mathbf{r}$, where the vector $\mathbf{r}$ has both magnitude and direction. The rectangular coordinate form is (x, y, z). The unit vector form is

$$\mathbf{r} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k} \qquad 72.1$$

5. LINEAR PARTICLE MOTION

A *linear system* is one in which particles move only in straight lines. (Another name is *rectilinear system*.) The relationships among position, velocity, and acceleration for a linear system are given by Eqs. 72.2 through 72.4. When values of t are substituted into these equations, the position, velocity, and acceleration are known as *instantaneous values*.

$$s(t) = \int \mathrm{v}(t)\,dt = \int \left(\int a(t)\,dt \right) dt \qquad 72.2$$

$$\mathrm{v}(t) = \frac{ds(t)}{dt} = \int a(t)\,dt \qquad 72.3$$

$$a(t) = \frac{d\mathrm{v}(t)}{dt} = \frac{d^2 s(t)}{dt^2} \qquad 72.4$$

The average velocity and acceleration over a period from t_1 to t_2 are

$$\mathrm{v}_{\mathrm{ave}} = \frac{\int_1^2 \mathrm{v}(t)\,dt}{t_2 - t_1} = \frac{s_2 - s_1}{t_2 - t_1} \qquad 72.5$$

$$a_{\mathrm{ave}} = \frac{\int_1^2 a(t)\,dt}{t_2 - t_1} = \frac{\mathrm{v}_2 - \mathrm{v}_1}{t_2 - t_1} \qquad 72.6$$

Example 72.1

A particle is constrained to move along a straight line. The velocity and location are both zero at $t = 0$. The particle's velocity as a function of time is

$$\mathrm{v}(t) = 8t - 6t^2$$

(a) What are the acceleration and position functions?
(b) What is the instantaneous velocity at $t = 5$?

Solution

(a)
$$a(t) = \frac{d\mathrm{v}(t)}{dt} = \frac{d(8t - 6t^2)}{dt}$$
$$= 8 - 12t$$
$$s(t) = \int \mathrm{v}(t)\,dt = \int (8t - 6t^2)\,dt$$
$$= 4t^2 - 2t^3$$

(b) Substituting $t = 5$ into the $\mathrm{v}(t)$ function,

$$\mathrm{v}(5) = (8)(5) - (6)(5)^2$$
$$= -110 \quad \text{[backward]}$$

6. DISTANCE AND SPEED

The terms "displacement" and "distance" have different meanings in kinematics. *Displacement* (or *linear displacement*) is the net change in a particle's position as determined from the position function, $s(t)$. *Distance traveled* is the accumulated length of the path traveled during all direction reversals, and it can be found by adding the path lengths covered during periods in which the velocity sign does not change. Thus, distance is always greater than or equal to displacement.

$$\text{displacement} = s(t_2) - s(t_1) \qquad 72.7$$

[1]The curve can be a straight line, as in the case of a mass hanging on a spring and oscillating up and down. In this case, the coordinate will be a linear coordinate.

Similarly, "velocity" and "speed" have different meanings: *velocity* is a vector, having both magnitude and direction; *speed* is a scalar quantity, equal to the magnitude of velocity. When specifying speed, direction is not considered.

Example 72.2

What distance is traveled during the period $t = 0$ to $t = 6$ by the particle described in Ex. 72.1?

Solution

Start by determining when, if ever, the velocity becomes negative. (This can be done by inspection, graphically, or algebraically.) Solving for the roots of the velocity equation, the velocity changes from positive to negative at

$$t = \tfrac{4}{3}$$

The initial displacement is zero. From the position function, the position at $t = 4/3$ is

$$s\left(\tfrac{4}{3}\right) = (4)\left(\tfrac{4}{3}\right)^2 - (2)\left(\tfrac{4}{3}\right)^3 = 2.37$$

The displacement while the velocity is positive is

$$\begin{aligned}\Delta s &= s\left(\tfrac{4}{3}\right) - s(0) = 2.37 - 0 \\ &= 2.37\end{aligned}$$

The position at $t = 6$ is

$$s(6) = (4)(6)^2 - (2)(6)^3 = -288$$

The displacement while the velocity is negative is

$$\begin{aligned}\Delta s &= s(6) - s\left(\tfrac{4}{3}\right) = -288 - 2.37 \\ &= -290.37\end{aligned}$$

The total distance traveled is

$$2.37 + 290.37 = 292.74$$

7. UNIFORM MOTION

The term *uniform motion* means uniform velocity. The velocity is constant and the acceleration is zero. For a constant velocity system, the position function varies linearly with time.

$$s(t) = s_0 + \mathrm{v}t \qquad 72.8$$

$$\mathrm{v}(t) = \mathrm{v} \qquad 72.9$$

$$a(t) = 0 \qquad 72.10$$

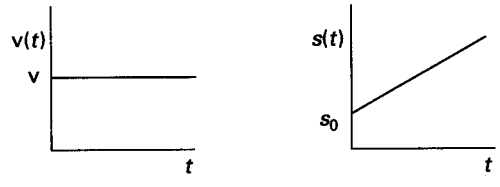

Figure 72.2 *Constant Velocity System*

8. UNIFORM ACCELERATION

The acceleration is constant in many cases. (Gravitational acceleration, where $a = g$, is a notable example.) If the acceleration is constant, the a term can be taken out of the integrals in Eqs. 72.12 and 72.13.

$$a(t) = a \qquad 72.11$$

$$\mathrm{v}(t) = a\int dt = \mathrm{v}_0 + at \qquad 72.12$$

$$s(t) = a\iint dt^2 = s_0 + \mathrm{v}_0 t + \tfrac{1}{2}at^2 \qquad 72.13$$

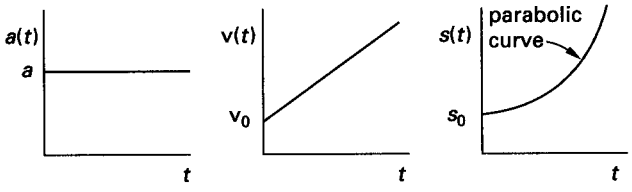

Figure 72.3 *Uniform Acceleration*

Table 72.1 summarizes the equations required to solve most uniform acceleration problems.

Table 72.1 *Uniform Acceleration Formulas*[a]

to find	given these	use this equation
a	$t, \mathrm{v}_0, \mathrm{v}$	$a = \dfrac{\mathrm{v} - \mathrm{v}_0}{t}$
a	t, v_0, s	$a = \dfrac{2s - 2\mathrm{v}_0 t}{t^2}$
a	$\mathrm{v}_0, \mathrm{v}, s$	$a = \dfrac{\mathrm{v}^2 - \mathrm{v}_0^2}{2s}$
s	t, a, v_0	$s = \mathrm{v}_0 t + \tfrac{1}{2}at^2$
s	$a, \mathrm{v}_0, \mathrm{v}$	$s = \dfrac{\mathrm{v}^2 - \mathrm{v}_0^2}{2a}$
s	$t, \mathrm{v}_0, \mathrm{v}$	$s = \tfrac{1}{2}t(\mathrm{v}_0 + \mathrm{v})$
t	$a, \mathrm{v}_0, \mathrm{v}$	$t = \dfrac{\mathrm{v} - \mathrm{v}_0}{a}$
t	a, v_0, s	$t = \dfrac{\sqrt{\mathrm{v}_0^2 + 2as} - \mathrm{v}_0}{a}$
t	$\mathrm{v}_0, \mathrm{v}, s$	$t = \dfrac{2s}{\mathrm{v}_0 + \mathrm{v}}$
v_0	t, a, v	$\mathrm{v}_0 = \mathrm{v} - at$
v_0	t, a, s	$\mathrm{v}_0 = \dfrac{s}{t} - \tfrac{1}{2}at$
v_0	a, v, s	$\mathrm{v}_0 = \sqrt{\mathrm{v}^2 - 2as}$
v	t, a, v_0	$\mathrm{v} = \mathrm{v}_0 + at$
v	a, v_0, s	$\mathrm{v} = \sqrt{\mathrm{v}_0^2 + 2as}$

[a]The table can be used for rotational problems by substituting α, ω, and θ for a, v, and s, respectively.

Transportation

Example 72.3

A locomotive traveling at 80 kph locks its wheels and skids 95 m before coming to a complete stop. If the deceleration is constant, how many seconds will it take for the locomotive to come to a standstill?

Solution

First, convert the 80 kph to meters per second.

$$v_0 = \frac{\left(80\ \frac{\text{km}}{\text{h}}\right)\left(1000\ \frac{\text{m}}{\text{km}}\right)}{3600\ \frac{\text{s}}{\text{h}}} = 22.22\ \text{m/s}$$

In this problem, $v_0 = 22.2$ m/s, $v = 0$, and $s = 95$ m are known. t is the unknown. From Table 72.1,

$$t = \frac{2s}{v_0 + v} = \frac{(2)(95\ \text{m})}{22.22 + 0}$$
$$= 8.55\ \text{s}$$

9. LINEAR ACCELERATION

Linear acceleration means that the acceleration increases uniformly with time. Figure 72.4 shows how the velocity and position vary with time.[2]

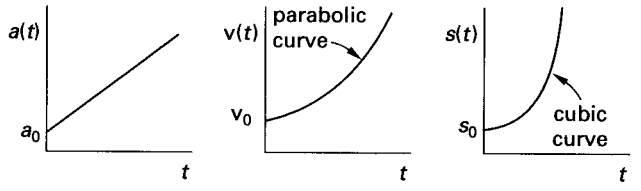

Figure 72.4 *Linear Acceleration*

10. PROJECTILE MOTION

A *projectile* is placed into motion by an initial impulse. (Kinematics deals only with dynamics during the flight. The force acting on the projectile during the launch phase is covered in kinetics.) Neglecting air drag, once the projectile is in motion it is acted upon only by the downward gravitational acceleration (i.e., its own weight). Thus, projectile motion is a special case of motion under constant acceleration.

Consider a general projectile set into motion at an angle of ϕ (from the horizontal plane) and initial velocity v_0. Its range is R, the maximum altitude attained is H, and the total flight time is T. In the absence of air drag, the following rules apply to the case of a level target.[3]

- The trajectory is parabolic.
- The impact velocity is equal to initial velocity, v_0.
- The impact angle is equal to the initial launch angle, ϕ.
- The range is maximum when $\phi = 45°$.
- The time for the projectile to travel from the launch point to the apex is equal to the time to travel from apex to impact point.
- The time for the projectile to travel from the apex of its flight path to impact is the same time an initially stationary object would take to fall a distance H.

Table 72.2 contains the solutions to most common projectile problems. These equations are derived from the laws of uniform acceleration and conservation of energy.

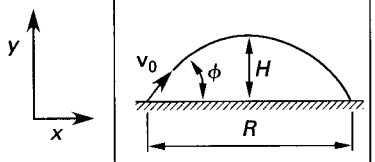
Example 72.4

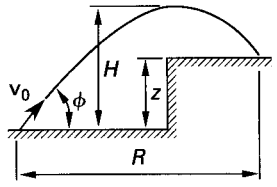
A projectile is launched at 600 ft/sec (180 m/s) with a 30° inclination from the horizontal. The launch point is on a plateau 500 ft (150 m) above the plane of impact. Neglecting friction, find the maximum altitude, H, above the plane of impact, the total flight time, T, and the range, R.

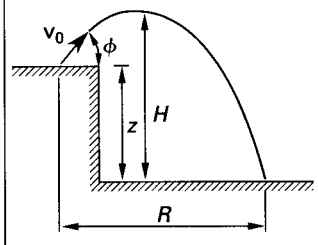
SI Solution

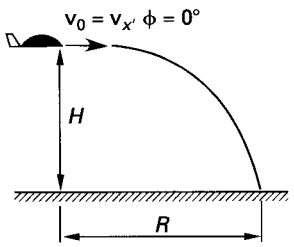
The maximum altitude above the impact plane includes the height of the plateau and the elevation achieved by the projectile.

$$H = z + \frac{v_0^2 \sin^2\phi}{2g}$$
$$= 150\ \text{m} + \frac{\left(180\ \frac{\text{m}}{\text{s}}\right)^2 (\sin^2 30°)}{(2)\left(9.81\ \frac{\text{m}}{\text{s}^2}\right)} = 563\ \text{m}$$









The total flight time includes the time to reach the maximum altitude and the time to fall from the maximum altitude to the impact plane below.

$$T = t_H + t_{\text{fall}}$$
$$= \frac{v_0 \sin\phi}{g} + \sqrt{\frac{2H}{g}}$$
$$= \frac{\left(180\ \frac{\text{m}}{\text{s}}\right)(\sin 30°)}{9.81\ \frac{\text{m}}{\text{s}^2}} + \sqrt{\frac{(2)(563\ \text{m})}{9.81\ \frac{\text{m}}{\text{s}^2}}}$$
$$= 19.9\ \text{s}$$

[2]Because of the successive integrations, if the acceleration function is a polynomial of degree n, the velocity function will be a polynomial of degree $n + 1$. Similarly, the position function will be a polynomial of degree $n + 2$.

[3]The case of projectile motion with air friction cannot be handled in kinematics, since a retarding force acts continuously on the projectile. In kinetics, various assumptions (e.g., friction varies linearly with the velocity or with the square of the velocity) can be made to include the effect of air friction.

Table 72.2 *Projectile Motion Equations*
(ϕ may be negative for projection downward)

	level target	target above	target below	horizontal projection
				
$x(t)$	$(v_0 \cos\phi)t$			$v_0 t$
$y(t)$	$(v_0 \sin\phi)t - \frac{1}{2}gt^2$			$H - \frac{1}{2}gt^2$
$v_x(t)$	$v_0 \cos\phi$			v_0
$v_y(t)$	$v_0 \sin\phi - gt$			$-gt$
$v(t)$	$\sqrt{v_0^2 - 2gy} = \sqrt{v_0^2 - 2gtv_0 \sin\phi + g^2t^2}$			$\sqrt{v_0^2 + g^2t^2}$
$v(y)$	$\sqrt{v_0^2 - 2gy}$			$\sqrt{v_0^2 + 2g(H-y)}$
H	$\frac{v_0^2 \sin^2\phi}{2g}$	$\frac{v_0^2 \sin^2\phi}{2g}$	$z + \frac{v_0^2 \sin^2\phi}{2g}$	$\frac{1}{2}gt^2$
R	$v_0 T \cos\phi$			$v_0 T$
	$\frac{v_0^2 \sin 2\phi}{g}$	$\left(\frac{v_0 \cos\phi}{g}\right)\left[v_0 \sin\phi + \sqrt{v_0^2 \sin^2\phi - 2gz}\right]$	$\left(\frac{v_0 \cos\phi}{g}\right)\left[v_0 \sin\phi + \sqrt{2gz + v_0^2 \sin^2\phi}\right]$	
T	$\frac{R}{v_0 \cos\phi}$			$\sqrt{\frac{2H}{g}}$
	$\frac{2v_0 \sin\phi}{g}$	$\frac{v_0 \sin\phi}{g} + \sqrt{\frac{(2)(H-z)}{g}}$	$\frac{v_0 \sin\phi}{g} + \sqrt{\frac{2H}{g}}$	
t_H	$\frac{v_0 \sin\phi}{g} = \frac{T}{2}$	$\frac{v_0 \sin\phi}{g}$		

Transportation

The x-component of velocity is

$$\begin{aligned} v_x &= v_0 \cos\phi = \left(180 \frac{\text{m}}{\text{s}}\right)(\cos 30^\circ) \\ &= 156 \text{ m/s} \end{aligned}$$

The range is

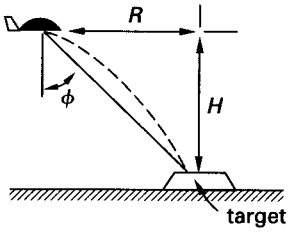
$$\begin{aligned} R &= v_x T = \left(156 \frac{\text{m}}{\text{s}}\right)(19.9 \text{ s}) \\ &= 3100 \text{ m} \end{aligned}$$

Customary U.S. Solution

The maximum altitude above the impact plane is given by Table 72.2.

$$\begin{aligned} H &= 500 \text{ ft} + \frac{\left(600 \frac{\text{ft}}{\text{sec}}\right)^2 (\sin^2 30^\circ)}{(2)\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)} \\ &= 1898 \text{ ft} \end{aligned}$$

The total flight time is



$$\begin{aligned} T &= \frac{\left(600 \frac{\text{ft}}{\text{sec}}\right)(\sin 30^\circ)}{32.2 \frac{\text{ft}}{\text{sec}^2}} + \sqrt{\frac{(2)(1898 \text{ ft})}{32.2 \frac{\text{ft}}{\text{sec}^2}}} \\ &= 20.2 \text{ sec} \end{aligned}$$

The maximum range is

$$\begin{aligned} R &= (v_0 \cos\phi)\, T = \left(600 \frac{\text{ft}}{\text{sec}}\right)(\cos 30^\circ)(20.2 \text{ sec}) \\ &= 10{,}500 \text{ ft } (1.99 \text{ mi}) \end{aligned}$$

Example 72.5

A bomber flies horizontally at 275 mph at an altitude of 9000 ft. At what viewing angle, ϕ, from the bomber to the target should the bombs be dropped?

Solution

This is a case of horizontal projection. The falling time depends only on the altitude of the bomber. From Table 72.2,

$$\begin{aligned} T &= \sqrt{\frac{2H}{g}} = \sqrt{\frac{(2)(9000 \text{ ft})}{32.2 \frac{\text{ft}}{\text{sec}^2}}} \\ &= 23.64 \text{ sec} \end{aligned}$$

If air friction is neglected, the bomb has the same horizontal velocity as the bomber. Since the time of flight, T, is known, the distance traveled during that time can be calculated.

$$\begin{aligned} R &= v_0 T = \frac{\left(275 \frac{\text{mi}}{\text{hr}}\right)\left(5280 \frac{\text{ft}}{\text{mi}}\right)(23.64 \text{ sec})}{3600 \frac{\text{sec}}{\text{hr}}} \\ &= 9535 \text{ ft} \end{aligned}$$

The viewing angle is found from trigonometry.

$$\begin{aligned} \phi &= \arctan\left(\frac{R}{H}\right) = \arctan\left(\frac{9535 \text{ ft}}{9000 \text{ ft}}\right) \\ &= 46.7^\circ \end{aligned}$$

11. ROTATIONAL PARTICLE MOTION

Rotational particle motion (also known as *angular motion* and *circular motion*) is motion of a particle around a circular path.

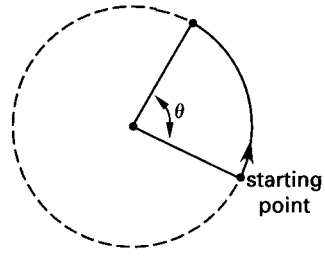


Figure 72.5 *Rotational Particle Motion*

The behavior of a rotating particle is defined by its *angular position*, θ, *angular velocity*, ω, and *angular acceleration*, α, functions. These variables are analogous to the $s(t)$, $v(t)$, and $a(t)$ functions for linear systems. Angular variables can be substituted one-for-one in place of linear variables in most equations.

The relationships among angular position, velocity, and acceleration for a rotational system are given by Eqs. 72.14 through 72.16. When values of t are substituted into these equations, the position, velocity, and acceleration are known as *instantaneous values*.

$$\theta(t) = \int \omega(t)\, dt = \iint \alpha(t)\, dt^2 \qquad 72.14$$

$$\omega(t) = \frac{d\theta(t)}{dt} = \int \alpha(t)\, dt \qquad 72.15$$

$$\alpha(t) = \frac{d\omega(t)}{dt} = \frac{d^2\theta(t)}{dt^2} \qquad 72.16$$

The average velocity and acceleration are

$$\omega_{\text{ave}} = \frac{\int_1^2 \omega(t)\, dt}{t_2 - t_1} = \frac{\theta_2 - \theta_1}{t_2 - t_1} \qquad 72.17$$

$$\alpha_{\text{ave}} = \frac{\int_1^2 \alpha(t)\, dt}{t_2 - t_1} = \frac{\omega_2 - \omega_1}{t_2 - t_1} \qquad 72.18$$

Example 72.6

A turntable starts from rest and accelerates uniformly at 1.5 rad/sec^2. How many revolutions will it take before a rotational speed of 33⅓ rpm is attained?

Solution

First, convert 33⅓ rpm into radians per second. Since there are 2π radians per complete revolution,

$$\omega = \frac{\left(33\frac{1}{3}\ \frac{\text{rev}}{\text{min}}\right)\left(2\pi\ \frac{\text{rad}}{\text{rev}}\right)}{60\ \frac{\text{sec}}{\text{min}}} = 3.49\ \text{rad/sec}$$

α, ω_0, and ω are known. θ is unknown. (This is analogous to knowing a, v_0, and v, and not knowing s.) From Table 72.1,

$$\theta = \frac{\omega^2 - \omega_0^2}{2\alpha} = \frac{\left(3.49\ \frac{\text{rad}}{\text{sec}}\right)^2 - \left(0\ \frac{\text{rad}}{\text{sec}}\right)^2}{(2)\left(1.5\ \frac{\text{rad}}{\text{sec}^2}\right)}$$

$$= 4.06\ \text{rad}$$

Converting from radians to revolutions,

$$n = \frac{4.06\ \text{rad}}{2\pi\ \frac{\text{rad}}{\text{rev}}} = 0.65\ \text{rev}$$

Example 72.7

A flywheel is brought to a standstill from 400 rpm in 8 sec. (a) What was its average angular acceleration in rad/sec during that period? (b) How far (in radians) did the flywheel travel?

Solution

(a) The initial rotational speed must be expressed in radians per second. Since there are 2π radians per revolution,

$$\omega_0 = \frac{\left(400\ \frac{\text{rev}}{\text{min}}\right)\left(2\pi\ \frac{\text{rad}}{\text{rev}}\right)}{60\ \frac{\text{sec}}{\text{min}}}$$

$$= 41.9\ \text{rad/sec}$$

t, ω_0, and ω are known, and α is unknown. These variables are analogous to t, v_0, v, and a in Table 72.1.

$$\alpha = \frac{\omega - \omega_0}{t} = \frac{0 - 41.9\ \frac{\text{rad}}{\text{sec}}}{8\ \text{sec}}$$

$$= -5.24\ \text{rad/sec}^2$$

(b) t, ω_0, and ω are known, and θ is unknown. Again, from Table 72.1,

$$\theta = \tfrac{1}{2}t(\omega + \omega_0) = \left(\tfrac{1}{2}\right)(8\ \text{sec})\left(41.9\ \frac{\text{rad}}{\text{sec}} + 0\right)$$

$$= 168\ \text{rad} \quad (26.7\ \text{rev})$$

12. RELATIONSHIP BETWEEN LINEAR AND ROTATIONAL VARIABLES

A particle moving in a curvilinear path will also have instantaneous linear velocity and linear acceleration. These linear variables will be directed tangentially to the path and, therefore, are known as *tangential velocity* and *tangential acceleration*, respectively. In general, the linear variables can be obtained by multiplying the rotational variables by the path radius, r.

$$v_t = \omega r \qquad 72.19$$

$$v_{t,x} = v_t \cos\phi = \omega r \cos\phi \qquad 72.20$$

$$v_{t,y} = v_t \sin\phi = \omega r \sin\phi \qquad 72.21$$

$$a_t = \frac{dv_t}{dt} = \alpha r \qquad 72.22$$

If the path radius is constant, as it would be in rotational motion, the linear distance (i.e., the *arc length*) traveled is

$$s = \theta r \qquad 72.23$$

13. NORMAL ACCELERATION

A moving particle will continue tangentially to its path unless constrained otherwise. For example, a rock twirled on a string will move in a circular path only as long as there is tension in the string. When the string is released, the rock will move off tangentially.

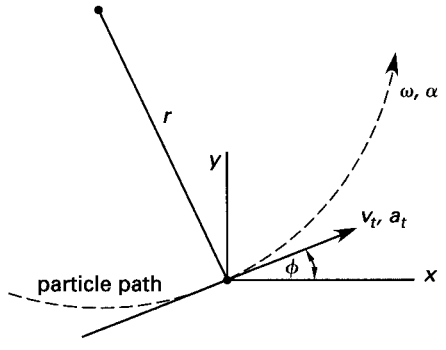

Figure 72.6 *Tangential Variables*

The twirled rock is acted upon by the tension in the string. In general, a restraining force will be directed

toward the center of rotation. Whenever a mass experiences a force, an acceleration is acting.[4] The acceleration has the same sense as the applied force (i.e., is directed toward the center of rotation). Since the inward acceleration is perpendicular to the tangential velocity and acceleration, it is known as *normal acceleration*, a_n.

$$a_n = \frac{v_t^2}{r} = r\omega^2 = v_t\omega \qquad 72.24$$

The *resultant acceleration*, a, is the vector sum of the tangential and normal accelerations. The magnitude of the resultant acceleration is

$$a = \sqrt{a_t^2 + a_n^2} \qquad 72.25$$

The x- and y-components of the resultant acceleration are

$$a_x = a_n \sin\phi \pm a_t \cos\phi \qquad 72.26$$

$$a_y = a_n \cos\phi \mp a_t \sin\phi \qquad 72.27$$

The normal and tangential accelerations can be expressed in terms of the x- and y-components of the resultant acceleration (not shown in Fig. 72.7).

$$a_n = a_x \sin\phi \pm a_y \cos\phi \qquad 72.28$$

$$a_t = a_x \cos\phi \mp a_y \sin\phi \qquad 72.29$$

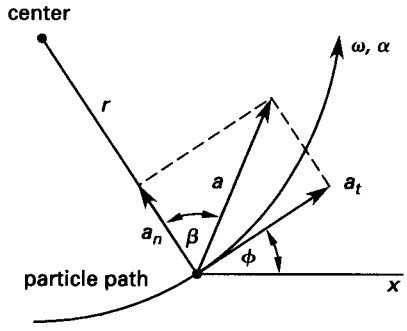

Figure 72.7 *Normal Acceleration*

14. CORIOLIS ACCELERATION

Consider a particle moving with linear radial velocity v_r away from the center of a flat disk rotating with constant velocity ω. Since $v_t = r\omega$, the particle's tangential velocity will increase as it moves away from the center of rotation. This increase is said to be produced by the tangential *Coriolis acceleration*, a_c.

$$a_c = 2v_r\omega \qquad 72.30$$

[4]This is a direct result of Newton's second law of motion, covered in Chap. 73.

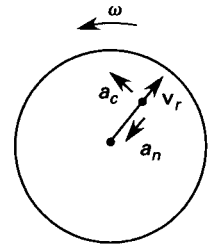

Figure 72.8 *Coriolis Acceleration on a Rotating Disk*

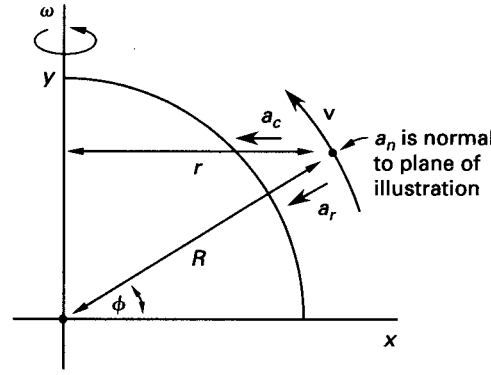
Coriolis acceleration also acts on particles moving on rotating spheres. Consider an aircraft flying with constant air speed v from the equator to the north pole while the earth rotates below it. Three accelerations act on the aircraft: normal, radial, and Coriolis accelerations, shown in Fig. 72.9. The Coriolis acceleration depends on the latitude, ϕ, because the earth's tangential velocity is less near the poles than at the equator.

$$a_n = r\omega^2 = R\omega^2 \cos\phi \qquad 72.31$$

$$a_r = \frac{v^2}{R} \qquad 72.32$$

$$a_c = 2\omega v_x = 2\omega v \sin\phi \qquad 72.33$$



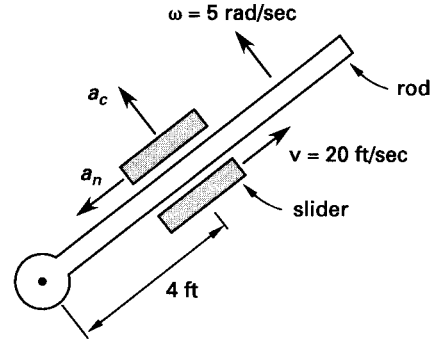


Figure 72.9 *Coriolis Acceleration on a Rotating Sphere*

Example 72.8

A slider moves with a constant velocity of 20 ft/sec along a rod rotating at 5 rad/sec. What is the magnitude of the slider's total acceleration when the slider is 4 ft from the center of rotation?

Solution

The normal acceleration is given by Eq. 72.31.

$$a_n = r\omega^2 = (4 \text{ ft})\left(5 \frac{\text{rad}}{\text{sec}}\right)^2$$
$$= 100 \text{ ft/sec}^2$$

The Coriolis acceleration is given by Eq. 72.33.

$$a_c = 2\text{v}\omega = (2)\left(20 \frac{\text{ft}}{\text{sec}}\right)\left(5 \frac{\text{rad}}{\text{sec}}\right)$$
$$= 200 \text{ ft/sec}^2$$

The total acceleration is given by 72.25.

$$a = \sqrt{a_n^2 + a_c^2} = \sqrt{\left(100 \frac{\text{ft}}{\text{sec}^2}\right)^2 + \left(200 \frac{\text{ft}}{\text{sec}^2}\right)^2}$$
$$= 223.6 \text{ ft/sec}^2$$

15. PARTICLE MOTION IN POLAR COORDINATES

In polar coordinates, the path of a particle is described by a radius vector, $\mathbf{r}$, and an angle, ϕ. Since the velocity of a particle is not usually directed radially out from the center of the coordinate system, it can be divided into two perpendicular components. The terms *normal* and *tangential* are not used with polar coordinates. Rather, the terms *radial* and *transverse* are used. Figure 72.10 illustrates the *radial* and *transverse components* of velocity in a polar coordinate system.

Figure 72.10 also illustrates the unit radial and unit transverse vectors, $\mathbf{e}_r$ and $\mathbf{e}_\phi$, used in the vector forms of the motion equations.

$$\text{position: } \mathbf{r} = r\mathbf{e}_r \qquad 72.34$$

$$\text{velocity: } \mathbf{v} = \text{v}_r\mathbf{e}_r + \text{v}_\phi\mathbf{e}_\phi = \frac{dr}{dt}\mathbf{e}_r + r\frac{d\phi}{dt}\mathbf{e}_\phi \qquad 72.35$$

$$\text{acceleration: } \mathbf{a} = a_r\mathbf{e}_r + a_\phi\mathbf{e}_\phi$$
$$= \left(\frac{d^2r}{dt^2} - r\left(\frac{d\phi}{dt}\right)^2\right)\mathbf{e}_r$$
$$+ \left(r\frac{d^2\phi}{dt^2} + 2\frac{dr}{dt}\frac{d\phi}{dt}\right)\mathbf{e}_\phi \qquad 72.36$$

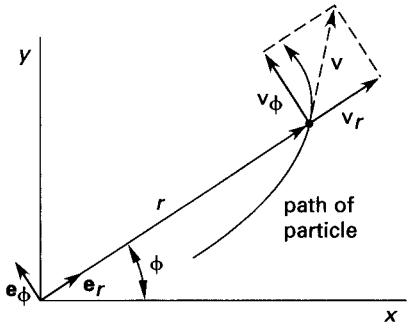

Figure 72.10 *Radial and Transverse Components*

The magnitudes of the radial and transverse components of velocity and acceleration are given by Eqs. 72.37 through 72.40.

$$\text{v}_r = \frac{dr}{dt} \qquad 72.37$$

$$\text{v}_\phi = r\frac{d\phi}{dt} \qquad 72.38$$

$$a_r = \frac{d^2r}{dt^2} - r\left(\frac{d\phi}{dt}\right)^2 \qquad 72.39$$

$$a_\phi = r\frac{d^2\phi}{dt^2} + 2\frac{dr}{dt}\frac{d\phi}{dt} \qquad 72.40$$

If the radial and transverse components of acceleration and velocity are known, they can be used to calculate the tangential and normal accelerations in a rectangular coordinate system.

$$a_t = \frac{a_r\text{v}_r + a_\phi\text{v}_\phi}{\text{v}_t} \qquad 72.41$$

$$a_n = \frac{a_\phi\text{v}_r - a_r\text{v}_\phi}{\text{v}_t} \qquad 72.42$$

16. RELATIVE MOTION

The term *relative motion* is used when motion of a particle is described with respect to something else in motion. The particle's position, velocity, and acceleration may be specified with respect to another moving particle or with respect to a moving frame of reference, known as a *Newtonian* or *inertial frame of reference*.

In Fig. 72.11, two particles, A and B, are moving with different velocities along a straight line. The separation between the two particles at any specific instant is the *relative position*, $s_{\text{B/A}}$, of B with respect to A, calculated as the difference between their two *absolute positions*.

$$s_{\text{B/A}} = s_\text{B} - s_\text{A} \qquad 72.43$$

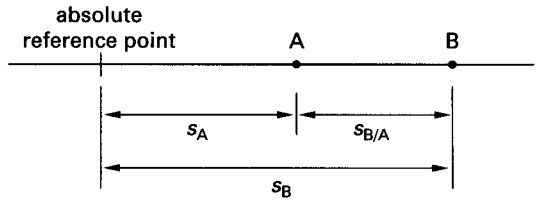

Figure 72.11 *Relative Motion of Two Particles*

Similarly, the *relative velocity* and *relative acceleration* of B with respect to A are the differences between the two *absolute velocities* and *absolute accelerations*, respectively.

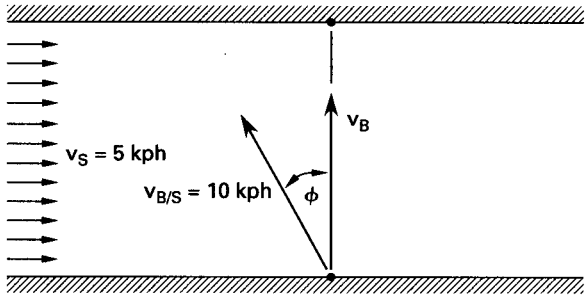
$$\text{v}_{\text{B/A}} = \text{v}_\text{B} - \text{v}_\text{A} \qquad 72.44$$

$$a_{\text{B/A}} = a_\text{B} - a_\text{A} \qquad 72.45$$

Transportation

Particles A and B are not constrained to move along a straight line. However, the subtraction must be done in vector or graphical form in all but the simplest cases.

$$\mathbf{s}_{B/A} = \mathbf{s}_B - \mathbf{s}_A \qquad 72.46$$



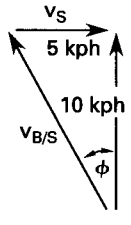
$$\mathbf{v}_{B/A} = \mathbf{v}_B - \mathbf{v}_A \qquad 72.47$$

$$\mathbf{a}_{B/A} = \mathbf{a}_B - \mathbf{a}_A \qquad 72.48$$

Since vector subtraction and addition operations can be performed graphically, many relative motion problems can be solved by a simplified graphical process.

Example 72.9

A stream flows at 5 kph. At what upstream angle, ϕ, should a 10 kph boat be piloted in order to reach the shore directly opposite the initial point?

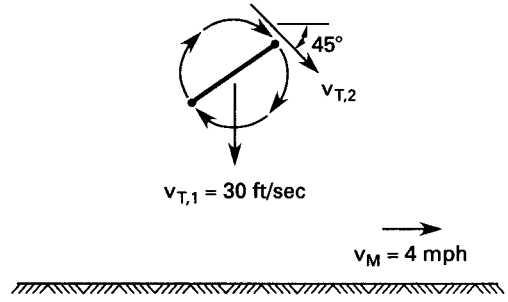


Solution

From Eq. 72.47, the absolute velocity of the boat, v_B, with respect to the shore is equal to the vector sum of the absolute velocity of the stream, v_S, and the relative velocity of the boat with respect to the stream, $v_{B/S}$. The magnitudes of these two velocities are known.

$$v_B = v_S + v_{B/S}$$

Since vector addition is accomplished graphically by placing the two vectors head to tail, the angle can be determined from trigonometry.



$$\sin\phi = \frac{v_S}{v_{B/S}} = \frac{5 \text{ kph}}{10 \text{ kph}} = 0.5$$

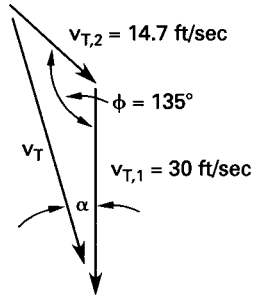
$$\phi = \arcsin(0.5) = 30^\circ$$

Example 72.10

A stationary member of a marching band tosses a 2.0 ft long balanced baton straight up into the air and then begins walking forward at 4 mph. At a particular moment, the baton is 20 ft in the air and is falling back toward the earth with a velocity of 30 ft/sec. The tip of the baton is rotating at 140 rpm in the orientation shown.

(a) What is the absolute velocity of the baton tip with respect to the ground? (b) What is the relative velocity of the baton tip with respect to the band member?

Solution



(a) The baton tip has two absolute velocity components. The first, with a magnitude of $v_{T,1} = 30$ ft/sec, is directed vertically downward. The second, with a magnitude of $v_{T,2}$, is directed as shown in the figure. The baton's radius, r, is 1 ft. From Eq. 72.19,

$$v_{T,2} = r\omega = \frac{(1 \text{ ft})\left(140 \frac{\text{rev}}{\text{min}}\right)\left(2\pi \frac{\text{rad}}{\text{rev}}\right)}{60 \frac{\text{sec}}{\text{min}}}$$

$$= 14.7 \text{ ft/sec}$$

The vector sum of these two absolute velocities is the velocity of the tip, $\mathbf{v}_T$, with respect to the earth.

$$\mathbf{v}_T = \mathbf{v}_{T,1} + \mathbf{v}_{T,2}$$

The velocity of the tip is found from the law of cosines.

$$v_T = \sqrt{v_{T,1}^2 + v_{T,2}^2 - 2v_{T,1}v_{T,2}\cos\phi}$$

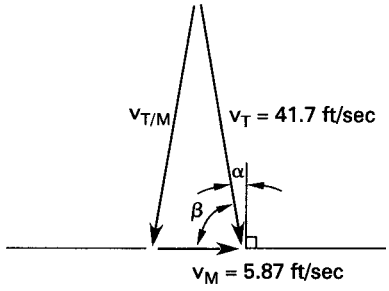
$$= \sqrt{(30)^2 + (14.7)^2 - (2)(30)(14.7)(\cos 135^\circ)}$$

$$= 41.7 \text{ ft/sec}$$

Angle α is found from the law of sines.

$$\frac{\sin\alpha}{14.7\ \frac{\text{ft}}{\text{sec}}} = \frac{\sin 135^\circ}{14.7\ \frac{\text{ft}}{\text{sec}}}$$

$$\alpha = 14.4^\circ$$



The band member's absolute velocity, v_M, is

$$v_M = \frac{\left(4\ \frac{\text{mi}}{\text{hr}}\right)\left(5280\ \frac{\text{ft}}{\text{mi}}\right)}{3600\ \frac{\text{sec}}{\text{hr}}} = 5.87\ \text{ft/sec}$$

(b) From Eq. 72.44, the velocity of the tip with respect to the band member is

$$v_{T/M} = v_T - v_M$$

Subtracting a vector is equivalent to adding its negative. The velocity triangle is as shown. The law of cosines is used again to determine the relative velocity.

$$\beta = 90^\circ - \alpha = 90^\circ - 14.4^\circ = 75.6^\circ$$

$$v_{T/M} = \sqrt{v_T^2 + v_M^2 - 2v_T v_M \cos\beta}$$

$$= \sqrt{\begin{array}{l}(41.7)^2 + (5.87)^2 \\ \quad - (2)(41.7)(5.87)(\cos 75.6^\circ)\end{array}}$$

$$= 40.6\ \text{ft/sec}\ (27.7\ \text{mph})$$

17. DEPENDENT MOTION

When the position of one particle in a multiple-particle system depends on the position of one or more other particles, the motions are said to be "dependent." A block-and-pulley system with one fixed rope end, as illustrated by Fig. 72.12, is a *dependent system.*

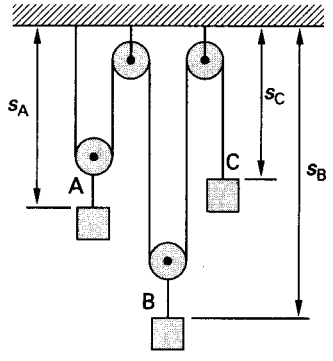


Figure 72.12 *Dependent System*

The following statements define the behavior of a dependent block-and-pulley system.

- Since the length of the rope is constant, the sum of the rope segments representing distances between the blocks and pulleys is constant. By convention, the distances are measured from the top of the block to the support point.[5] Since in Fig. 72.12 there are two ropes supporting block A, two ropes supporting block B, and one rope supporting block C,

$$2s_A + 2s_B + s_C = \text{constant} \qquad \textit{72.49}$$

- Since the position of the nth block in an n-block system is determined when the remaining $n - 1$ positions are known, the number of *degrees of freedom* is one less than the number of blocks.
- The movement, velocity, and acceleration of a block supported by two ropes are half the same quantities of a block supported by one rope.
- The relative relationships between the blocks' velocities or accelerations are the same as the relationships between the blocks' positions. For Fig. 72.12,

$$2v_A + 2v_B + v_C = 0 \qquad \textit{72.50}$$

$$2a_A + 2a_B + a_C = 0 \qquad \textit{72.51}$$

18. GENERAL PLANE MOTION

Rigid body *plane motion* can be described in two dimensions. Examples include rolling wheels, gear sets, and linkages. Plane motion can be considered as the sum of a translational component and a rotation about a fixed axis, as illustrated by Fig. 72.13.

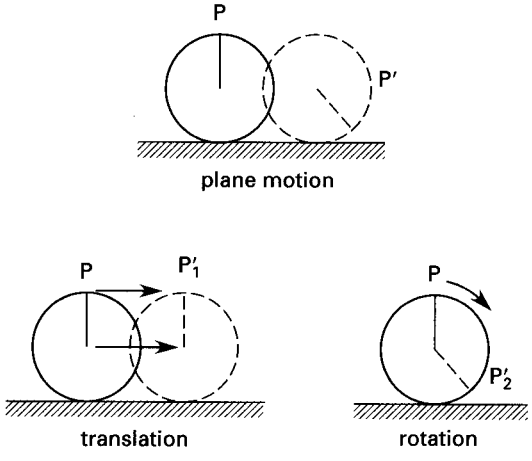

Figure 72.13 *Components of Plane Motion*

[5] In measuring distances, the finite diameters of the pulleys and the lengths of rope wrapped around the pulleys are disregarded.

Transportation

19. ROTATION ABOUT A FIXED AXIS

Analysis of the rotational component of a rigid body's plane motion can sometimes be simplified if the location of the body's instantaneous center is known. Using the instantaneous center reduces many relative motion problems to simple geometry. The *instantaneous center* (also known as the *instant center* and IC) is a point at which the body could be fixed (pinned) without changing the instantaneous angular velocities of any point on the body. Thus, with the angular velocities, the body seems to rotate about a fixed instantaneous center.

The instantaneous center is located by finding two points for which the absolute velocity directions are known. Lines drawn perpendicular to these two velocities will intersect at the instantaneous center. (This graphical procedure is slightly different if the two velocities are parallel, as Fig. 72.14 shows. In that case, use is made of the fact that the tangential velocity is proportional to the distance from the instantaneous center.) For a rolling wheel, the instantaneous center is the point of contact with the supporting surface.

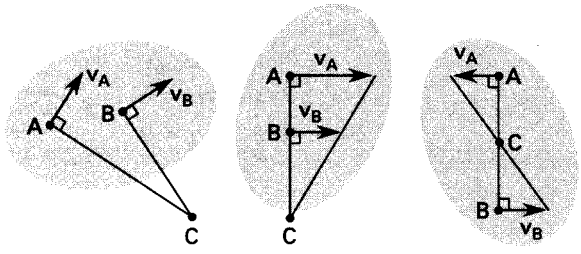

Figure 72.14 *Graphical Method of Finding the Instantaneous Center*

The absolute velocity of any point P on a wheel rolling (Fig. 72.15) with translational velocity, v_O, can be found by geometry. Assume that the wheel is pinned at C and rotates with its actual angular velocity, $\omega = v_O/r$. The direction of the point's velocity will be perpendicular to the line of length l between the instantaneous center and the point.

$$v = l\omega = \frac{lv_O}{r} \qquad 72.52$$

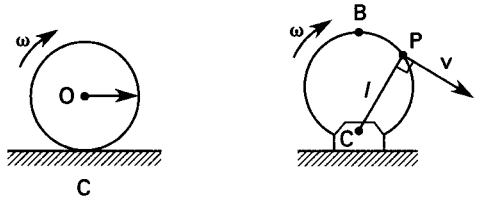

Figure 72.15 *Instantaneous Center of a Rolling Wheel*

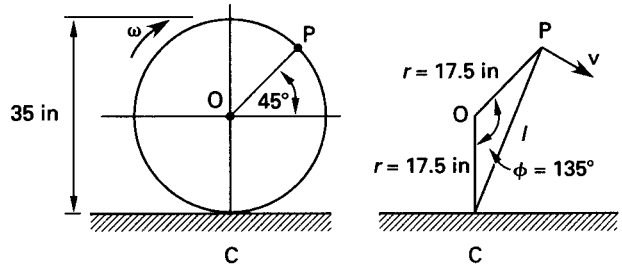

Equation 72.52 is valid only for a velocity referenced to the instantaneous center, point C. Table 72.3 can be used to find the velocities with respect to other points.

Table 72.3 *Relative Velocities of a Rolling Wheel*

	reference point		
point	O	C	B
v_O	0	$v_O\rightarrow$	$\leftarrow v_O$
v_C	$\leftarrow v_O$	0	$\leftarrow 2v_O$
v_B	$v_O\rightarrow$	$2v_O\rightarrow$	0

Example 72.11

A truck with 35 in diameter tires travels at a constant 35 mph. What is the absolute velocity of point P on the circumference of the tire?

Solution

The translational velocity of the center of the wheel is

$$v_O = \frac{\left(35\ \frac{\text{mi}}{\text{hr}}\right)\left(5280\ \frac{\text{ft}}{\text{mi}}\right)}{3600\ \frac{\text{sec}}{\text{hr}}} = 51.33\ \text{ft/sec}$$

The wheel radius is

$$r = \frac{35\ \text{in}}{(2)\left(12\ \frac{\text{in}}{\text{ft}}\right)} = 1.458\ \text{ft}$$

The angular velocity of the wheel is

$$\omega = \frac{v_O}{r} = \frac{51.33\ \frac{\text{ft}}{\text{sec}}}{1.458\ \text{ft}} = 35.21\ \text{rad/sec}$$

The instantaneous center is the contact point, C. The law of cosines is used to find the distance l.

$$l^2 = r^2 + r^2 - 2r^2\cos\phi = 2r^2(1 - \cos\phi)$$

$$l = \sqrt{(2)(1.458\ \text{ft})^2(1 - \cos 135^\circ)} = 2.694\ \text{ft}$$

From Eq. 72.52, the absolute velocity of point P is

$$v_P = l\omega = (2.694\ \text{ft})\left(35.21\ \frac{\text{rad}}{\text{sec}}\right)$$

$$= 94.9\ \text{ft/sec}$$

20. INSTANTANEOUS CENTER OF ACCELERATION

The *instantaneous center of acceleration* is used to compute the absolute acceleration of a point as if a body were in pure rotation about that point. It is the same as the instantaneous center of rotation only for a body starting from rest and accelerating uniformly with angular acceleration, α.

$$a = l\alpha = \frac{la_O}{r} \qquad 72.53$$

In general, the instantaneous center of acceleration, C_a, will be deflected an angle β from the absolute acceleration vectors, as shown in Fig. 72.16. The relationship among the angle β, the instantaneous acceleration, α, and the instantaneous velocity, ω, is

$$\tan\beta = \frac{\alpha}{\omega^2} \qquad 72.54$$

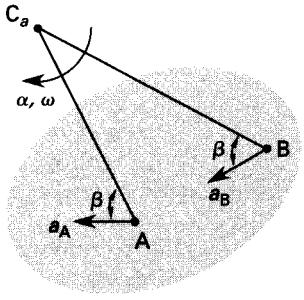

Figure 72.16 *Instantaneous Center of Acceleration*

The absolute acceleration, a, determined from Eq. 72.53 is the same as the *resultant acceleration* in Fig. 72.7.

21. SLIDER RODS

The absolute velocity of any point, P, on a slider rod assembly can be found from the instantaneous center concept. The instantaneous center, C, is located by extending perpendiculars from the velocity vectors.

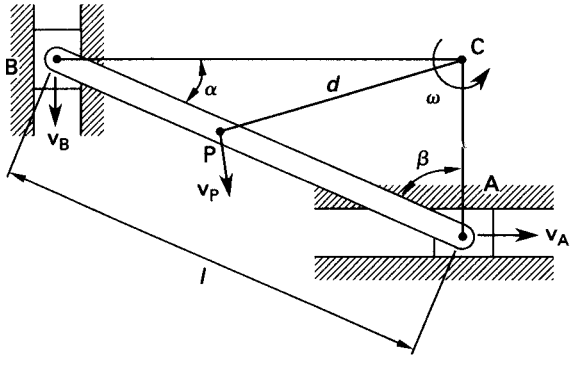

Figure 72.17 *Instantaneous Center of Slider Rod Assembly*

If the velocity with respect to point C of one end of the slider is known, say v_A, then v_B can be found from geometry. Since the slider can be assumed to rotate about point C with angular velocity ω,

$$\omega = \frac{v_A}{AC} = \frac{v_A}{l\cos\beta} = \frac{v_B}{BC} = \frac{v_B}{l\cos\alpha} \qquad 72.55$$

Since $\cos\alpha = \sin\beta$,

$$v_B = v_A(\tan\beta) \qquad 72.56$$

If the velocity with respect to point C of any other point P is required, it can be found from

$$v_P = d\omega \qquad 72.57$$

22. SLIDER-CRANK ASSEMBLIES

Figure 72.18 illustrates a slider-crank assembly for which points A and D are in the same plane and at the same elevation. The velocity of any point, P, on the rod can be found if the distance to the instantaneous center is known.

$$v_P = d\omega \qquad 72.58$$

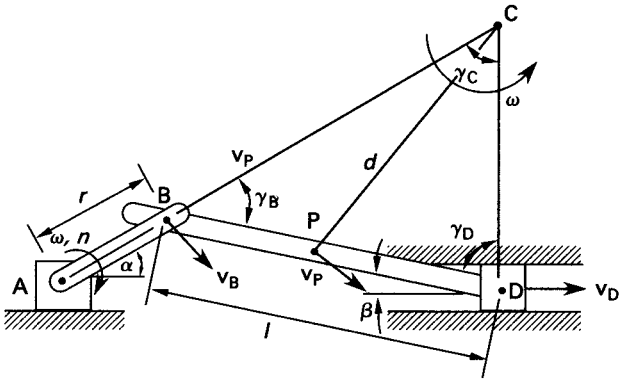

Figure 72.18 *Slider-Crank Assembly*

The tangential velocity of point B on the crank with respect to point A is perpendicular to the end of the crank. Slider D moves with a horizontal velocity. The intersection of lines drawn perpendicular to these velocity vectors locates the instantaneous center, point C. At any given instant, the connecting rod seems to rotate about point C with angular velocity ω.

$$\omega = \frac{2\pi n}{60} \qquad 72.59$$

The velocity of point D, v_D, is

$$v_D = (CD)\omega \qquad 72.60$$

Similarly, the velocity of point B, v_B, is

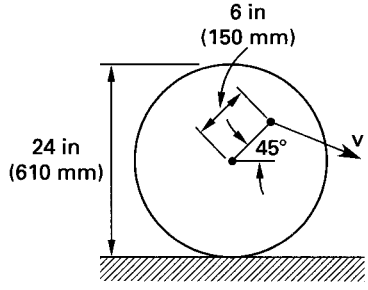
$$v_B = (BC)\omega \qquad 72.61$$

Transportation

The following geometric relationships exist between the various points.

$$\frac{\sin\alpha}{l} = \frac{\sin\beta}{r} \qquad 72.62$$

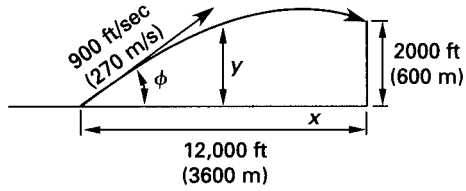
$$\frac{\sin\gamma_D}{BC} = \frac{\sin\gamma_B}{CD} = \frac{\sin\gamma_C}{l} \qquad 72.63$$



$$\gamma_B = \alpha + \beta \qquad 72.64$$

$$\gamma_D = 90 - \beta \qquad 72.65$$

$$\gamma_C = 90 - \alpha \qquad 72.66$$



PRACTICE PROBLEMS

1. The center of a wheel with an outer diameter of 24 in (610 mm) is moving at 28 mi/hr (12.5 m/s). There is no slippage between the wheel and surface. A valve stem is mounted 6 in (150 mm) from the center. What are the velocity and direction of the valve stem when it is 45° from the horizontal?

Answer: 57.5 ft/sec (17.4 m/s); perpendicular to the line connecting the valve stem and the surface contact point

2. A projectile is launched with an initial velocity of 900 ft/sec (270 m/s). The target is 12,000 ft (3600 m) away and 2000 ft (600 m) higher than the launch point. Air friction is to be neglected. At what angle should the projectile be launched?

Answer: 75°; 25°

1. INTRODUCTION TO KINETICS

Kinetics is the study of motion and the forces that cause motion. Kinetics includes an analysis of the relationship between the force and mass for translational motion and between torque and moment of inertia for rotational motion. Newton's laws form the basis of the governing theory in the subject of kinetics.

2. RIGID BODY MOTION

The most general type of motion is *rigid body motion*. There are five types.

- *pure translation*: The orientation of the object is unchanged as its position changes. (Motion can be in straight or curved paths.)
- *rotation about a fixed axis*: All particles within the body move in concentric circles about the *axis of rotation*.
- *general plane motion*: The motion can be represented in two dimensions (i.e., the *plane of motion*).
- *motion about a fixed point*: This describes any three-dimensional motion with one fixed point, such as a spinning top or a truck-mounted crane. The distance from a fixed point to any particle in the body is constant.
- *general motion*: This is any motion not falling into one of the other four categories.

Figure 73.1 illustrates the terms yaw, pitch, and roll as they relate to general motion. *Yaw* is a left or right swinging motion of the leading edge. *Pitch* is an up or down swinging motion of the leading edge. *Roll* is rotation about the leading edge's longitudinal axis.

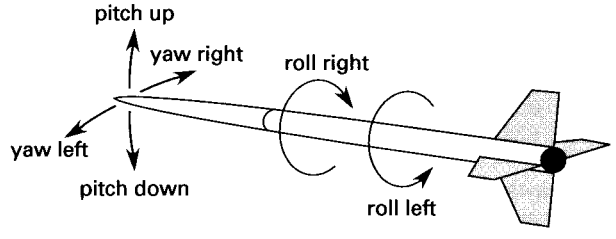

Figure 73.1 *Yaw, Pitch, and Roll*

3. STABILITY OF EQUILIBRIUM POSITIONS

Stability is defined in terms of a body's relationship with an equilibrium position. *Neutral equilibrium* exists if a body, when displaced from its equilibrium position, remains in its displaced state. *Stable equilibrium* exists if the body returns to the original equilibrium position after experiencing a displacement. *Unstable equilibrium* exists if the body moves away from the equilibrium position. These terms are illustrated by Fig. 73.2.

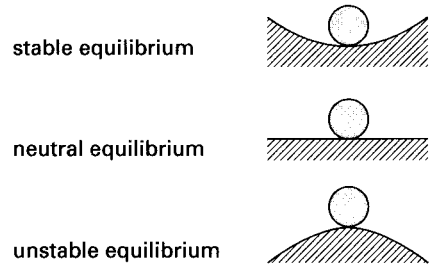

Figure 73.2 *Types of Equilibrium Positions*

4. CONSTANT FORCES

Force is a push or a pull that one body exerts on another, including gravitational, electrostatic, magnetic, and contact influences. Forces that do not vary with time are *constant forces*.

Strictly speaking, actions of other bodies on a rigid body are known as *external forces*. External forces are responsible for external motion of a body. *Internal forces* hold together parts of a rigid body.

5. LINEAR MOMENTUM

The vector *linear momentum* (usually just *momentum*) is defined by Eq. 73.1.[1] It has the same direction as the velocity vector. Momentum has units of force × time (e.g., lbf-sec or N·s).

$$\mathbf{p} = m\mathbf{v} \qquad \text{[SI]} \qquad 73.1(a)$$

$$\mathbf{p} = \frac{m\mathbf{v}}{g_c} \qquad \text{[U.S.]} \qquad 73.1(b)$$

Momentum is conserved when no external forces act on a particle. If no forces act on the particle, the velocity and direction of the particle are unchanged. The *law of conservation of momentum* states that the linear momentum is unchanged if no unbalanced forces act on the particle. This does not prohibit the mass and velocity from changing, however. Only the product of mass or

[1] The symbols **P**, **mom**, $m\mathrm{v}$, and others are also used for momentum. Some authorities assign no symbol and just use the word momentum.

velocity is constant. Depending on the nature of the problem, momentum can be conserved in any or all of the three coordinate directions.

$$\sum m_0 \mathbf{v}_0 = \sum m_f \mathbf{v}_f \qquad 73.2$$

6. BALLISTIC PENDULUM

Figure 73.3 illustrates a *ballistic pendulum*. A projectile of known mass but unknown velocity is fired into a hanging target (the *pendulum*). The projectile is captured by the pendulum, which moves forward and upward. Kinetic energy is not conserved during impact because some of the projectile's kinetic energy is transformed into heat. However, momentum is conserved during impact, and the movement of the pendulum can be used to calculate the impact velocity of the projectile.[2]

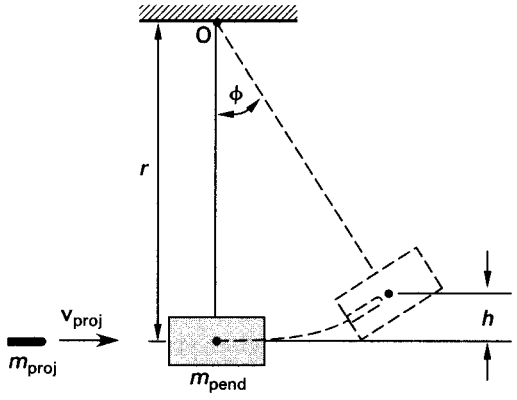

Figure 73.3 *Ballistic Pendulum*

Since no external forces act on the block during impact, the momentum of the system is conserved.

$$\mathbf{p}_{\text{before impact}} = \mathbf{p}_{\text{after impact}} \qquad 73.3$$

$$m_{\text{proj}} \mathbf{v}_{\text{proj}} = (m_{\text{proj}} + m_{\text{pend}})\, \mathbf{v}_{\text{pend}} \qquad 73.4$$

Although kinetic energy before impact is not conserved, the total remaining energy after impact is conserved. That is, once the projectile has been captured by the pendulum, the kinetic energy of the pendulum-projectile combination is converted totally to potential energy as the pendulum swings upward.

$$\left(\tfrac{1}{2}\right)(m_{\text{proj}} + m_{\text{pend}})\, v_{\text{pend}}^2 = (m_{\text{proj}} + m_{\text{pend}})\, gh \qquad 73.5$$

$$v_{\text{pend}} = \sqrt{2gh} \qquad 73.6$$

[2]In this type of problem, it is important to be specific about when the energy and momentum are evaluated. During impact, kinetic energy is not conserved, but momentum is conserved. After impact, as the pendulum swings, energy is conserved but momentum is not conserved because gravity (an external force) acts on the pendulum during its swing.

The relationship between the rise of the pendulum, h, and the swing angle, ϕ, is

$$h = r(1 - \cos\phi) \qquad 73.7$$

Since the time during which the force acts is not well defined, there is no single equivalent force that can be assumed to initiate the motion. Any force that produces the same impulse over a given contact time will be applicable.

7. ANGULAR MOMENTUM

The vector *angular momentum* (also known as *moment of momentum*) taken about a point O is the moment of the linear momentum vector. Angular momentum has units of distance × force × time (e.g., ft-lbf-sec or N·m·s). It has the same direction as the rotation vector and can be determined by use of the right-hand rule. (That is, it acts in a direction perpendicular to the plane containing the position and linear momentum vectors.)

$$\mathbf{h}_O = \mathbf{r} \times m\mathbf{v} \qquad \text{[SI]} \qquad 73.8(a)$$

$$\mathbf{h}_O = \frac{\mathbf{r} \times m\mathbf{v}}{g_c} \qquad \text{[U.S.]} \qquad 73.8(b)$$

Any of the methods normally used to evaluate cross-products can be used with angular momentum. The scalar form of Eq. 73.8 is

$$h_O = rmv\sin\phi \qquad \text{[SI]} \qquad 73.9(a)$$

$$h_O = \frac{rmv\sin\phi}{g_c} \qquad \text{[U.S.]} \qquad 73.9(b)$$

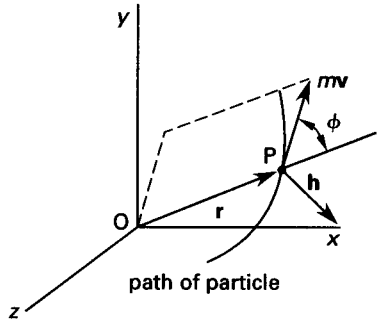

Figure 73.4 *Angular Momentum*

For a rigid body rotating about an axis passing through its center of gravity located at point O, the scalar value of angular momentum is given by Eq. 73.10.

$$h_O = I\omega \qquad \text{[SI]} \qquad 73.10(a)$$

$$h_O = \frac{I\omega}{g_c} \qquad \text{[U.S.]} \qquad 73.10(b)$$

Transportation

8. NEWTON'S FIRST LAW OF MOTION

Much of this chapter is based on Newton's laws of motion. *Newton's first law of motion* can be stated in several forms.

common form: A particle will remain in a state of rest or will continue to move with constant velocity unless an unbalanced external force acts on it.

law of conservation of momentum form: If the resultant external force acting on a particle is zero, then the linear momentum of the particle is constant.

9. NEWTON'S SECOND LAW OF MOTION

Newton's second law of motion is stated as follows.

second law: The acceleration of a particle is directly proportional to the force acting on it and inversely proportional to the particle mass. The direction of acceleration is the same as the force of direction.

This law can be stated in terms of the force vector required to cause a change in momentum. The resultant force is equal to the rate of change of linear momentum.

$$\mathbf{F} = \frac{d\mathbf{p}}{dt} \qquad 73.11$$

If the mass is constant with respect to time, the scalar form of Eq. 73.11 is[3]

$$F = m\left(\frac{dv}{dt}\right) = ma \qquad \text{[SI]} \qquad 73.12(a)$$

$$F = \left(\frac{m}{g_c}\right)\left(\frac{dv}{dt}\right) = \frac{ma}{g_c} \qquad \text{[U.S.]} \qquad 73.12(b)$$

Equation 73.12 can be written in rectangular coordinates form (i.e., in terms of x- and y- component forces), in polar coordinates form (i.e, tangential and normal components), and in cylindrical coordinates form (i.e., radial and transverse components).

Although Newton's laws do not specifically deal with rotation, there is an analogous relationship between torque and change in angular momentum. For a rotating body, the torque, $\mathbf{T}$, required to change the angular momentum is

$$\mathbf{T} = \frac{d\mathbf{h}_0}{dt} \qquad 73.13$$

If the moment of inertia is constant, the scalar form of Eq. 73.13 is

$$T = I\left(\frac{d\omega}{dt}\right) = I\alpha \qquad \text{[SI]} \qquad 73.14(a)$$

$$T = \left(\frac{I}{g_c}\right)\left(\frac{d\omega}{dt}\right) = \frac{I\alpha}{g_c} \qquad \text{[U.S.]} \qquad 73.14(b)$$

[3]Equation 73.12 shows that force is a scalar multiple of acceleration. Any consistent set of units can be used. For example, if both sides are divided by the acceleration of gravity (i.e., so that acceleration in Eq. 73.12 is in gravities), the force will have units of *g-forces* or *gees* (i.e., multiples of the gravitational force).

Example 73.1

The acceleration in $\mathrm{m/s^2}$ of a 40 kg body is specified by the equation

$$a(t) = 8 - 12t$$

What is the instantaneous force acting on the body at $t = 6$ s?

Solution

The acceleration is

$$a(6) = 8\ \frac{\mathrm{m}}{\mathrm{s}^2} - \left(12\ \frac{\mathrm{m}}{\mathrm{s}^3}\right)(6\ \mathrm{s}) = -64\ \mathrm{m/s^2}$$

From Newton's second law, the instantaneous force is

$$F = ma = (40\ \mathrm{kg})\left(-64\ \frac{\mathrm{m}}{\mathrm{s}^2}\right)$$
$$= -2560\ \mathrm{N}$$

Example 73.2

During start-up, a 4.0 ft diameter wheel with centroidal moment of inertia of 1610 lbm-ft^2 is subjected to tight-side and loose-side belt tensions of 200 lbf and 100 lbf, respectively. A frictional torque of 15 ft-lbf is acting to resist pulley rotation. (a) What is the angular acceleration? (b) How long will it take the wheel to reach a speed of 30 rpm?

Solution

(a) From Eq. 73.24, the net torque is

$$T = rF_{\mathrm{net}} = (2\ \mathrm{ft})(200\ \mathrm{lbf} - 100\ \mathrm{lbf}) - 15\ \mathrm{ft\text{-}lbf}$$
$$= 185\ \mathrm{ft\text{-}lbf}$$

From Eq. 73.14, the angular acceleration is

$$\alpha = \frac{g_c T}{I} = \frac{\left(32.2\ \frac{\mathrm{lbm\text{-}ft}}{\mathrm{lbf\text{-}sec}^2}\right)(185\ \mathrm{ft\text{-}lbf})}{1610\ \mathrm{lbm\text{-}ft}^2}$$
$$= 3.7\ \mathrm{rad/sec}^2$$

(b) The rotational speed is

$$\omega = \frac{\left(120\ \frac{\mathrm{rev}}{\mathrm{min}}\right)\left(2\pi\ \frac{\mathrm{rad}}{\mathrm{rev}}\right)}{60\ \frac{\mathrm{sec}}{\mathrm{min}}}$$
$$= 12.6\ \mathrm{rad/sec}$$

This is a case of constant angular acceleration starting from rest.

$$t = \frac{\omega}{\alpha} = \frac{12.6\ \frac{\mathrm{rad}}{\mathrm{sec}}}{3.7\ \frac{\mathrm{rad}}{\mathrm{sec}^2}}$$
$$= 3.4\ \mathrm{sec}$$

10. CENTRIPETAL FORCE

Newton's second law says there is a force for every acceleration a body experiences. For a body moving around a curved path, the total acceleration can be separated into tangential and normal components. By Newton's second law, there are corresponding forces in the tangential and normal directions. The force associated with the normal acceleration is known as the *centripetal force.*[4]

$$F_c = ma_n = \frac{mv_t^2}{r} \qquad \text{[SI]} \qquad 73.15(a)$$

$$F_c = \frac{mv_t^2}{g_c r} \qquad \text{[U.S.]} \qquad 73.15(b)$$

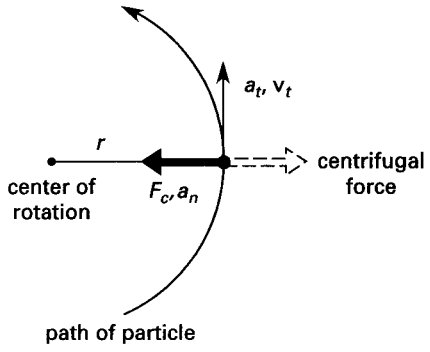

Figure 73.5 *Centripetal Force*

The centripetal force is a real force on the body toward the center of rotation. The so-called *centrifugal force* is an apparent force on the body directed away from the center of rotation. The centripetal and centrifugal forces are equal in magnitude but opposite in sign.

Example 73.3

A 4500 lbm (2000 kg) car travels at 40 mph (65 kph) around a curve with a radius of 200 ft (60 m). What is the centripetal force?

SI Solution

The tangential velocity is

$$v_t = \frac{\left(65\ \frac{\text{km}}{\text{h}}\right)\left(1000\ \frac{\text{m}}{\text{km}}\right)}{3600\ \frac{\text{s}}{\text{h}}} = 18.06\ \text{m/s}$$

From Eq. 73.15(a), the centripetal force is

$$F_c = \frac{mv_t^2}{r} = \frac{(2000\ \text{kg})\left(18.06\ \frac{\text{m}}{\text{s}}\right)^2}{60\ \text{m}} = 10\,900\ \text{N}$$

[4]The term *normal force* is reserved for the plane reaction in friction calculations.

Customary U.S. Solution

The tangential velocity is

$$v_t = \frac{\left(40\ \frac{\text{mi}}{\text{hr}}\right)\left(5280\ \frac{\text{ft}}{\text{mi}}\right)}{3600\ \frac{\text{sec}}{\text{hr}}} = 58.7\ \text{ft/sec}$$

From Eq. 73.15(b), the centripetal force is

$$F_c = \frac{mv_t^2}{g_c r} = \frac{(4500\ \text{lbm})\left(58.7\ \frac{\text{ft}}{\text{sec}}\right)^2}{\left(32.2\ \frac{\text{lbm-ft}}{\text{lbf-sec}^2}\right)(200\ \text{ft})} = 2400\ \text{lbf}$$

An unbalanced rotating body (vehicle wheel, clutch disk, rotor of an electrical motor, etc.) will experience a dynamic *unbalanced force.* Though the force is essentially centripetal in nature and is given by Eq. 73.15, it is generally difficult to assign a value to the radius. For that reason, the force is often determined directly on the rotating body or from the deflection of its supports.

Since the body is rotating, the force will be experienced in all directions perpendicular to the axis of rotation. If the supports are flexible, the force will cause the body to vibrate, and the frequency of vibration will essentially be the rotational speed. If the supports are rigid, the bearings will carry the unbalanced force and transmit it to other parts of the frame.

11. NEWTON'S THIRD LAW OF MOTION

Newton's third law of motion is as follows.

third law: For every acting force between two bodies, there is an equal but opposite reacting force on the same line of action.

$$\mathbf{F}_{\text{reacting}} = -\mathbf{F}_{\text{acting}} \qquad 73.16$$

12. DYNAMIC EQUILIBRIUM

An accelerating body is not in static equilibrium. Accordingly, the familiar equations of statics ($\sum F = 0$ and $\sum M = 0$) do not apply. However, if the *inertial force,* $m\mathbf{a}$, is included in the static equilibrium equation, the body is said to be in *dynamic equilibrium.*[5,6]

[5]Other names for the inertial force are *inertia vector* (when written as $m\mathbf{a}$), *dynamic reaction,* and *reversed effective force.* The term $\sum \mathbf{F}$ is known as the *effective force.*

[6]*Dynamic* and *equilibrium* are contradictory terms. A better term is *simulated equilibrium,* but this form has not caught on.

Transportation

This is known as *D'Alembert's principle*. Since the inertial force acts to oppose changes in motion, it is negative in the summation.

$$\sum \mathbf{F} - m\mathbf{a} = 0 \qquad \text{[SI]} \qquad 73.17(a)$$

$$\sum \mathbf{F} - \frac{m\mathbf{a}}{g_c} = 0 \qquad \text{[U.S.]} \qquad 73.17(b)$$

It should be clear that D'Alembert's principle is just a different form of Newton's second law, with the ma term transposed to the left-hand side.

The analogous rotational form of the dynamic equilibrium principle is

$$\sum \mathbf{T} - I\boldsymbol{\alpha} = 0 \qquad \text{[SI]} \qquad 73.18(a)$$

$$\sum \mathbf{T} - \frac{I\boldsymbol{\alpha}}{g_c} = 0 \qquad \text{[U.S.]} \qquad 73.18(b)$$

13. FLAT FRICTION

Friction is a force that always resists motion or impending motion. It always acts parallel to the contacting surfaces. The frictional force, F_f, exerted on a stationary body is known as *static friction*, *Coulomb friction*, and *fluid friction*. If the body is moving, the friction is known as *dynamic friction* and is less than the static friction.

The actual magnitude of the frictional force depends on the *normal force*, N, and the *coefficient of friction*, f, between the body and the surface.[7] For a body resting on a horizontal surface, the normal force is the weight of the body.

$$N = mg \qquad \text{[SI]} \qquad 73.19(a)$$

$$N = \frac{mg}{g_c} \qquad \text{[U.S.]} \qquad 73.19(b)$$

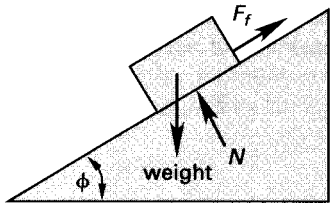

Figure 73.6 *Frictional and Normal Forces*

If the body rests on an inclined surface, the normal force is calculated from the weight.

$$N = mg\cos\phi \qquad \text{[SI]} \qquad 73.20(a)$$

$$N = \frac{mg\cos\phi}{g_c} \qquad \text{[U.S.]} \qquad 73.20(b)$$

[7]The symbol μ is also widely used by engineers to represent the coefficient of friction.

The maximum static frictional force, F_f, is the product of the coefficient of friction, f, and the normal force, N. (The subscripts s and k are used to distinguish between the static and dynamic (kinetic) coefficients of friction.)

$$F_{f,\max} = f_s N \qquad 73.21$$

The frictional force acts only in response to a disturbing force. If a small disturbing force (i.e., a force less than $F_{f,\max}$) acts on a body, then the frictional force will equal the disturbing force, and the maximum frictional force will not develop. This is known as the *equilibrium phase*. The *motion impending phase* is where the disturbing force equals the maximum frictional force, $F_{f,\max}$. Once motion begins, however, the coefficient of friction drops slightly, and a lower frictional force opposes movement. These cases are illustrated in Fig. 73.7.

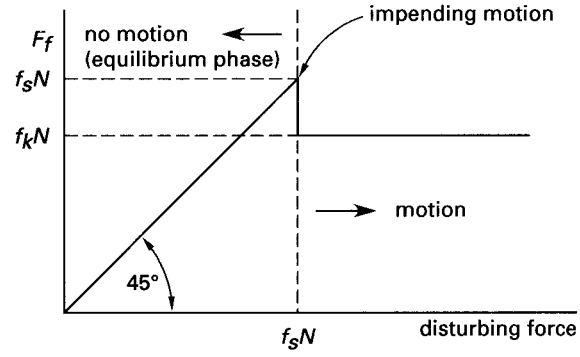

Figure 73.7 *Frictional Force versus Disturbing Force*

A body on an inclined plane will not begin to slip down the plane until the component of weight parallel to the plane exceeds the frictional force. If the plane's inclination angle can be varied, the body will not slip until the angle reaches a critical angle known as the *angle of repose* or *angle of static friction*, ϕ. Equation 73.22 relates this angle to the coefficient of static friction.

$$\tan\phi = f_s \qquad 73.22$$

Tabulations of coefficients of friction distinguish between types of surfaces and between static and dynamic cases. They might also list values for dry conditions and oiled conditions. The term *dry* is synonymous with *nonlubricated*. The ambiguous term *wet*, although a natural antonym for *dry*, is sometimes used to mean *oily*. However, it usually means wet with water, as in tires on a wet roadway after a rain. Typical values of the coefficient of friction are given in Table 73.1.[8]

[8]Experimental and reported values of the coefficient of friction vary greatly from researcher to researcher and experiment to experiment. The values in Table 73.1 are more for use in solving practice problems than serving as the last word in available data.

Table 73.1 *Typical Coefficients of Friction*

material	condition	dynamic	static
cast iron on cast iron	dry	0.15	1.00
plastic on steel	dry	0.35	0.45
grooved rubber on pavement	dry	0.40	0.55
bronze on steel	oiled	0.07	0.09
steel on graphite	dry	0.16	0.21
steel on steel	dry	0.42	0.78
steel on steel	oiled	0.08	0.10
steel on asbestos-faced steel	dry	0.11	0.15
steel on asbestos-faced steel	oiled	0.09	0.12
press fits (shaft in hole)	oiled	–	0.10–0.15

A special case of the angle of repose is the *angle of internal friction*, ϕ, of soil, grain, or other granular material. The angle made by a pile of granular material depends on how much friction there is between the granular particles. Liquids have angles of internal friction of zero, because they do not form piles.

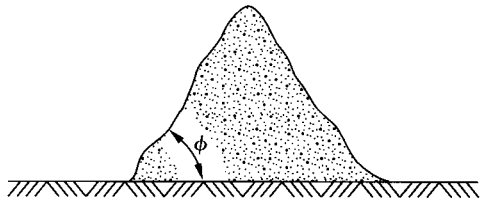

Figure 73.8 *Angle of Internal Friction*

14. WEDGES

Wedges are machines that are able to raise heavy loads. The wedge angles are chosen so that friction will keep the wedge in place once it is driven between the load and support. As with any situation where friction is present, the frictional force is parallel to the contacting surfaces.

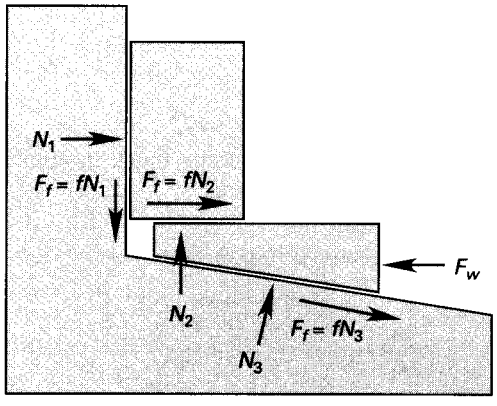

Figure 73.9 *Typical Wedge Problem*

15. BELT FRICTION

Friction from a belt, rope, or band wrapped around a pulley or sheave is responsible for the transfer of torque. Except at start-up, one side of the belt (the tight side) will have a higher tension than the other (the slack side). The basic relationship between these belt tensions and the coefficient of friction neglects centrifugal effects and is given by Eq. 73.23.[9] (The angle of wrap, ϕ, must be expressed in radians.)

$$\frac{F_{\max}}{F_{\min}} = e^{f\phi} \qquad 73.23$$

The net transmitted torque is

$$T = (F_{\max} - F_{\min})\, r \qquad 73.24$$

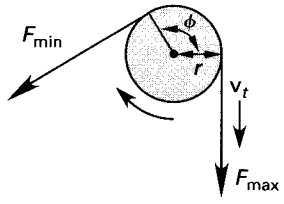

Figure 73.10 *Belt Friction*

The power transmitted by the belt running at tangential velocity v_t is given by Eq. 73.25.[10]

$$P = (F_{\max} - F_{\min})\, v_t \qquad 73.25$$

The centrifugal force experienced by the belt should be considered when the velocity or belt mass is very large. Equation 73.26 can be used, where m is the mass per unit length of belt.

$$\frac{F_{\max} - F_c}{F_{\min} - F_c} = \frac{F_{\max} - mv_t^2}{F_{\min} - mv_t^2} = e^{f\phi} \quad \text{[consistent units]} \qquad 73.26$$

16. ROLLING RESISTANCE

Rolling resistance is a force that opposes motion, but it is not friction. Rather, it is caused by the deformation of the rolling body and the supporting surface. Rolling resistance is characterized by a *coefficient of rolling resistance*, a, which has units of length.[11] Since

[9]This equation does not apply to V-belts. V-belt design and analysis is dependent on the cross-sectional geometry of the belt.

[10]When designing a belt system, the horsepower to be transmitted should be multiplied by a *service factor* to obtain the *design power*. Service factors range from 1.0 to 1.5 and depend on the nature of the power source, the load, and the starting characteristics.

[11]Rolling resistance is traditionally derived by assuming the roller encounters a small step in its path a distance a in front of the center of gravity. The forces acting on the roller are the weight and driving force acting through the centroid and the normal force and rolling resistance acting at the contact point. Equation 73.27 is derived by taking moments about the contact point, P.

this deformation is very small, the rolling resistance in the direction of motion is

$$F_r = \frac{mga}{r} \quad \text{[SI]} \qquad 73.27(a)$$

$$F_r = \frac{mga}{rg_c} = \frac{wa}{r} \quad \text{[U.S.]} \qquad 73.27(b)$$

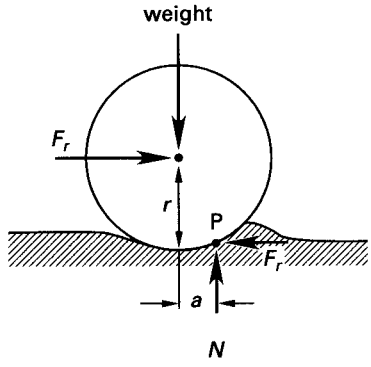

Figure 73.11 *Rolling Resistance*

The term *coefficient of rolling friction*, f_r, is occasionally encountered, although friction is not the cause of rolling resistance.

$$f_r = \frac{F_r}{w} = \frac{a}{r} \qquad 73.28$$

17. MOTION OF RIGID BODIES

When a rigid body experiences pure translation, its position changes without any change in orientation. At any instant, all points on the body have the same displacement, velocity, and acceleration. The behavior of a rigid body in translation is given by Eqs. 73.29 and 73.30. All equations are written for the center of mass. (These equations represent Newton's second law written in component form.)

$$\sum F_x = ma_x \quad \text{[consistent units]} \qquad 73.29$$

$$\sum F_y = ma_y \quad \text{[consistent units]} \qquad 73.30$$

When a torque acts on a rigid body, the rotation will be about the center of gravity unless the body is constrained otherwise. In the case of rotation, the torque and angular acceleration are related by Eq. 73.31.

$$T = I\alpha \quad \text{[SI]} \qquad 73.31(a)$$

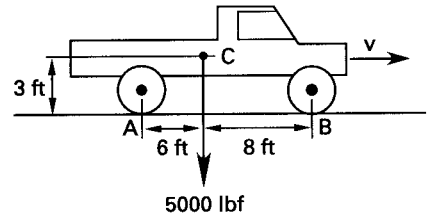
$$T = \frac{I\alpha}{g_c} \quad \text{[U.S.]} \qquad 73.31(b)$$

Euler's equations of motion are used to analyze the motion of a rigid body about a fixed point, O. This class of problem is particularly difficult because the mass moments of products of inertia change with time if a fixed set of axes is used. Therefore, it is more convenient to define the x-, y-, and z-axes with respect to the body. Such an action is acceptable because the angular momentum about the origin, $\mathbf{h}_O$, corresponding to a given angular velocity, ω, is independent of the choice of coordinate axes.

An infinite number of axes can be chosen. (A general relationship between moments and angular momentum is given in most dynamics textbooks.) However, if the origin is at the mass center and the x-, y-, and z-axes coincide with the principal axes of inertia of the body (such that the product of inertia is zero), the angular momentum of the body about the origin (i.e., point O at (0,0,0)) is given by the simplified relationship

$$\mathbf{h}_O = I_x\omega_x\mathbf{i} + I_y\omega_y\mathbf{j} + I_z\omega_z\mathbf{k} \qquad 73.32$$

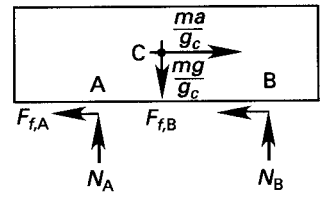
The three scalar Euler equations of motion can be derived from this simplified relationship.



$$\sum M_x = I_x\alpha_x - (I_y - I_z)\omega_y\omega_z \qquad 73.33$$

$$\sum M_y = I_y\alpha_y - (I_z - I_x)\omega_z\omega_x \qquad 73.34$$

$$\sum M_z = I_z\alpha_z - (I_x - I_y)\omega_x\omega_y \qquad 73.35$$



Example 73.4

A 5000 lbm truck skids with a deceleration of 15 ft/sec^2. (a) What is the coefficient of sliding friction? (b) What are the frictional forces and normal reactions (per axle) at the tires?

Solution

(a) The free-body diagram of the truck in equilibrium with the inertial force is shown.

The equation of dynamic equilibrium in the horizontal direction is

$$\sum F_x = \frac{ma}{g_c} - F_{f,\mathrm{A}} - F_{f,\mathrm{B}} = 0$$

$$= \frac{ma}{g_c} - Nf = 0$$

$$\frac{(5000 \text{ lbm})\left(15 \frac{\text{ft}}{\text{sec}^2}\right)}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}} - (5000 \text{ lbf})f = 0$$

The coefficient of friction is

$$f = 0.466$$

(b) The vertical reactions at the tires can be found by taking moments about one of the contact points.

$$\sum M_{\mathrm{A}}: \quad 14N_{\mathrm{B}} - (6 \text{ ft})(5000 \text{ lbf})$$

$$- (3 \text{ ft})\left(\frac{5000 \text{ lbm}}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}}\right)\left(15 \frac{\text{ft}}{\text{sec}^2}\right) = 0$$

$$N_{\mathrm{B}} = 2642 \text{ lbf}$$

The remaining vertical reaction is found by summing vertical forces.

$$\sum F_y: \quad N_{\mathrm{A}} + N_{\mathrm{B}} - \frac{mg}{g_c} = 0$$

$$N_{\mathrm{A}} + 2642 \text{ lbf} - 5000 \text{ lbf} = 0$$

$$N_{\mathrm{A}} = 2358 \text{ lbf}$$

The horizontal frictional forces at the front and rear axles are

$$F_{f,\mathrm{A}} = (0.466)(2358 \text{ lbf}) = 1099 \text{ lbf}$$

$$F_{f,\mathrm{B}} = (0.466)(2642 \text{ lbf}) = 1231 \text{ lbf}$$

18. CONSTRAINED MOTION

Figure 73.12 shows a cylinder (or sphere) on an inclined plane. If there is no friction, there will be no torque to start the cylinder rolling. Regardless of the angle, the cylinder will slide down the incline in *unconstrained motion.*

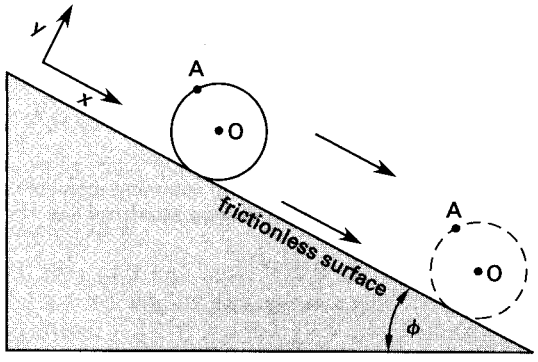


Figure 73.12 *Unconstrained Motion*

The acceleration sliding down the incline can be calculated by writing Newton's second law for an axis parallel to the plane.[12] Once the acceleration is known, the velocity can be found from the constant-acceleration equations.

$$ma_{\mathrm{O},x} = mg \sin\phi \qquad 73.36$$

If friction is sufficiently large, or if the inclination is sufficiently small, there will be no slipping. This condition occurs if

$$\phi < \arctan(f_s) \qquad 73.37$$

The frictional force acting at the cylinder's radius r supplies a torque that starts and keeps the cylinder rolling. The frictional force is

$$F_f = fN \qquad 73.38$$

$$F_f = fmg\cos\phi \quad \text{[SI]} \qquad 73.39(a)$$

$$F_f = \frac{fmg\cos\phi}{g_c} \quad \text{[U.S.]} \qquad 73.39(b)$$

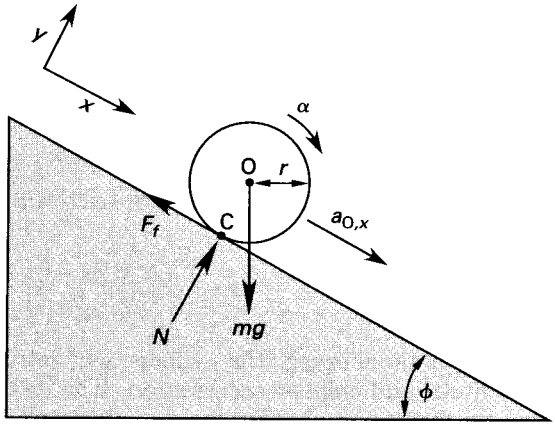

Figure 73.13 *Constrained Motion*

Thus, with no slipping, the cylinder has two degrees of freedom (the x-directional and rotation), and motion of the center of mass must simultaneously satisfy (i.e., is constrained by) two equations. (This excludes motion perpendicular to the plane.) This is called *constrained motion.*

$$mg\sin\phi - F_f = ma_{\mathrm{O},x} \quad \text{[consistent units]} \qquad 73.40$$

$$F_f r = I_{\mathrm{O}}\alpha \quad \text{[consistent units]} \qquad 73.41$$

The mass moment of inertia used in calculating angular acceleration can be either the centroidal moment of inertia, I_{O}, or the moment of inertia taken about the contact point, I_{C}, depending on whether torques (moments) are evaluated with respect to point O or point C, respectively.

[12] Most inclined plane problems are conveniently solved by resolving all forces into components parallel and perpendicular to the plane.

Transportation

If moments are evaluated with respect to point O, the coefficient of friction, f, must be known, and the centroidal moment of inertia (found from a table) can be used. If moments are evaluated with respect to the contact point, the frictional and normal forces drop out of the torque summation. The cylinder instantaneously rotates as though it were pinned at point C. If the centroidal moment of inertia, I_O, is known, the parallel axis theorem can be used to find the required moment of inertia.

$$I_C = I_O + mr^2 \qquad 73.42$$

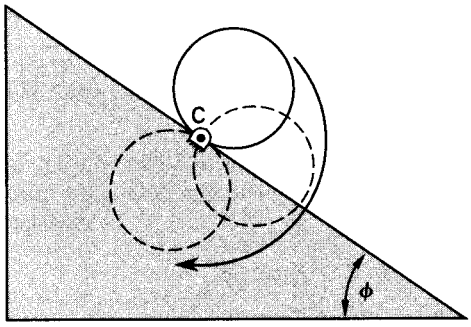

Figure 73.14 *Instantaneous Center of a Constrained Cylinder*

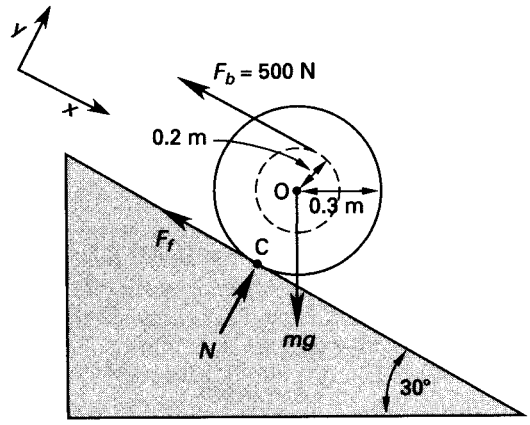


When there is no slipping, the cylinder will roll with constant linear and angular acceleration. The distance traveled by the center of mass can be calculated from the angle of rotation.

$$s_O = r\theta \qquad 73.43$$

If $\phi \geq \arctan f_s$, the cylinder will simultaneously roll and slide down the incline. The analysis is similar to the no-sliding case, except that the coefficient of sliding friction is used. Once sliding has started, the inclination angle can be reduced to $\arctan f_k$, and rolling with sliding will continue.

Example 73.5

A 150 kg cylinder with radius 0.3 m is pulled up a plane inclined at 30° as fast as possible without the cylinder slipping. The coefficient of friction is 0.236. There is a groove in the cylinder at radius = 0.2 m. A rope in the groove applies a force of 500 N up the ramp. What is the linear acceleration of the cylinder?

Solution

To solve by summing forces in the x-direction:

The normal force is

$$N = mg\cos\phi = (150\text{ kg})\left(9.81\ \frac{\text{m}}{\text{s}^2}\right)(\cos 30°)$$
$$= 1274.4\text{ N}$$

The frictional maximum (friction impending) force is

$$F_f = fN = (0.236)(1274.4\text{ N}) = 300.8\text{ N}$$

The summation of forces in the x-direction is

$$ma_{O,x} = mg\sin\phi - F_f - F_b$$
$$a_{O,x} = \frac{(150\text{ kg})\left(9.81\ \frac{\text{m}}{\text{s}^2}\right)(\sin 30°) - 300.8\text{ N} - 500\text{ N}}{150\text{ kg}}$$
$$= -0.433\text{ m/s}^2 \quad \text{[up the incline]}$$

To solve by taking moment about the contact point:[13]

From App. 71.A, the centroidal mass moment of inertia of the cylinder is

$$I_O = \tfrac{1}{2}mr^2 = (0.5)(150\text{ kg})(0.3\text{ m})^2$$
$$= 6.75\text{ kg·m}^2$$

The mass moment of inertia with respect to the contact point, C, is given by the parallel axis theorem.

$$I_C = I_O + mr^2 = \tfrac{1}{2}mr^2 + mr^2 = \tfrac{3}{2}mr^2$$
$$= \left(\tfrac{3}{2}\right)(150\text{ kg})(0.3\text{ m})^2 = 20.25\text{ kg·m}^2$$

[13]This example can also be solved by summing moments about the center. If this is done, the governing equations are

$$I_O = \tfrac{1}{2}mr^2$$
$$M_O = I_O\alpha = F_b r' - F_f r$$
$$\tfrac{1}{2}mr^2\alpha = F_b r' - \mu mg\cos\phi r$$
$$a_{O,x} = r\alpha$$

The x-component of the weight acts through the center of gravity. (This term dropped out when moments were taken with respect to the center of gravity.)

$$(mg)_x = (150 \text{ kg})\left(9.81 \frac{\text{m}}{\text{s}^2}\right)(\sin 30^\circ)$$
$$= 735.8 \text{ N}$$

The summation of torques about point C gives the angular acceleration with respect to point C.

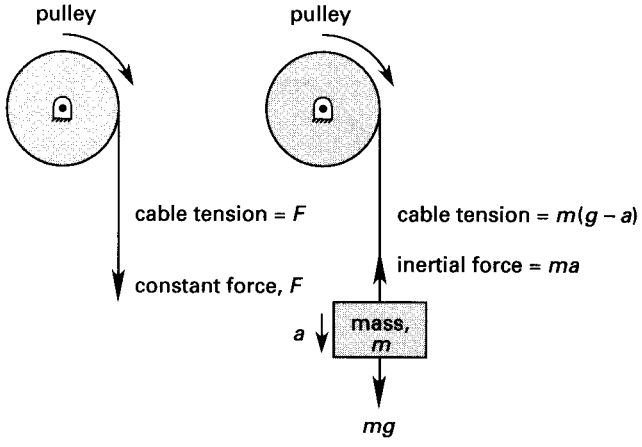
$$(735.8 \text{ N})(0.3 \text{ m})$$
$$-(500 \text{ N})(0.3 \text{ m} + 0.2 \text{ m}) = (20.25 \text{ kg·m}^2)\alpha$$
$$\alpha = -1.445 \text{ rad/s}^2$$

The linear acceleration can be calculated from the angular acceleration and the distance between points C and O.

$$a_{O,x} = r\alpha = (0.3 \text{ m})\left(-1.445 \frac{\text{rad}}{\text{s}^2}\right)$$
$$= -0.433 \text{ m/s}^2 \quad \text{[up the incline]}$$

19. CABLE TENSION FROM A SUSPENDED MASS

When a mass hangs motionless from a cable, or when the mass is moving with a uniform velocity, the cable tension will equal the weight of the mass. However, when the mass is accelerating, the weight must be reduced by the inertial force. If the mass experiences a downward acceleration equal to the gravitational acceleration, there is no tension in the cable. Thus, the two cases shown in Fig. 73.15 are not the same.



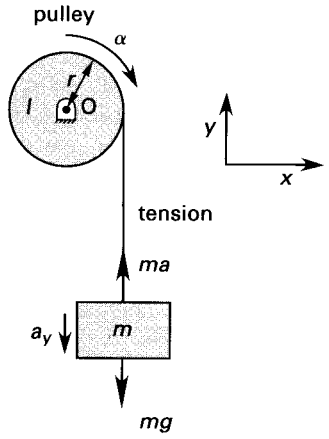


Figure 73.15 *Cable Tension from a Suspended Mass*

Example 73.6

A 10.0 lbm (4.6 kg) mass hangs from a rope wrapped around a 2.0 ft (0.6 m) diameter pulley (centroidal moment of inertia of 70 lbm-ft^2 (2.9 kg·m^2)). (a) What is the angular acceleration of the pulley? (b) What is the linear acceleration of the mass?

SI Solution

(a) The two equations of motion are

$$\sum F_{y,\text{mass}}\text{: tension} + ma - mg = 0$$
$$\text{tension} - (4.6 \text{ kg})\left(9.81 \frac{\text{m}}{\text{s}^2}\right) = -(4.6 \text{ kg})a_y$$
$$\sum M_{O,\text{pulley}}\text{: (tension)}r = I\alpha$$
$$(\text{tension})(0.3 \text{ m}) = (2.9 \text{ kg·m}^2)\alpha$$

Both a_y and α are unknown but are related by $a_y = r\alpha$. Substituting into the $\sum F$ equation and eliminating the tension,

$$\frac{(2.9 \text{ kg·m}^2)\alpha}{0.3 \text{ m}} - 45.1 \text{ N} = -(4.6 \text{ kg})(0.3 \text{ m})\alpha$$
$$9.67\alpha - 45.1 = -1.38\alpha$$
$$\alpha = 4.08 \text{ rad/s}^2$$

(b) The linear acceleration of the mass is

$$a_y = r\alpha = (0.3 \text{ m})\left(4.08 \frac{\text{rad}}{\text{s}^2}\right)$$
$$= 1.22 \text{ m/s}^2$$

Customary U.S. Solution

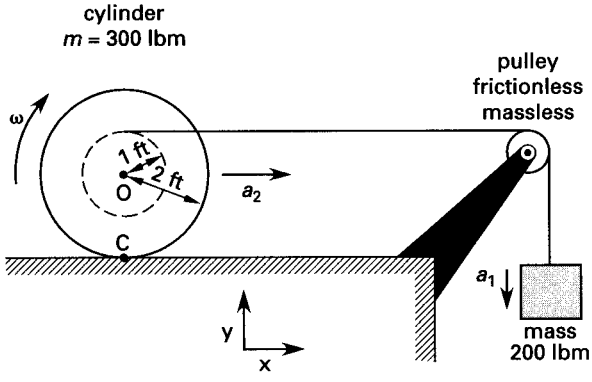
(a) The two equations of motion are

$$\sum F_{y,\text{mass}}\text{: tension} + \frac{ma_y}{g_c} - \frac{mg}{g_c} = 0$$
$$\text{tension} - \frac{(10 \text{ lbm})\left(32.2 \frac{\text{ft}}{\text{sec}^2}\right)}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}} = -\frac{(10 \text{ lbm})a_y}{32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}}$$
$$\sum M_{O,\text{pulley}}\text{: (tension)}r = I\alpha$$
$$(\text{tension})(1.0 \text{ ft}) = (70 \text{ lbm-ft}^2)\alpha$$
$$a_y = r\alpha$$

(b) Substituting into the $\sum F$ equation and eliminating the tension,

$$\frac{(70 \text{ lbm-ft}^2)\,\alpha}{\left(32.2 \dfrac{\text{lbm-ft}}{\text{lbf-sec}^2}\right)(1.0 \text{ ft})} - 10 \text{ lbf} = -\frac{(10 \text{ lbm})(1.0 \text{ ft})\alpha}{32.2 \dfrac{\text{lbm-ft}}{\text{lbf-sec}^2}}$$

$$2.174\,\alpha - 10 = -0.311\,\alpha$$



$$\alpha = 4.02 \text{ rad/sec}^2$$

$$a_y = r\alpha = (1.0 \text{ ft})\left(4.02 \frac{\text{rad}}{\text{sec}^2}\right)$$

$$= 4.02 \text{ ft/sec}^2$$

Example 73.7

A 300 lbm cylinder ($I_O = 710$ lbm-ft^2) has a narrow groove cut in it as shown. One end of the cable is wrapped around the cylinder in the groove, while the other end supports a 200 lbm mass. The pulley is massless and frictionless, and there is no slipping. What are the linear accelerations of the 200 lbm mass and the cylinder?

Solution

Since there is no slipping, there is friction between the cylinder and the plane. However, the coefficient of friction is not given. Therefore, moments must be taken about the contact point (the instantaneous center). The moment of inertia about the contact point is

$$I_C = I_O + mr^2$$

$$= 710 \text{ lbm-ft}^2 + (300 \text{ lbm})(2 \text{ ft})^2 = 1910 \text{ lbm-ft}^2$$

The first equation is a summation of forces on the mass.

$$\sum F_y: \quad \text{tension} + \frac{ma_1}{g_c} - \frac{mg}{g_c} = 0$$

The second equation is a summation of moments about the instantaneous center. The frictional force passes through the instantaneous center and is disregarded.

$$\sum M_C: \quad (\text{tension})(2.0 + 1.0 \text{ ft}) = \frac{I_C\alpha}{g_c}$$

Since there are two unknowns, a third equation is needed. This is the relationship between the linear and angular accelerations. a_2 is the acceleration of point O, located 2 ft from point C. a_1 is the acceleration of the cable, whose groove is located 3 ft from point C.

$$\alpha = \frac{a_2}{2.0} = \frac{a_1}{3.0}$$

$$a_1 = \tfrac{3}{2}a_2$$

Solving the three equations simultaneously yields

$$\text{cylinder: } a_2 = 10.4 \text{ ft/sec}^2$$

$$\text{mass: } a_1 = 15.6 \text{ ft/sec}^2$$

$$\text{tension} = 103 \text{ lbf}$$

$$\alpha = 5.2 \text{ rad/sec}^2$$

20. IMPULSE

Impulse, **Imp**, is a vector quantity equal to the change in momentum.[14] Units of linear impulse are the same as for linear momentum: lbf-sec and N·s. Units of lbf-ft-sec and N·m·s are used for angular impulse. Equations 73.44 and 73.45 define the scalar magnitudes of *linear impulse* and *angular impulse*. Figure 73.16 illustrates that impulse is represented by the area under the F-t (or T-t) curve.

$$\text{Imp} = \int_{t_1}^{t_2} F\,dt \quad \text{[linear]} \qquad 73.44$$

$$\text{Imp} = \int_{t_1}^{t_2} T\,dt \quad \text{[angular]} \qquad 73.45$$

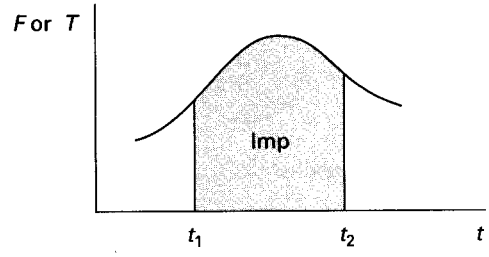


Figure 73.16 *Impulse*

If the applied force or torque is constant, impulse is easily calculated. A large force acting for a very short period of time is known as an *impulsive force*.

$$\text{Imp} = F(t_2 - t_1) \quad \text{[linear]} \qquad 73.46$$

$$\text{Imp} = T(t_2 - t_1) \quad \text{[angular]} \qquad 73.47$$

[14] Although **Imp** is the most common notation, engineers have no universal symbol for impulse. Some authors use I, **I**, and i, but these symbols can be mistaken for moment of inertia. Other authors merely use the word *impulse* in their equations.

If the impulse is known, the average force acting over the duration of the impulse is

$$F_{ave} = \frac{\text{Imp}}{\Delta t} \qquad 73.48$$

21. IMPULSE-MOMENTUM PRINCIPLE

The change in momentum is equal to the applied *impulse*. This is known as the *impulse-momentum* principle. For a linear system with constant force and mass, the scalar magnitude form of this principle is

$$\text{Imp} = \Delta \text{p} \qquad 73.49$$

$$F(t_2 - t_1) = m(\text{v}_2 - \text{v}_1) \quad \text{[SI]} \qquad 73.50(a)$$

$$F(t_2 - t_1) = \frac{m(\text{v}_2 - \text{v}_1)}{g_c} \quad \text{[U.S.]} \qquad 73.50(b)$$

For an angular system with constant torque and moment of inertia, the analogous equations are

$$T(t_2 - t_1) = I(\omega_2 - \omega_1) \quad \text{[SI]} \qquad 73.51(a)$$

$$T(t_2 - t_1) = \frac{I(\omega_2 - \omega_1)}{g_c} \quad \text{[U.S.]} \qquad 73.51(b)$$

Example 73.8

A 1.62 oz (0.046 kg) marble attains a velocity of 170 mph (76 m/s) in a hunting slingshot. Contact with the sling is 1/25th of a second. What is the average force on the marble during contact?

SI Solution

From Eq. 73.50(a), the average force is

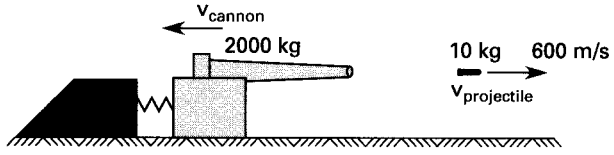
$$F = \frac{m\Delta \text{v}}{\Delta t} = \frac{(0.046 \text{ kg})\left(76 \frac{\text{m}}{\text{s}}\right)}{\frac{1}{25} \text{ s}}$$
$$= 87.4 \text{ N}$$

Customary U.S. Solution

The mass of the marble is

$$m = \frac{1.62 \text{ oz}}{16 \frac{\text{oz}}{\text{lbm}}} = 0.101 \text{ lbm}$$

The velocity of the marble is



$$\text{v} = \frac{\left(170 \frac{\text{mi}}{\text{hr}}\right)\left(5280 \frac{\text{ft}}{\text{mi}}\right)}{3600 \frac{\text{sec}}{\text{hr}}} = 249.3 \text{ ft/sec}$$

From Eq. 73.50(b), the average force is

$$F = \frac{m\Delta \text{v}}{g_c \Delta t} = \frac{(0.101 \text{ lbm})\left(249.3 \frac{\text{ft}}{\text{sec}}\right)}{\left(32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}\right)\left(\frac{1}{25} \text{ sec}\right)}$$
$$= 19.5 \text{ lbf}$$

Example 73.9

A 2000 kg cannon fires a 10 kg projectile horizontally at 600 m/s. It takes 0.007 s for the projectile to pass through the barrel. The cannon has a spring mechanism to absorb the recoil. (a) What is the cannon's initial recoil velocity? (b) What force is exerted on the recoil spring?

Solution

(a) The accelerating force is applied to the projectile quickly, and external forces such as gravity and friction are not a significant factor. Therefore, momentum is conserved.

$$\sum p: \quad m_{\text{projectile}}\Delta \text{v}_{\text{projectile}} = m_{\text{cannon}}\Delta \text{v}_{\text{cannon}}$$
$$(10 \text{ kg})\left(600 \frac{\text{m}}{\text{s}}\right) = (2000 \text{ kg})\,(\text{v}_{\text{cannon}})$$
$$\text{v}_{\text{cannon}} = 3 \text{ m/s}$$

(b) From Eq. 73.50(a), the recoil force is

$$F = \frac{m\Delta \text{v}}{\Delta t} = \frac{(10 \text{ kg})\left(600 \frac{\text{m}}{\text{s}}\right)}{0.007 \text{ s}}$$
$$= 8.57 \times 10^5 \text{ N}$$

22. IMPULSE-MOMENTUM PRINCIPLE IN OPEN SYSTEMS

The impulse-momentum principle can be used to determine the forces acting on flowing fluids (i.e., in open systems). This is the method used to calculate forces in jet engines and on pipe bends, and forces due to other changes in flow geometry. Equation 73.52 is rearranged in terms of a mass flow rate.

$$F = \frac{m\Delta \text{v}}{\Delta t} = \dot{m}\Delta \text{v} \quad \text{[SI]} \qquad 73.52(a)$$

$$F = \frac{m\Delta \text{v}}{g_c \Delta t} = \frac{\dot{m}\Delta \text{v}}{g_c} \quad \text{[U.S.]} \qquad 73.52(b)$$

Example 73.10

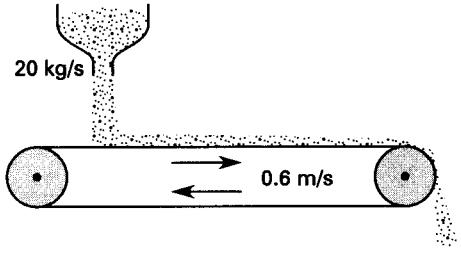
Air enters a jet engine at 1500 ft/sec (450 m/s) and leaves at 3000 ft/sec (900 m/s). The thrust produced is 10,000 lbf (44 500 N). Disregarding the small amount of fuel added during combustion, what is the mass flow rate?

Transportation

SI Solution

From Eq. 73.52(a),

$$\dot{m} = \frac{F}{\Delta v} = \frac{44\,500 \text{ N}}{900 \frac{\text{m}}{\text{s}} - 450 \frac{\text{m}}{\text{s}}}$$
$$= 98.9 \text{ kg/s}$$



Customary U.S. Solution

From Eq. 73.52(b),

$$\dot{m} = \frac{Fg_c}{\Delta v} = \frac{(10{,}000 \text{ lbf})\left(32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}\right)}{3000 \frac{\text{ft}}{\text{sec}} - 1500 \frac{\text{ft}}{\text{sec}}}$$
$$= 215 \text{ lbm/sec}$$

Example 73.11

20 kg of sand fall continuously each second on a conveyor belt moving horizontally at 0.6 m/s. What power is required to keep the belt moving?

Solution

From Eq. 73.52(a), the force on the sand is

$$F = \dot{m}\Delta v = \left(20 \frac{\text{kg}}{\text{s}}\right)\left(0.6 \frac{\text{m}}{\text{s}}\right)$$
$$= 12 \text{ N}$$

The power required is

$$P = Fv = (12 \text{ N})\left(0.6 \frac{\text{m}}{\text{s}}\right)$$
$$= 7.2 \text{ W}$$

Example 73.12

A 6 × 9, $\frac{5}{8}$ in diameter hoisting cable (area of 0.158 in^2, modulus of elasticity of 12×10^6 lbf/in^2) carries a 1000 lbm load at its end. The load is being lowered vertically at the rate of 4 ft/sec. When 200 ft of cable have been reeled out, the take-up reel suddenly locks. Neglect the cable mass. What are the (a) cable stretch, (b) maximum force in the cable, (c) maximum stress in the cable, and (d) approximate time for the load to come to a stop vertically?

Solution

(a) The stiffness of the cable is

$$k = \frac{F}{x} = \frac{AE}{L}$$
$$= \frac{(0.158 \text{ in}^2)\left(12 \times 10^6 \frac{\text{lbf}}{\text{in}^2}\right)}{(200 \text{ ft})\left(12 \frac{\text{in}}{\text{ft}}\right)}$$
$$= 790 \text{ lbf/in}$$

Neglecting the cable mass, the kinetic energy of the moving load is

$$\text{KE} = \frac{mv^2}{2g_c}$$
$$= \frac{(1000 \text{ lbm})\left(4 \frac{\text{ft}}{\text{sec}}\right)^2\left(12 \frac{\text{in}}{\text{ft}}\right)}{(2)\left(32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}\right)}$$
$$= 2981 \text{ in-lbf}$$

By the work-energy principle, the decrease in kinetic energy is equal to the work of lengthening the cable (i.e., the energy stored in the spring).

$$\Delta\text{KE} = \tfrac{1}{2}k\delta^2$$
$$2981 \text{ in-lbf} = \left(\tfrac{1}{2}\right)\left(790 \frac{\text{lbf}}{\text{in}}\right)\delta^2$$
$$\delta = 2.75 \text{ in}$$

(b) The maximum force in the cable is

$$F = k\delta = \left(790 \frac{\text{lbf}}{\text{in}}\right)(2.75 \text{ in})$$
$$= 2173 \text{ lbf}$$

(c) The maximum tensile stress in the cable is

$$\sigma = \frac{F}{A} = \frac{2173 \text{ lbf}}{0.158 \text{ in}^2}$$
$$= 13{,}750 \text{ lbf/in}^2$$

(d) Since the tensile force in the cable increases from zero to the maximum while the load decelerates, the average decelerating force is half of the maximum force. From the impulse momentum principle, Eq. 70.50,

$$F\Delta t = \frac{m\Delta v}{g_c}$$
$$\left(\tfrac{1}{2}\right)(2173 \text{ lbf})\Delta t = \frac{(1000 \text{ lbm})\left(4 \frac{\text{ft}}{\text{sec}}\right)}{\left(32.2 \frac{\text{lbm-ft}}{\text{lbf-sec}^2}\right)}$$
$$\Delta t = 0.114 \text{ sec}$$

23. IMPACTS

According to Newton's second law, momentum is conserved unless a body is acted upon by an external force such as gravity or friction from another object. In an *impact* or *collision*, contact is very brief and the effect of external forces is insignificant. Therefore, momentum is conserved, even though energy may be lost through heat generation and deformation of the bodies.

Consider two particles, initially moving with velocities v_1 and v_2 on a collision path, as shown in Fig. 73.17. The conservation of momentum equation can be used to find the velocities after impact, v_1' and v_2'. (Observe algebraic signs with velocities.)

$$m_1 v_1 + m_2 v_2 = m_1 v_1' + m_2 v_2' \qquad 73.53$$

Figure 73.17 *Direct Central Impact*

The impact is said to be an *inelastic impact* if kinetic energy is lost. (Other names for an inelastic impact are *plastic impact* and *endoergic impact*.[15]) The impact is said to be *perfectly inelastic* or *perfectly plastic* if the two particles stick together and move on with the same final velocity.[16] The impact is said to be *elastic* only if kinetic energy is conserved.

$$m_1 v_1^2 + m_2 v_2^2 = m_1 v_1'^2 + m_2 v_2'^2 \Big|_{\text{elastic impact}} \qquad 73.54$$

24. COEFFICIENT OF RESTITUTION

A simple way to determine whether the impact is elastic or inelastic is by calculating the *coefficient of restitution*, e. The collision is inelastic if $e < 1.0$, perfectly inelastic if $e = 0$, and elastic if $e = 1.0$. The coefficient of restitution is the ratio of relative velocity differences along a mutual straight line. (When both impact velocities are not directed along the same straight line, the coefficient of restitution should be calculated separately for each velocity component.)

$$e = \frac{\text{relative separation velocity}}{\text{relative approach velocity}} = \frac{v_1' - v_2'}{v_2 - v_1} \qquad 73.55$$

[15]Theoretically, there is also an *exoergic impact* (i.e., one in which kinetic energy is gained during the impact). However, this can occur only in special cases, such as in nuclear reactions.

[16]In traditional textbook problems, clay balls should be considered perfectly inelastic.

25. REBOUND FROM STATIONARY PLANES

Figure 73.18 illustrates the case of an object rebounding from a massive, stationary plane.[17] This is an impact where $m_2 = \infty$ and $v_2 = 0$. The impact force acts perpendicular to the plane, regardless of whether the impact is elastic or inelastic. Therefore, the x-component of velocity is unchanged. Only the y-component of velocity is affected, and then only if the impact is inelastic.

$$v_x = v_x' \qquad 73.56$$

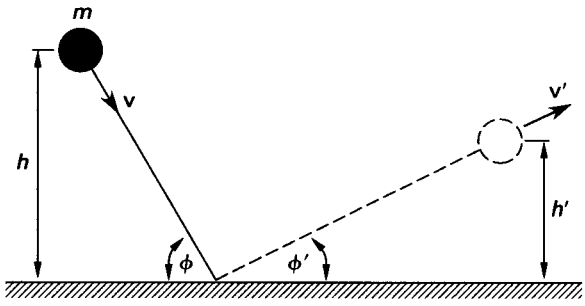


Figure 73.18 *Rebound from a Stationary Plane*

The coefficient of restitution can be used to calculate the *rebound angle*, *rebound height*, and *rebound velocity*.

$$e = \frac{\sin\phi'}{\sin\phi} = \sqrt{\frac{h'}{h}} = \frac{-v_y'}{v_y} \qquad 73.57$$

Example 73.13

A golf ball dropped vertically from a height of 8.0 ft (2.4 m) onto a hard surface rebounds to a height of 6.0 ft (1.8 m). What are the (a) impact velocity, (b) rebound velocity, and (c) coefficient of restitution?

SI Solution

The impact velocity of the golf ball is found by equating the initial potential energy to the incident kinetic energy.

$$\tfrac{1}{2}mv^2 = mgh$$

$$v = \sqrt{2gh} = \sqrt{(2)\left(9.81 \frac{\text{m}}{\text{s}^2}\right)(2.4 \text{ m})}$$

$$= -6.86 \text{ m/s} \quad \text{[negative because down]}$$

The rebound velocity can be found from the rebound height.

$$v' = \sqrt{2gh'} = \sqrt{(2)\left(9.81 \frac{\text{m}}{\text{s}^2}\right)(1.8 \text{ m})}$$

$$= 5.94 \text{ m/s}$$

[17]The particle path is shown as a straight line in Fig. 73.18 for convenience. The path will be a straight line only when the particle is dropped straight down. Otherwise, the path will be parabolic.

Transportation

From Eq. 73.55 with $v_2 = v'_2 = 0$ (or Eq. 73.57),

$$e = \frac{5.94\ \frac{\text{m}}{\text{s}} - 0}{0 - \left(-6.86\ \frac{\text{m}}{\text{s}}\right)} = 0.87$$

Customary U.S. Solution

The impact velocity is

$$v = \sqrt{2gh} = \sqrt{(2)\left(32.2\ \frac{\text{ft}}{\text{sec}^2}\right)(8.0\ \text{ft})}$$

$$= -22.7\ \text{ft/sec} \quad \text{[negative because down]}$$

Similarly, the rebound velocity is

$$v' = \sqrt{(2)\left(32.2\ \frac{\text{ft}}{\text{sec}^2}\right)(6.0\ \text{ft})} = 19.7\ \text{ft/sec}$$

From Eq. 73.55 with $v_2 = v'_2 = 0$ (or from Eq. 73.57),

$$e = \frac{19.7\ \frac{\text{ft}}{\text{sec}} - 0}{0 - \left(-22.7\ \frac{\text{ft}}{\text{sec}}\right)} = 0.87$$

26. COMPLEX IMPACTS

The simplest type of impact problem is the direct central impact, shown in Fig. 73.17. An impact is said to be a *direct impact* when the velocities of the two bodies are perpendicular to the contacting surfaces. *Central impact* occurs when the force of the impact is along the line of connecting centers of gravity. Round bodies (i.e., spheres) always experience central impact, whether or not the impact is direct.

When the velocities of the bodies are not along the same line, the impact is said to be an *oblique impact*, as illustrated in Fig. 73.19. The coefficient of restitution can be used to find the x-components of the resultant velocities. Since impact is central, the y-components of velocities will be unaffected by the collision.

$$v_{1y} = v'_{1y} \qquad 73.58$$

$$v_{2y} = v'_{2y} \qquad 73.59$$

$$e = \frac{v'_{1x} - v'_{2x}}{v_{2x} - v_{1x}} \qquad 73.60$$

$$m_1 v_{1x} + m_2 v_{2x} = m_1 v'_{1x} + m_2 v'_{2x} \qquad 73.61$$

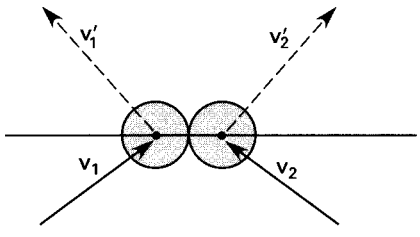

Figure 73.19 Central Oblique Impact

Eccentric impacts are neither direct nor central. The coefficient of restitution can be used to calculate the linear velocities immediately after impact along a line normal to the contact surfaces. Since the impact is not central, the bodies will rotate. Other methods must be used to calculate the rate of rotation.

$$e = \frac{v'_{1n} - v'_{2n}}{v_{2n} - v_{1n}} \qquad 73.62$$

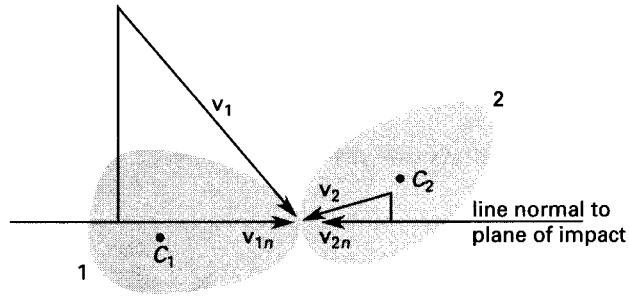

Figure 73.20 Eccentric Impact

27. VELOCITY-DEPENDENT FORCE

A force that is a function of velocity is known as a *velocity-dependent force*. A common example of a velocity-dependent force is the *viscous drag* a particle experiences when falling through a fluid. There are two main cases of viscous drag: linear and quadratic.

A *linear velocity-dependent force* is proportional to the first power of the velocity. A linear relationship is typical of a particle falling slowly through a fluid (i.e., viscous drag in laminar flow). In Eq. 73.63, C is a constant of proportionality known as the *viscous coefficient* or *coefficient of viscous damping*.

$$F_b = Cv \qquad 73.63$$

In the case of a particle falling slowly through a viscous liquid, the differential equation of motion and its solution are derived from Newton's second law.

$$mg - Cv = ma \quad \text{[SI]} \qquad 73.64(a)$$

$$\frac{mg}{g_c} - Cv = \frac{ma}{g_c} \quad \text{[U.S.]} \qquad 73.64(b)$$

$$v(t) = v_t\left(1 - e^{-\frac{Ct}{m}}\right) \quad \text{[SI]} \qquad 73.65(a)$$

$$v(t) = v_t\left(1 - e^{-\frac{Cg_c t}{m}}\right) \quad \text{[U.S.]} \qquad 73.65(b)$$

Equation 73.65 shows that the velocity asymptotically approaches a final value known as the *terminal velocity*, v_t. For laminar flow, the terminal velocity is

$$v_t = \frac{mg}{C} \quad \text{[SI]} \qquad 73.66(a)$$

$$v_t = \frac{mg}{Cg_c} \quad \text{[U.S.]} \qquad 73.66(b)$$

A *quadratic velocity-dependent force* is proportional to the second power of the velocity. A quadratic relationship is typical of a particle falling quickly through a fluid (i.e., turbulent flow).

$$F_b = C\mathrm{v}^2 \qquad 73.67$$

In the case of a particle falling quickly through a liquid under the influence of gravity, the differential equation of motion is

$$mg - C\mathrm{v}^2 = ma \qquad \text{[SI]} \qquad 73.68(a)$$

$$\frac{mg}{g_c} - C\mathrm{v}^2 = \frac{ma}{g_c} \qquad \text{[U.S.]} \qquad 73.68(b)$$

For turbulent flow, the terminal velocity is

$$\mathrm{v}_t = \sqrt{\frac{mg}{C}} \qquad \text{[SI]} \qquad 73.69(a)$$

$$\mathrm{v}_t = \sqrt{\frac{mg}{Cg_c}} \qquad \text{[U.S.]} \qquad 73.69(b)$$

If a skydiver falls far enough, a turbulent terminal velocity of approximately 125 mph (200 kph) will be achieved. With a parachute (but still in turbulent flow), the terminal velocity is reduced to approximately 25 mph (40 kph).

28. VARYING MASS

Integral momentum equations must be used when the mass of an object varies with time. Most varying mass problems are complex, but the simplified case of an ideal rocket can be evaluated. This discussion assumes constant gravitational force, constant fuel usage, and constant exhaust velocity. (For brevity of presentation, all of the following equations are presented in consistent form.)

The forces acting on the rocket are its thrust, F, and gravity. Newton's second law is

$$F(t) - F_{\text{gravity}} = \frac{d}{dt}(m(t)\mathrm{v}(t)) \qquad 73.70$$

If $\dot{m}$ is the constant fuel usage, the thrust and gravitational forces are

$$F(t) = \dot{m}\mathrm{v}_{\text{exhaust,absolute}} = \dot{m}(\mathrm{v}_{\text{exhaust}} - \mathrm{v}(t)) \qquad 73.71$$

$$F_{\text{gravity}} = m(t)g \qquad 73.72$$

The velocity as a function of time is found by solving the following differential equation.

$$\dot{m}\mathrm{v}_{\text{exhaust,absolute}} - m(t)g = \dot{m}\mathrm{v}(t) + m(t)\left(\frac{d\mathrm{v}(t)}{dt}\right) \qquad 73.73$$

$$\mathrm{v}(t) = \mathrm{v}_0 - gt + \mathrm{v}_{\text{exhaust}} \ln\left(\frac{m_0}{m_0 - \dot{m}t}\right) \qquad 73.74$$

The final *burnout velocity*, v_f, depends on the initial mass, m_0, and the final mass, m_f.

$$\mathrm{v}_f = \mathrm{v}_0 - g\left(\frac{m_0}{\dot{m}}\right)\left(1 - \frac{m_f}{m_0}\right) + \mathrm{v}_{\text{exhaust}} \ln\left(\frac{m_0}{m_f}\right) \qquad 73.75$$

A simple relationship exists for a rocket starting from standstill in a gravity-free environment (i.e., $\mathrm{v}_0 = 0$ and $g = 0$).

$$\frac{m_f}{m_0} = e^{-\mathrm{v}_f/\mathrm{v}_{\text{exhaust}}} \qquad 73.76$$

29. CENTRAL FORCE FIELDS

When the force on a particle is always directed toward or away from a fixed point, the particle is moving in a *central force field*. Examples of central force fields are gravitational fields (*inverse-square attractive fields*) and electrostatic fields (*inverse-square repulsive fields*). Particles traveling in inverse-square attractive fields can have circular, elliptical, parabolic, or hyperbolic paths. Particles traveling in inverse-square repulsive fields always travel in hyperbolic paths.

The fixed point, O in Fig. 73.21, is known as the *center of force*. The magnitude of the force depends on the distance between the particle and the center of force.

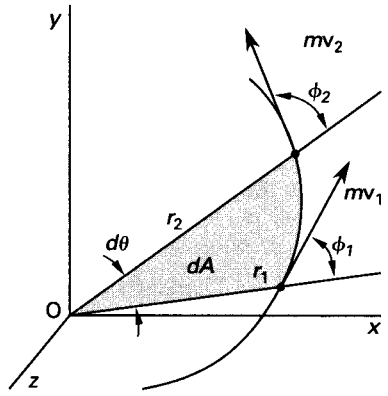

Figure 73.21 *Motion in a Central Force Field*

The angular momentum of a particle moving in a central force field is constant.

$$\mathbf{h}_O = \mathbf{r} \times m\mathbf{v} = \text{constant} \qquad 73.77$$

Equation 73.77 can be written in scalar form.

$$r_1 m\mathrm{v}_1 \sin\phi_1 = r_2 m\mathrm{v}_2 \sin\phi_2 \qquad 73.78$$

For a particle moving in a central force field, the *areal velocity* is constant.

$$\text{areal velocity} = \frac{dA}{dt} = \tfrac{1}{2}r^2\frac{d\theta}{dt} = \frac{h_O}{2} \qquad 73.79$$

Transportation

30. NEWTON'S LAW OF GRAVITATION

For a particle far enough away from a large body, gravity can be considered to be a central force field. *Newton's law of gravitation*, also known as *Newton's law of universal gravitation*, describes the force of attraction between the two masses. The law states that the attractive gravitational force between the two masses is directly proportional to the product of masses, is inversely proportional to the square of the distance between their centers of mass, and is directed along a line passing through the centers of gravity of both masses.

$$F = \frac{Gm_1m_2}{r^2} \qquad 73.80$$

G is *Newton's gravitational constant* (*Newton's universal constant*). Approximate values of G for the earth are given in Table 73.2 for different sets of units. For an earth-particle combination, the product Gm_{earth} has the value of 4.39×10^{14} lbf-ft^2/lbm (4.00×10^{14} N·m^2/kg).

Table 73.2 *Approximate Values of the Universal Constant, G*

6.673×10^{-11}	N·m^2/kg^2
6.673×10^{-8}	cm^3/g·s^2
3.436×10^{-8}	lbf-ft^2/slug^2
3.320×10^{-11}	lbf-ft^2/lbm^2
3.436×10^{-8}	ft^4/lbf-sec^4

31. KEPLER'S LAWS OF PLANETARY MOTION

Kepler's three *laws of planetary motion* are as follows.

- *the law of orbits*: The path of each planet is an ellipse with the sun at one focus.
- *the law of areas*: The radius vector drawn from the sun to a planet sweeps equal areas in equal times. (The areal velocity is constant.)

$$\frac{dA}{dt} = \frac{h_0}{2} = \text{constant} \qquad 73.81$$

- *the law of periods*: The square of a planet's periodic time is proportional to the cube of the semimajor axis of its orbit.

$$t_p^2 \propto a^3 \qquad 73.82$$

The *periodic time* referenced in Kepler's third law is the time required for a satellite to travel once around the parent body. If the parent body rotates in the same plane and with the same periodic time as the satellite, the satellite will always be above the same point on the parent body. This condition defines a *geostationary orbit*. Referring to Fig. 73.22, the periodic time is

$$t_p = \frac{2\pi ab}{h_0} = \frac{\pi ab}{\frac{dA}{dt}} = \frac{\pi ab}{\text{areal velocity}} \qquad 73.83$$

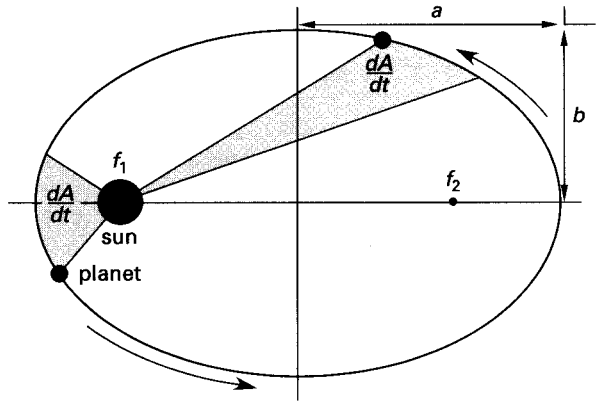

Figure 73.22 *Planetary Motion*

32. SPACE MECHANICS

Figure 73.23 illustrates the motion of a satellite that is released in a path parallel to the earth's surface. (The dotted line represents the launch phase and is not relevant to the analysis.)

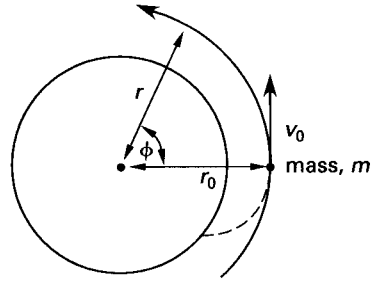

Figure 73.23 *Space Mechanics Nomenclature*

At the instant of release, the magnitude of the angular momentum, **h**, is

$$\mathbf{h} = h_0 = r_0 m v_0 \qquad 73.84$$

The force exerted on the satellite by the earth is given by Newton's law of gravitation. For any angle, ϕ, swept out by the satellite, the separation distance can be found from Eq. 73.85. C is a constant.

$$\frac{1}{r} = \frac{GM}{h^2} + C\cos\phi \qquad 73.85$$

$$C = \frac{1}{r_0} - \frac{GM}{h^2} \qquad 73.86$$

The *orbit eccentricity*, ϵ, can be calculated and used to determine the type of orbit, as listed in Table 73.3.

$$\epsilon = \frac{Ch^2}{GM} \qquad 73.87$$

Table 73.3 Orbit Eccentricities

value of ϵ	type of orbit
> 1.0	nonreturning hyperbola
$= 1.0$	nonreturning parabola
< 1.0	ellipse
$= 0.0$	circle

The limiting value of the initial release velocity, $v_{0,max}$, to prevent a nonreturning orbit ($\epsilon = 1.0$) is known as the *escape velocity*. For the earth, the escape velocity is approximately 7.0 mi/sec (25,000 mph, or 11.2 km/s).

$$v_{escape} = v_{0,max} = \sqrt{\frac{2GM}{r_0}} \qquad 73.88$$

The release velocity, $v_{0,circular}$, that results in a circular orbit is

$$v_{0,circular} = \sqrt{\frac{GM}{r_0}} \qquad 73.89$$

For an elliptical orbit, the minimum separation is known as the *perigee distance*. The maximum separation distance is known as the *apogee*. The terms perigee and apogee are traditionally used for earth satellites. The terms *perihelion* (closest) and *aphelion* (farthest) are used to describe distances between the sun and earth.

33. ROADWAY BANKING

If a vehicle travels in a circular path with instantaneous radius r and tangential velocity v_t, it will experience an apparent centrifugal force. The centrifugal force is resisted by a combination of roadway banking (*superelevation*) and *sideways friction*.[18] If the roadway is banked so that friction is not required to resist the centrifugal force, the superelevation angle, ϕ, can be calculated from Eq. 73.90.[19]

$$\tan\phi = \frac{v_t^2}{gr} \qquad 73.90$$

Equation 73.90 can be solved for the *normal speed* corresponding to the geometry of a curve.

$$v_t = \sqrt{gr\tan\phi} \qquad 73.91$$

[18]The *superelevation* is the slope (in ft/ft or m/m) in the transverse direction (i.e., across the roadway).

[19]Generally it is not desirable to rely on roadway banking alone, since a particular superelevation angle would correspond to only a single speed.

When friction is used to counteract some of the centrifugal force, the *side friction factor*, f, between the tires and roadway is incorporated into the calculation of the superelevation angle.

$$\tan\phi = \frac{v_t^2}{gr} - f \quad \text{[small banking angles]} \qquad 73.92$$

$$\tan\phi = \frac{v_t^2 - fgr}{gr + fv_t^2} \quad \text{[large banking angles]} \qquad 73.93$$

If the banking angle, ϕ, is set to zero, Eq. 73.92 can be used to calculate the maximum velocity of a vehicle making a turn when there is no banking.

The *superelevation*, y, is the rise in the outer edge of the roadway. This is illustrated in Fig. 73.24.

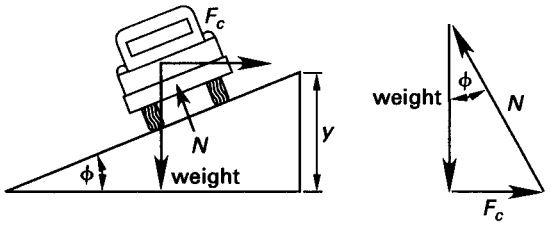

Figure 73.24 Roadway Banking

Example 73.14

A 4000 lbm car travels at 40 mph around a banked curve with a radius of 500 ft. What should be the superelevation angle so that tire friction is not needed to prevent the car from sliding?

Solution

The tangential velocity of the car is

$$v_t = \frac{\left(40\ \frac{\text{mi}}{\text{hr}}\right)\left(5280\ \frac{\text{ft}}{\text{mi}}\right)}{3600\ \frac{\text{sec}}{\text{hr}}} = 58.7\ \text{ft/sec}$$

From Eq. 73.90,

$$\phi = \arctan\left(\frac{v_t^2}{gr}\right) = \arctan\left(\frac{\left(58.7\ \frac{\text{ft}}{\text{sec}}\right)^2}{\left(32.2\ \frac{\text{ft}}{\text{sec}^2}\right)(500\ \text{ft})}\right)$$

$$= 12.1^\circ$$

Example 73.15

A vehicle is traveling at 70 mph when it enters a circular curve. The curve radius is 240 ft. The sideways sliding coefficient of friction between the tires and the roadway is 0.57. (a) At what minimum angle from the horizontal must the curve be banked in order to prevent the vehicle from sliding off the top of the curve?

Transportation

(b) If the roadway is banked at 20° from the horizontal, what is the maximum vehicle speed such that no sliding occurs?

Solution

(a) The speed of the vehicle is

$$v_t = \frac{\left(70\ \frac{\text{mi}}{\text{hr}}\right)\left(5280\ \frac{\text{ft}}{\text{mi}}\right)}{3600\ \frac{\text{sec}}{\text{hr}}}$$
$$= 102.7\ \text{ft/sec}$$

From Eq. 73.93, the required banking angle is

$$\phi = \arctan\left(\frac{v_t^2 - fgr}{gr + fv_t^2}\right)$$
$$= \frac{\left(102.7\ \frac{\text{ft}}{\text{sec}}\right)^2 - (0.57)\left(32.2\ \frac{\text{ft}}{\text{sec}^2}\right)(240\ \text{ft})}{\left(32.2\ \frac{\text{ft}}{\text{sec}^2}\right)(240\ \text{ft}) + (0.57)\left(102.7\ \frac{\text{ft}}{\text{sec}}\right)^2}$$
$$= 24.1°$$

(b) Solve Eq. 73.93 for the velocity.

$$v_t = \sqrt{\frac{rg(\tan\phi + f)}{1 - f\tan\phi}}$$
$$= \sqrt{\frac{(240\ \text{ft})\left(32.2\ \frac{\text{ft}}{\text{sec}^2}\right)(\tan 20° + 0.57)}{1 + (0.57)\tan 20°}}$$
$$= 95.4\ \text{ft/sec}\ \ (65.1\ \text{mi/hr})$$

PRACTICE PROBLEMS

1. The rim of a spoked cast-iron flywheel in a punch press has a mean diameter of 30 in (76.2 cm) and a width of 12 in (30.5 cm). The flywheel rotates at 200 rpm. It supplies 1500 ft-lbf (2 kJ) of energy and slows to 175 rpm each time a punch press is cycled. The density of the cast iron is 0.26 lbm/in^3 (7200 kg/m^3). The hub and arms increase the rotational moment of inertia by 10%. What is the rim thickness?

Answer: 1.86 in (47 mm)

1. STANDARD TRAFFIC REFERENCES

The standard references for the subject matter in this chapter include the *Highway Capacity Manual*, referred to as the "HCM" (Transportation Research Board, National Research Council); *A Policy on Geometric Design of Highways and Streets*, known as the "Green Book" or "PGDHS" (AASHTO); and the *Manual on Uniform Traffic Control Devices*, referred to as the "MUTCD" (Federal Highway Administration). Except for trivial exercises, traffic/transportation designs and analyses cannot be performed without these references. Calculations using the HCM and Green Book may be performed in either customary U.S. or SI units.

Many of the methods used to design and analyze specific facilities are highly proceduralized. These methods often rely on empirical correlations and graphical/nomographical solutions rather than on pure engineering fundamentals. In that sense, they are not difficult to implement. However, each feature uses a unique procedure, different nomenclature, and specific criteria. Due to the variety and complexity of these procedures, it is not possible to present them without making significant reference to the major supporting documents, particularly the HCM. Even with the supporting documents, it soon becomes apparent why the majority of traffic design is computer-assisted. Analysis of existing facilities is somewhat more tractable.

In recent years and in response to mounting liability issues, these references (the Green Book, in particular) have backed away from appearing to be mandatory standards by softening their unequivocal language. These documents are currently considered to be "suggested policies" by their originating organizations. State departments of transportation are expected to accept responsibility for proper evaluation and implementation of these "nonstandards."

2. ABBREVIATIONS AND UNITS

Following standard practice, the units and abbreviations shown in Table 74.1 are used in this chapter. (Explicit units are shown in numerical calculations to facilitate cancellation.) Some commonly used HCM abbreviations conflict with commonly used SI abbreviations, and some inconsistencies may be noted.

- The letter "p" signifying "per" is not used in SI units. While the HCM still uses "pcph" for calculations in English units, it has adopted "pc/h" for calculations in SI units.
- "ln" is used for "lane" in SI calculations.
- The word "seat" is spelled out to avoid confusion with "s" for "seconds."
- "Minute" is abbreviated "min"; "minimum" is abbreviated "Min."

Table 74.1 *Abbreviations*

abbreviation	meaning
ln	lane
km/h	kilometers per hour
mph	miles per hour
p	people or person (SI units)
pc	passenger car
pcph	passenger cars per hour
pcphg	passenger cars per hour of green signal
pcphpl	passenger cars per hour per lane
pcphgpl	passenger cars per hour of green signal per lane
pc/km/ln	passenger cars per kilometer per lane
pcpmpl	passenger cars per mile per lane
ped	pedestrian
pers	person
veh	vehicle
vph	vehicles per hour
veh/km	vehicles per kilometer
vph/lane	vehicles per hour per lane
vpm	vehicles per mile

3. FACILITIES TERMINOLOGY

Although common usage does not always distinguish between highways, freeways, and other types of roadways, the major traffic/transportation references are more specific. For example, "vehicle" and "car" have different meanings. "Vehicle" encompasses trucks, buses, and recreational vehicles as well as passenger cars.

A *freeway* is a divided corridor with at least two lanes in each direction that operates in an *uninterrupted flow* mode (i.e., without *fixed elements* such as signals, stop signs, and at-grade intersections). *Access points* are limited to ramp locations. Since grades, turns, and other features can change along a freeway, performance measures (e.g., capacity) are evaluated along shorter *freeway segments*.

Multilane and two-lane *highways*, on the other hand, contain some fixed elements and access points from at-grade intersections, though relatively uninterrupted flow can occur if signal spacing is greater than 2 mi (3.2 km). Where signal spacing is less than 2 mi (3.2 km), the

roadway is classified as an *arterial*, and flow is considered to be interrupted. *Divided highways* have separate roadbeds for the opposing directions, whereas *undivided highways* do not.

Smaller roadways are classified as *local roads* and *streets*. All roadways can be classified as *urban*, *suburban*, or *rural*, depending on the surrounding population density. *Urban areas* have populations greater than 5000. *Rural areas* are outside the boundaries of urban areas.

Table 74.2 *General Classifications of Roadways*[a]

road designation	ADT (vpd)
local road	2000 or less
collector road	2000–12,000
arterial	12,000–40,000
freeway	30,000 and above

[a]Classifications can also be established based on percentages of total length and travel volume.

4. DESIGN VEHICLES

Standardized *design vehicles* have been established to ensure that geometric features will accommodate all commonly sized vehicles. Standardized design vehicles are given specific designations in the Green Book, as listed in Table 74.3. The Green Book also contains information on *wheelbase* and *turning radius*. (See Green Book Table II-2.)

5. LEVELS OF SERVICE

A user's quality of service through or over a specific facility (e.g., over a highway, through an intersection, across a crosswalk) is classified by a *level of service* (LOS). Levels of service are designated A through F. Level A represents unimpeded flow, which is ideal but only possible when the volume of traffic is small. Level F represents a highly impeded, packed condition. Generally, level E will have the maximum flow rate (i.e., capacity).

The desired design condition is generally between levels A and F. Economic considerations favor higher volumes and more obstructed levels of service. However, political considerations favor less obstructed levels of service. The parameter used to define the level of service varies with the type of facility, as listed in Table 74.4.

Since levels of service can vary considerably during an hour, capacity and LOS evaluations focus on the peak 15 min of flow.

6. SPEED PARAMETERS

Several measures of vehicle speed are used in highway design and capacity calculations. Most measures will not be needed in every capacity calculation. The *design speed* is the maximum safe speed that can be maintained over a specified section of roadway when conditions are so favorable that the design features of the roadway govern. Most elements of roadway design depend on the

Table 74.3 *Standard Design Vehicles*

		dimensions, ft (m)		
designation	symbol[a]	height	width	length
passenger car	P	4.25 (1.3)	7 (2.1)	19 (5.8)
single-unit truck	SU	13.5 (4.1)	8.5 (2.6)	30 (9.1)

Transportation

Table 74.4 *Measures of Level of Service*

type of facility	level of service parameter
freeways	
basic freeway segment	density (pc/mi/ln or pc/km/ln)
weaving areas	density (pc/mi/ln or pc/km/ln)
ramp junctions	flow rates (pcph or pc/h)
multilane highways	density (pc/mi/ln or pc/km/ln)
	free-flow speed (mph or km/h)
two-lane rural highways	time delay (%)
signalized intersections	average control delay (sec/veh or s/veh)
unsignalized intersections	average control delay (sec/veh or s/veh)
arterials	average travel speed (mph or km/h)
mass transit	load factor (pers/seat, veh/hr, people/hr, p/seat, veh/h, p/h)
pedestrians	space per pedestrian (ft^2/ped or m^2/p)

Adapted from *Highway Capacity Manual* Table I-2.

design speed. The *legal speed limit* is set at approximately the *85th percentile speed*, determined by observation of a sizable sample of vehicles. Thus, the legal speed limit and the design speed are often identical. Typical design speeds are given in Table 74.5.

The *average highway speed*, AHS, is the weighted average of the observed speeds within a highway section based on each subsection's proportional contribution to total mileage. The *operating speed* is the highest overall speed at which a driver can safely travel on a given highway under favorable weather conditions and prevailing traffic conditions. The *running speed* is the speed over a specified section of roadway equal to the distance divided by the running time, or the total time required to travel over the roadway section, disregarding any stationary time. The *average running speed* is the running speed for all traffic equal to the distance summation for all cars divided by the time summation for all cars.

The *average spot speed*, also known as the *time mean speed*, is the arithmetic mean of the instantaneous speeds of all cars at a particular point. The *average travel speed* is the speed over a specified section of highway, including operational delays such as stops for traffic signals. The *free-flow speed* is the theoretical speed of traffic as the density approaches zero. (The term *operating speed*, as used by AASHTO and in previous HCMs, is similar to free-flow speed when evaluated at low-volume conditions.) The term *space mean speed* is ambiguous, referring to both running speed and travel speeds, though running speed is the common intended usage. *Crawl speed* is the maximum sustained speed that heavy vehicles can maintain on a given extended upgrade.

The HCM uses average travel speed as the primary defining parameter. Except for LOS F, the average travel and average running speeds are identical.

Table 74.5 *Minimum Design Speeds (mph (km/h))*
(local and rural roads)

design volumes, ADT	terrain		
	level	rolling	mountainous

7. SPOT SPEED STUDIES

The analysis of *spot speed data* draws on traditional statistical methods. The *mean*, *mode*, and *median speeds* are commonly determined. Certain percentile rank speeds may also be needed. For example, the *50th percentile speed* (i.e., the median speed) and the 85th percentile speed (i.e., the *design speed*) can be found from the frequency distribution. The *pace interval* (also known as the *pace range*, *group pace*, or just *pace*) is the 10 mph speed range containing the most observations.

8. VOLUME PARAMETERS

There are several volume parameters, and not all parameters will be needed in every capacity investigation. It is important to note if volumes are for both directions combined, for all lanes of one direction, or just for one lane.

The *average daily traffic*, ADT, and *average annual daily traffic*, AADT, may be one- or two-way. The *design hour volume*, DHV, is evaluated for the design year. DHV is usually the 30th highest hourly expected volume in the design year, hence its nickname "30th hour volume." It is not an average or a maximum. DHV is two-way unless noted otherwise. The ratio of DHV to AADT is designated as the "*K-factor*."

$$K = \frac{\text{DHV}}{\text{AADT}} \qquad 74.1$$

The *directional factor*, D, is the percentage of the dominant flow direction. It can range from up to 80% for rural roadways at peak hours to 50% for central business district traffic, though values between 55 and 65% are more common. The *directional design hour volume*, DDHV, is calculated as the product of the directional factor, D (also known as the "*D-factor*"), and DHV.

$$\text{DDHV} = D(\text{DHV}) = DK(\text{AADT}) \qquad 74.2$$

The *design capacity* is the maximum volume of traffic that the roadway can handle. The upper bound on *ideal capacity*, c, at free-flow speeds of 70 mph and higher with level of service E is considered to be 2400 passenger cars per hour per lane (pcphpl). Different values apply for other levels of service, speeds, and types of facilities. The actual flow rate, v, can be used to calculate the *volume-capacity ratio*, v/c, for a particular level of service, i.

$$\text{volume-capacity ratio}_i = (v/c)_i \qquad 74.3$$

The *maximum service flow rate*, MSF, is the maximum capacity in passenger cars per hour per lane under ideal conditions for a particular level of service, i.

$$\text{MSF}_i = c(v/c)_i \qquad 74.4$$

The *rate of flow*, v, is the equivalent hourly rate at which vehicles pass a given point during a given time interval of less than 1 hr, usually 15 min. Thus, the rate of flow changes every 15 min.

The *peak hour factor*, PHF, is the ratio of the total actual hourly volume to the peak rate of flow within the hour.

$$\text{PHF} = \frac{\text{actual hourly volume}_{\text{vph}}}{\text{peak rate of flow}_{\text{vph}}} = \frac{V_{\text{vph}}}{v_p} = \frac{V_{\text{vph}}}{4V_{15\text{ min,peak}}} \qquad 74.5$$

The *service flow rate*, SF, is the actual capacity in passenger cars per hour under nonideal conditions. Service flow rate is calculated from the maximum service flow rate, MSF, the number of lanes, N, and other factors that correct for nonideal conditions.

$$\text{SF} = (\text{MSF})N(\text{adjustment factors}) \qquad 74.6$$

Example 74.1

Using the following traffic counts, determine the (a) peak hourly traffic volume and (b) peak hour factor.

interval	volume (vph)
4:15–4:30	520
4:30–4:45	580
4:45–5:00	670
5:00–5:15	790
5:15–5:30	700
5:30–5:45	630
5:45–6:00	570
6:00–6:15	510

Solution

(a) For the 1 hr time period of 4:15 through 5:15, the total hourly traffic volume was

$$520 \text{ vph} + 580 \text{ vph} + 670 \text{ vph} + 790 \text{ vph} = 2560 \text{ vph}$$

The hourly traffic volumes for the subsequent 1 hr intervals are found similarly.

4:15–5:15	2560 vph
4:30–5:30	2740 vph
4:45–5:45	2790 vph
5:00–6:00	2690 vph
5:15–6:15	2410 vph

The maximum hourly volume is 2790 vph.

(b) The peak 15 min volume occurs between 5:00 and 5:15 and is 790. From Eq. 74.5,

$$\text{PHF} = \frac{V_{\text{vph}}}{4V_{15\text{ min,peak}}} = \frac{2790\ \frac{\text{veh}}{\text{hr}}}{\left(4\ \frac{\text{periods}}{\text{hr}}\right)\left(790\ \frac{\text{veh}}{\text{period}}\right)} = 0.883$$

9. TRIP GENERATION

Trip generation requires estimating the number of trips that will result from a particular population or occupancy. Estimates can be obtained from general or area-specific tables or correlations. There are many general trip generation correlations that can be used if specific, targeted data are not available. Since predictive formulas are highly dependent on the characteristics of the local area and population as well as on time of day and year, numerous assumptions must be made and verified before such correlations are relied upon.

Although linear equations with constant coefficients are sometimes used, more sophisticated correlations are easily obtained. Many take on the forms of either Eq. 74.7 or the equivalent 74.8. The calling population parameter in these equations may be population quantity, number of homes, square footage (as in the case of retail shops), or any other convenient characteristic that can be quantified.

$$\ln(\text{no. of trips}) = A + B \log\left(\begin{array}{c}\text{calling population}\\ \text{parameter}\end{array}\right) \qquad 74.7$$

$$\text{no. of trips} = \frac{C}{\left(\begin{array}{c}\text{calling population}\\ \text{parameter}\end{array}\right)^D} \qquad 74.8$$

The best trip data are actual counts obtained from *automatic traffic recorders* (ATRs). These devices can be used where roads are already in existence. Since

ATRs count the number of tires (i.e., axles) that pass over their detectors, counts must be corrected for truck movement.

Logical methods, including straight-line extrapolation or exponential growth, should be used in the estimation of future traffic counts. Expansion factors can be determined for each axle classification.

Example 74.2

An ATR record indicates that 483 vehicles passed over its detector. It is known that 10% of the vehicles were five-axle trucks. How many two-axle passenger cars and five-axle trucks actually passed over the detector?

Solution

The number of axles passing over the detector was

$$(2)(483) = 966$$

$$(2)(\text{no. of cars}) + (5)(\text{no. trucks}) = 966$$

The fraction of trucks is known to be 10%.

$$\frac{\text{no. of trucks}}{\text{no. of cars} + \text{no. of trucks}} = 0.10$$

Solving these two equations simultaneously,

$$\text{no. of cars} = 378$$

$$\text{no. of trucks} = 42$$

10. SPEED, FLOW, AND DENSITY RELATIONSHIPS

With uninterrupted flow, the speed of travel decreases as the number of cars occupying a freeway increases. The *free-flow speed*, FFS, is the maximum speed for which the density does not affect travel speed. (The HCM also uses S_f to designate free-flow speed.) Free-flow speed is measured in the field as the average speed of passenger cars when flow rates are less than 1300 pcphpl. Free-flow speed can be determined from actual measurements or estimated from the ideal value.

Density, D, is defined as the number of vehicles per mile per lane (vpm/lane or vpk/lane) or, for pedestrians, in pedestrians per unit area. The *critical density*, D_o (also referred to as the *optimum density*), is the density at which maximum capacity occurs. The *jam density*, D_j, is the density when the vehicles (or pedestrians) are all at a standstill. The average travel speed, S, for any given density can be related to the free-flow speed by Eq. 74.9.

$$S = \text{FFS}\left(1 - \frac{D}{D_j}\right) \qquad 74.9$$

The *flow* (*rate of flow*), v (number of vehicles or volume), crossing a point per hour per lane (vph/lane) is given in Eq. 74.10.

$$v = SD \qquad 74.10$$

Spacing is the distance between common points (e.g., the front bumper) on successive vehicles. The *headway* is the time between successive vehicles.

$$\text{spacing}_{\text{m/veh}} = \frac{1000\ \frac{\text{m}}{\text{km}}}{D_{\text{vpk/lane}}} \qquad \text{[SI]} \quad 74.11(a)$$

$$\text{spacing}_{\text{ft/veh}} = \frac{5280\ \frac{\text{ft}}{\text{mi}}}{D_{\text{vpm/lane}}} \qquad \text{[U.S.]} \quad 74.11(b)$$

$$\text{headway}_{\text{s/veh}} = \frac{\text{spacing}_{\text{m/veh}}}{\text{speed}_{\text{m/s}}} \qquad \text{[SI]} \quad 74.12(a)$$

$$\text{headway}_{\text{sec/veh}} = \frac{\text{spacing}_{\text{ft/veh}}}{\text{speed}_{\text{ft/sec}}} \qquad \text{[U.S.]} \quad 74.12(b)$$

$$v_{\text{vph}} = \frac{3600\ \frac{\text{sec}}{\text{hr}}}{\text{headway}_{\text{sec/veh}}} \qquad 74.13$$

Gap is an important concept, particularly in unsignalized intersections where pedestrians or cross-street traffic are waiting for opportunities to cross. A *gap* is the time interval between vehicles in a major traffic stream. The *critical gap* is the minimum time interval between successive vehicles that will permit pedestrians or cross-street traffic to enter the intersection.

As Figs. 74.1 through 74.3 indicate, the *optimum density* (*critical density*), *optimum speed* (*critical speed*), and *maximum flow* (*maximum capacity*) coincide with the same point.

11. LANE DISTRIBUTION

It may be necessary to estimate the distribution of truck traffic on the various lanes of a multilane facility. The distribution of lane use varies widely, being dependent on traffic regulations, traffic composition, speed, volume, number and location of access points, origin-destination patterns of drivers, development environment, and local driver habits. Because there are so many factors, there are no typical values available for lane distribution.

Lane distribution values based on various vehicle types for selected freeways are provided in the HCM, but they are not intended to represent typical values.

12. VEHICLE EQUIVALENTS

Since trucks, buses, and recreational vehicles (known as RVs) take up more space on a roadway than cars and since they tend to travel more slowly up grades, they degrade the quality of travel more than the same number of cars would. Therefore, their traffic volumes are converted to equivalent passenger car volumes, E, when computing flow.

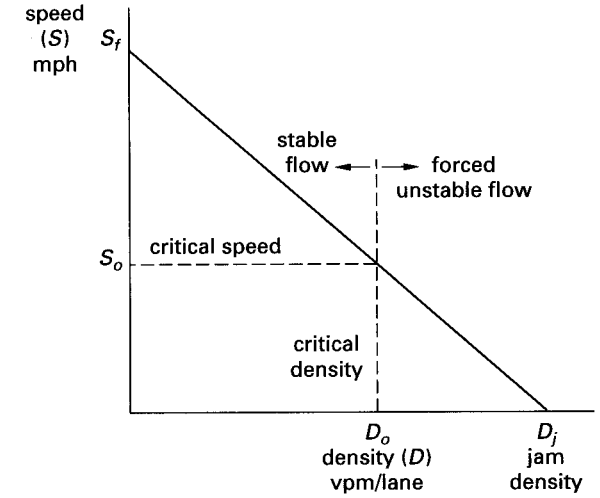

Figure 74.1 *Speed Versus Density*

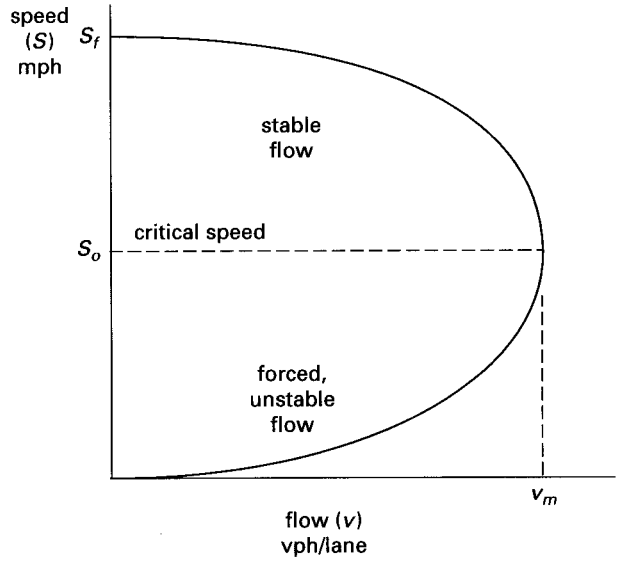

Figure 74.2 *Speed Versus Flow*

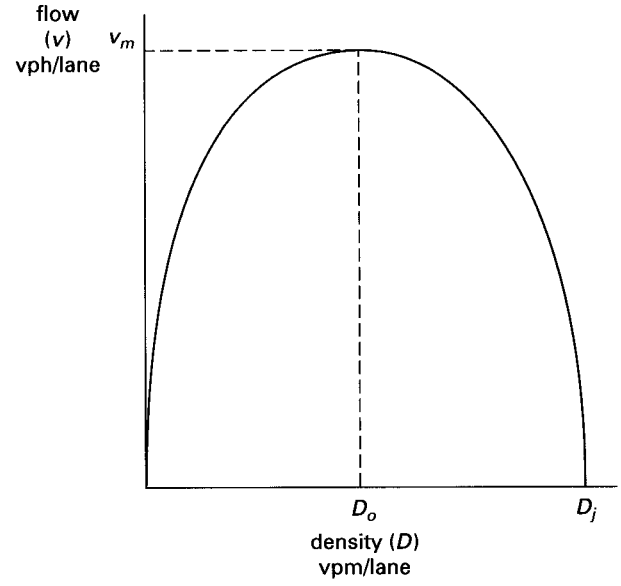

Figure 74.3 *Density Versus Flow*

Passenger car equivalents for trucks and RVs on grades depend on the percent grade, the length of the grade, the number of lanes, and the percentage of trucks and buses. Table 74.6 lists passenger car equivalents for general conditions. However these values are applicable only to long sections of highways. For operation on specific grades of specific lengths, the HCM or AASHTO *Design Guide* must be used.

High-occupancy vehicles (HOVs) include taxis, buses, and carpool vehicles. HCM procedures are not generally intended to apply to HOV lanes.

Table 74.6 *Passenger-Car Equivalents on Extended General Freeway Segments*[a]

terrain	E_T (trucks and buses)	E_R (RVs)
level	1.5	1.2
rolling	3	2
mountainous	6	4

[a]Primarily for use in determining approximate capacity during planning stages when specific alignments are not known.

13. FREEWAYS

(Capacity analysis of freeways is covered in the HCM, Ch. 3.)

Freeway conditions are classified into levels of service A through F. Level A represents conditions where there are no physical restrictions on operating speeds. Since there are only a few vehicles on the freeway, operation at highest speeds is possible. However, the traffic volume is small. Level F represents stop-and-go, low-speed conditions with poor safety and maneuverability. The desired design condition is between levels A and F. Typically, levels B and C are chosen for initial design.

The actual level of service is determined by comparing the actual density (in pcpmpl) with the density limits given in Table 74.8. Other criteria may also be used, such as speed, service flow rate, and the v/c ratio for a given design speed.

The maximum *service flow rate*, v_m (also referred to as "MSF"), per lane for a particular level of service is calculated from the ideal capacity, c, for ideal conditions and the maximum v/c ratio. Table 74.8 contains maximum v/c ratios for given design speeds and levels of service. The actual service flow rate, v, per lane for a particular level of service is calculated from the ideal capacity, c, for ideal conditions and the actual v/c ratio.

$$v_{m,i} = \text{MSF}_i = c(v/c)_{m,i} \qquad 74.14$$

$$v = \text{SF} = c(v/c) \qquad 74.15$$

The *hourly volume* (*flow rate*), V, can be calculated from the number of lanes, N; a factor to adjust for the presence of heavy vehicles such as buses, trucks, and recreational vehicles, f_{HV}; and a factor to adjust for the effect of the driver population, f_p.

$$V = v_p(\text{PHF})Nf_{HV}f_p \qquad 74.16$$

Unless other information is available, the HCM suggests using estimated PHF values of 0.85 and 0.90 for rural and urban-suburban freeways, respectively.

The *heavy vehicle factor*, f_{HV}, is a function of the truck, bus and recreational vehicle fractions and is given by Eq. 74.17. E_T and E_R are the passenger car equivalents of trucks/buses and recreational vehicles, respectively, as given in the HCM as a function of specific grades. The fraction of trucks and buses, P_T, is sometimes referred to as the *T-factor*. Trucks do not include light delivery vans.

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1) + P_R(E_R - 1)} \qquad 74.17$$

The *population adjustment factor*, f_p, is 1.0 for weekday or commuter traffic (drivers familiar with the route) and 0.75 to 0.90 for weekend, recreational, or other types of traffic that do not use the available space as efficiently. Engineering judgment is required in selecting the population's adjustment factor in those instances.

For freeway analysis, *free-flow speed*, FFS, is determined from the ideal free-flow speed (FFS_i) with adjustments for lane width (f_{LW}), right shoulder clearance (f_{LC}), number of lanes (f_N), and interchange density (f_{ID}). These factors are given in Ch. 3 of the HCM.

$$\text{FFS} = \text{FFS}_i - f_{LW} - f_{LC} - f_N - f_{ID} \qquad 74.18$$

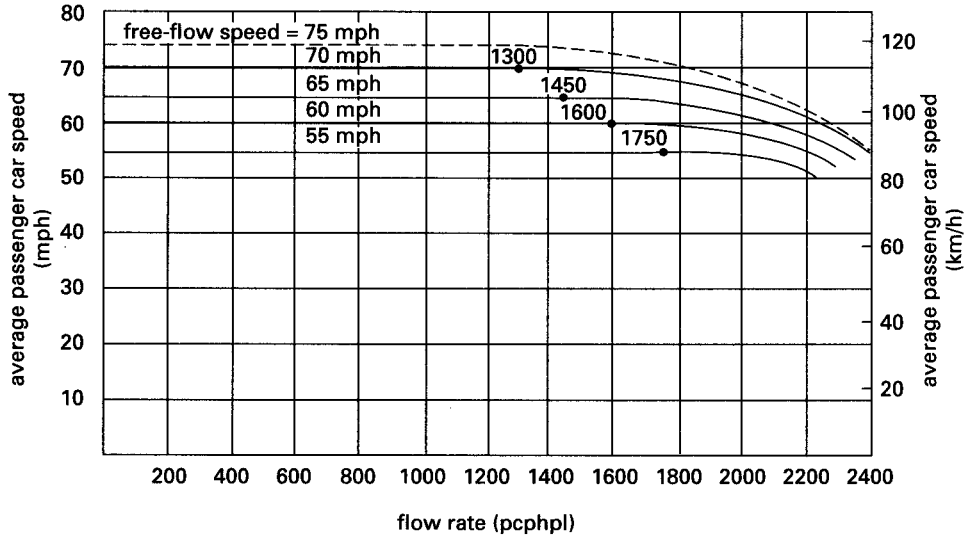

Table 74.7 *Levels of Service for Basic Freeway Sections*

level	density range (pc/mi/ln)	description
A	0–10.0	free flow with low volumes and high speeds
B	10.1–16.0	stable flow, but speeds are beginning to be restricted by traffic conditions
C	16.1–24.0	stable flow, but most drivers cannot select their own speed
D	24.1–32.0	approaching unstable flow, and drivers have little room to maneuver
E	32.1–45.0	unstable flow with short stoppages
F	> 45	forced flow at slow speeds; localized lines of vehicles

Adapted from *Highway Capacity Manual*, pp. 3–9.

Example 74.3

A four-lane (two lanes in each direction) freeway passes through rolling terrain in an urban area. The freeway is constructed with 11 ft lanes and abutment walls 2 ft from the outer pavement edges of both slow lanes. The one-direction peak hourly volume during the weekday commute is 1800 vph. Traffic includes 3% buses and 5% trucks. There is one interchange per mile. The peak hourly factor is 0.90. The posted speed limit is 65 mph. The ideal free-flow speed is 70 mph. (a) What is the 15 min passenger car equivalent flow rate per lane? (b) What is the speed during peak-hour travel? (c) What is the density? (d) What is the weekday peak-hour level of service?

(Multiply mph by 1.609 to obtain km/h.)
(Multiply pcpmpl by 0.621 to obtain pc/km/ln.)

Reprinted with permission from Special Report 209: *Highway Capacity Manual*, 3d ed., Table 3-1, copyright © 1998, by the Transportation Research Board, National Research Council, Washington, D.C.

Solution

(a) Trucks and buses have the same vehicle equivalents, so the "truck" fraction is 8%. There are no RVs. From Table 74.6, $E_T = 3$. From Eq. 74.17,

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1)} = \frac{1}{1 + (0.08)(3 - 1)} = 0.862$$

Convert the volume to flow rate per lane. The commute population knows the route, so $f_P = 1.0$. From Eq. 74.16,

$$v_p = \frac{V}{(\text{PHF})N f_{HV} f_P} = \frac{1800 \text{ vph}}{(0.90)(2)(0.862)(1)} = 1160 \text{ pcphpl}$$

(b) The ideal free-flow speed was given as 70 mph. The actual free-flow speed is calculated from Eq. 74.18.

$f_{LW} = 2.0$ mph (HCM Table 3-6)
$f_{LC} = 2.4$ mph (HCM Table 3-7)
$f_N = 4.5$ mph (HCM Table 3-8)
$f_{ID} = 2.5$ mph (HCM Table 3-9)

$$\begin{aligned}\text{FFS} &= \text{FFS}_i - f_{LW} - f_{LC} - f_N - f_{ID} \\ &= 70 \text{ mph} - 2.0 \text{ mph} - 2.4 \text{ mph} - 4.5 \text{ mph} \\ &\quad - 2.5 \text{ mph} \\ &= 58.6 \text{ mph} \quad \text{[say 59 mph]}\end{aligned}$$

(c) The density is

$$D = \frac{v_p}{S} = \frac{1160 \text{ pcphpl}}{59 \frac{\text{mi}}{\text{hr}}} = 19.7 \text{ pc/mi-ln (pcpmpl)}$$

(d) From Table 74.8 with a free-flow speed of 70 mph, the level of service (based on speed or density) is C.

Example 74.4

A freeway segment is being designed for an ADT of 46,000 weekday commuters traveling at 60 mph in 12 ft lanes. Heavy trucks constitute 5% of the total traffic. The directionality factor is 75%. The K-factor is 9.8%. The freeway segment consists of 1 mi of 4% upward grade. The lateral clearances are 10 ft on the right and 6 ft on the left. Assume reasonable values for PHF and FFS. How many lanes are needed for LOS D?

Solution

Use Eq. 74.2 to convert AADT to design hourly volume.

$$\text{DDHV} = DK(\text{AADT}) = (0.75)(0.098)\left(46{,}000 \frac{\text{veh}}{\text{day}}\right) = 3381 \text{ vph}$$

From HCM Table 3-4, for a 4% grade 1 mi in length with 5% trucks, the passenger car equivalent for trucks is 7.0. From Eq. 74.17,

$$f_{HV} = \frac{1}{1 + P_T(E_T - 1)} = \frac{1}{1 + (0.05)(7 - 1)} = 0.769$$

Transportation

Assume a free-flow speed of 65 mph and peak hour factor of 0.90.

From Table 74.8 with FFS = 65 and LOS D, the maximum service flow rate is 1984 pcphpl.

The adjustment factor for a driver population of weekday commuters is $f_p = 1.0$.

$$\begin{aligned} V_{2 \text{ lanes}} &= v_p(\text{PHF})N f_{\text{HV}} f_p \\ &= \left(1984 \frac{\text{pc}}{\text{hr-ln}}\right)(0.90)(2 \text{ ln})(0.769)(1) \\ &= 2746 \text{ vph } [< 3381] \\ V_{3 \text{ lanes}} &= v_p(\text{PHF})N f_{\text{HV}} f_p \\ &= \left(1984 \frac{\text{pc}}{\text{hr-ln}}\right)(0.90)(3 \text{ ln})(0.769)(1) \\ &= 4119 \text{ vph } [> 3381] \end{aligned}$$

Three lanes are required.

14. MULTILANE HIGHWAYS

(Capacity analysis of multilane highways is covered in the HCM, Ch. 7.)

The *free-flow speed*, FFS, is the theoretical speed of a vehicle under all actual conditions except interference by other vehicles. Free-flow speed is the theoretical speed when density is zero, but is essentially unchanged for densities up to 1400 pcphpl. Free-flow speed is determined from the ideal free-flow speed (FFS_I) with adjustments for median type (F_M), lane width (F_{LW}), total lateral clearance (F_{LC}), and density of access points (F_A). Values of the adjustments are obtained from the appropriate tables in the HCM, Ch. 7. (Though similar in concept to freeway adjustments, some highway values are different. Accordingly, different symbols are also used.)

$$\text{FFS} = \text{FFS}_I - F_M - F_{\text{LW}} - F_{\text{LC}} - F_A \qquad 74.19$$

The *service flow rate*, v_p, in pcphpl is given by Eq. 74.20. V is the volume of vehicles passing a point each hour, f_{HV} is the same heavy-vehicle factor used in freeway analysis, and PHF is the peak hour factor. Where specific local data are not available, the HCM recommends reasonable estimates of PHF of 0.85 for rural multilane highways and 0.92 for suburban multilane highways.

$$v_p = D_m(\text{FFS}) = \frac{V}{N(\text{PHF})f_{\text{HV}}} \qquad 74.20$$

Example 74.5

An undivided suburban multilane highway segment with four 11 ft lanes (two in each direction) is used by weekday commuters. The estimated free-flow speed under ideal conditions is 60 mph. The segment contains a 4% grade 0.8 mi long. The fraction of recreational vehicles on this segment is essentially zero. However, the fraction of trucks is 10%. The lateral clearance on the right-hand side of the slow lane is 2 ft from the pavement edge. There are no points of entry to the highway segment.

(a) What is the hourly volume in the upgrade direction for LOS C? (b) What is the capacity of the downgrade section? (c) What is the LOS in the downgrade section during the morning peak if the peak-hour traffic volume is 1300 vph?

Solution

(a) The ideal free-flow speed is given as $\text{FFS}_I = 60$ mph.

The median type adjustment factor for undivided highways is found from the HCM, Table 7-2, as $F_M = 1.6$.

The lane width adjustment factor for 11 ft lanes is found from the HCM, Table 7-3, as $F_{\text{LW}} = 1.9$.

For undivided highways, the left-hand side clearance is taken as 6 ft. The total lateral clearance is 6 ft + 2 ft = 8 ft. The adjustment factor for lateral clearance for four-lane highways is found from the HCM, Table 7.4 as $F_{\text{LC}} = 0.9$.

If there are no access points, Table 7-5 of the HCM gives the access-point density adjustment factor as $F_A = 0$.

Use Eq. 74.19.

$$\begin{aligned} \text{FFS} &= \text{FFS}_I - F_M - F_{\text{LW}} - F_{\text{LC}} - F_A \\ &= 60 \frac{\text{mi}}{\text{hr}} - 1.6 \frac{\text{mi}}{\text{hr}} - 1.9 \frac{\text{mi}}{\text{hr}} - 0.9 \frac{\text{mi}}{\text{hr}} - 0 \\ &= 55.6 \text{ mi/hr} \end{aligned}$$

Round down to 55 mi/hr in order to use data from HCM Table 7-1. The maximum density at LOS C is 28 pcpmpl.

Use Eq. 74.20.

$$\begin{aligned} v_p = D_m(\text{FFS}) &= \left(28 \frac{\text{pc}}{\text{mi-lane}}\right)\left(55 \frac{\text{mi}}{\text{hr}}\right) \\ &= 1540 \text{ pc/hr-lane (pcphpl)} \end{aligned}$$

From Table 7-8 of the HCM, the passenger car equivalent of trucks on a 4% grade 0.8 mi long with 10% trucks is $E_T = 5.5$. From Eq. 74.17, the heavy-vehicle adjustment factor is

$$\begin{aligned} f_{\text{HV}} &= \frac{1}{1 + P_T(E_T - 1)} \\ &= \frac{1}{1 + (0.10)(5.5 - 1)} \\ &= 0.690 \end{aligned}$$

Assume a value of 0.92 for the peak hour factor as recommended by the HCM. Solve Eq. 74.20 for the volume.

$$\begin{aligned} V &= v_p N(\text{PHF}) f_{\text{HV}} \\ &= \left(1540 \frac{\text{pc}}{\text{hr-lane}}\right)(2 \text{ lanes})(0.92)(0.690) \\ &= 1955 \text{ pc/hr (pcph)} \end{aligned}$$

(b) From Table 7-1 of the HCM, at 55 mph, a maximum capacity of 2100 vph will be reached at LOS E.

From Table 7-10 of the HCM, the passenger car equivalent of trucks on a 4% downgrade 0.8 mi long is $E_T = 1.5$. From Eq. 74.17, the heavy-vehicle adjustment factor is

$$\begin{aligned} f_{HV} &= \frac{1}{1 + P_T(E_T - 1)} \\ &= \frac{1}{1 + (0.10)(1.5 - 1)} \\ &= 0.952 \end{aligned}$$

Use Eq. 74.20 to calculate the hourly volume.

$$\begin{aligned} V &= v_p N(\text{PHF}) f_{\text{HV}} \\ &= \left(2100 \frac{\text{pc}}{\text{hr-lane}}\right)(2 \text{ lanes})(0.92)(0.952) \\ &= 3678 \text{ pc/hr (pcph)} \end{aligned}$$

(c) Use Eq. 74.20 to calculate the service flow rate.

$$\begin{aligned} v_p &= \frac{V}{N(\text{PHF}) f_{\text{HV}}} \\ &= \frac{1300 \frac{\text{pc}}{\text{hr}}}{(2)(0.92)(0.952)} \\ &= 742 \text{ pc/hr-lane (pcphpl)} \end{aligned}$$

From part (a), the free-flow speed is 55 mph. From Eq. 74.20, the peak density is

$$\begin{aligned} D_m &= \frac{v_p}{\text{FFS}} = \frac{742 \frac{\text{pc}}{\text{hr-lane}}}{55 \frac{\text{mi}}{\text{hr}}} \\ &= 13.5 \text{ pc/mi-lane (pcphpl)} \end{aligned}$$

Use Table 7-1 of the HCM for 55 mi/hr. Since 12 pcpmpl < 13.5 pcpmpl < 20 pcpmpl, the level of service is B.

15. SIGNALIZED INTERSECTIONS

(Capacity analysis of signalized intersections is covered in the HCM, Ch. 9.)

Signalized intersections are controlled by signals operating in two or more phases. Each phase consists of three intervals: green, amber (i.e., "yellow"), and red. A *two-phase signal* is one that has one phase for each direction of travel (e.g., one phase of north-south movements and one phase of east-west movements). A *three-phase signal* provides one of the roads with a left-turn phase. In a *four-phase signal*, both roads have left-turn phases.

Level of service for signalized intersections is defined in terms of control delay in the intersection. *Control delay* consists of only the portion of delay attributable to the control facility (e.g., initial deceleration delay, queue move-up time, stopped delay, and final acceleration delay), but not geometric delay or incident delay. Delay can be measured in the field, or it can be estimated using procedures as outlined in the HCM. LOS criteria are stated in terms of control delay per vehicle for a 15 min analysis period, as given in Table 74.9. Because of this criterion, an intersection may be operating below its maximum capacity but have an unacceptable delay, and therefore it would be classified as LOS F (failure). This is a different meaning for "LOS F," which generally indicates that demand exceeds capacity.

The capacity of a signalized intersection is calculated for each lane group. *Capacity* is the maximum rate of flow for the subject lane group that may pass through the intersection under prevailing traffic, roadway, and signalization conditions. The rate of flow is generally measured or projected for a 15 min period. Capacity is given in terms of vehicles per hour and is dependent on many factors, including the width of approach, parking conditions, traffic direction (one-way or two-way traffic), environment, bus and truck traffic, and percentage of turning vehicles.

Rather than calculate the capacity of the entire intersection, a total volume-capacity (v/c) ratio is computed for all of the critical lane groups within the intersection as a measure of the overall intersection performance. The *critical lane groups* are those lane groups or approaches that have the maximum *flow ratio*, v/s, for each signal phase. The *critical movements* are those that consume the maximum amount of time during each signal phase.

In capacity analysis, volume-capacity ratios (v/c) are computed for each intersection movement and for all of the critical movements together. The v/c ratios are determined by dividing the peak 15 min rate of flow on an approach or lane group by the capacity of the approach or lane group. Both the traffic flow and the geometric characteristics are taken into consideration. The objective is to provide the minimum number of lane groups to adequately characterize the intersection operation.

The capacity of an approach or lane group is given by Eq. 74.21. s_i is the *saturation flow rate* in vphg for lane group i (i.e., in vphgpl), which is the flow rate per lane at which vehicles can pass through a signalized intersection in a stable moving queue. g_i/C is the *effective green ratio* for the lane group.

$$c_i = s_i(g_i/C) \qquad 74.21$$

$$s_{\text{vphgpl}} = \frac{3600 \frac{\text{sec}}{\text{hr}}}{\text{saturation headway}_{\text{sec/veh}}} \qquad 74.22$$

The ratio of flow to capacity (v/c) is known as the *degree of saturation* and *volume-capacity ratio*. For convenience and consistency with the literature, the degree of saturation for lane group or approach i is designated as

X_i instead of $(v/c)_i$, which might be confused with level of service i. When the flow rate equals the capacity, X_i equals 1.00; when flow rate is zero, X_i is zero.

$$X_i = (v/c)_i = \frac{v_i}{s_i(g_i/C)} = \frac{v_i C}{s_i g_i} \qquad 74.23$$

When the overall intersection is to be evaluated with respect to its geometry and the total cycle time, the concept of the critical v/c ratio, X_c, is used. The *critical v/c ratio* is usually obtained for the overall intersection considering only the critical lane groups or approaches. In Eq. 74.24, C is the total cycle length and L is the *lost time* per cycle. Time is lost when the intersection is not used effectively, as during start-up through the intersection. Lost time includes start-up time and some of the amber signal time. In conservative studies, lost time includes all of the amber signal time.

$$X_c = \sum_i (v/s)_{ci} \left(\frac{C}{C-L}\right) \qquad 74.24$$

Equation 74.24 can be used to estimate the signal timing for the intersection if a critical v/c ratio is specified for the intersection. This equation can also be used to estimate the overall sufficiency of the intersection by substituting the specified maximum permitted cycle length and determining the resultant critical v/c ratio for the intersection.

When the critical v/c ratio is less than 1.00, the cycle length provided is adequate for all critical movements to pass through the intersection if the green time is proportionately distributed to the different phases. If the total green time is not proportionately distributed to the different phases, it is possible to have a critical v/c ratio of less than 1.00, but one or more individual oversaturated movements may occur within a cycle.

Saturation flow rate, s, is defined as the total maximum flow rate on the approach or group of lanes that can pass through the intersection under prevailing traffic and roadway conditions when 100% of the effective green time is available. Saturation flow rate is expressed in units of vehicles per hour of effective green time (vphg) for a given lane group.

Saturation flow rate is calculated from the ideal saturation flow rate, s_o, which is assumed to be 1900 passenger cars per hour of green per lane (abbreviated "pcphgpl"). Adjustments are made for lane width (f_w), heavy vehicles (f_{HV}), grade (f_g), existence of parking lanes (f_p), stopped bus blocking (f_{bb}), type of area (f_a), lane utilization (f_{LU}), right-hand turns (f_{RT}), and left-hand turns (f_{LT}). All of the adjustments are tabulated in the HCM.

$$s = s_o N f_w f_{HV} f_g f_p f_{bb} f_a f_{LU} f_{RT} f_{LT} \qquad 74.25$$

Other important concepts in signalized intersection analysis are arrival type and platoon ratio. The *arrival type* (AT) is a categorization of the quality of progression through the intersection. There are six categories—arrival types 1 through 6. Arrival type 1 represents a "very poor progression" where 80% or more of the lane group arrives at the start of the red signal phase. Arrival type 6 represents near-ideal "exceptional progression" with the percentage of arrivals at the start of the green signal phase approaching 100%. The *platoon ratio*, R_p, is the ratio of the fraction of all vehicles in movement arriving during the green phase and the green signal time fraction. HCM Table 9-2 quantifies arrival type by platoon ratio.

$$R_p = \frac{P_{green}}{g/C} \qquad 74.26$$

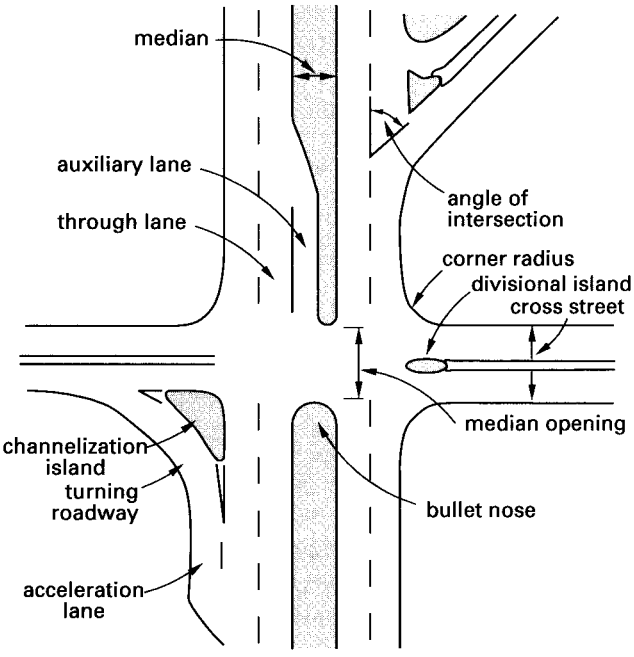

Figure 74.5 *Elements of an Intersection*

Example 74.6

A signalized intersection located in a central business district has two 11 ft lanes, both of which are approached on a 2% downgrade. 10% of the traffic

consists of heavy trucks, but there are no buses or RVs. Both lanes are through lanes; no turns are permitted. There are no parking lanes. Arrivals to the intersection are random. What is the saturation flow rate of the intersection?

Solution

Refer to the HCM to obtain the required adjustment factors.

$s_o = 1900$ pcphgpl

$N = 2$

$f_w = 0.967$ [HCM Table 9-5]

$f_{HV} = 0.909$ [HCM Table 9-6]

$f_g = 1.010$ [HCM Table 9-7]

$f_p = 1.000$ [HCM Table 9-8]

$f_{bb} = 1.000$ [HCM Table 9-9]

$f_a = 0.90$ [HCM Table 9-10]

$f_{LU} = 0.95$ [HCM Table 9-4]

$f_{RT} = 1.000$ [HCM Table 9-11]

$f_{LT} = 1.000$ [HCM Table 9-12]

$$\begin{aligned} s &= s_o N f_w f_{HV} f_g f_p f_{bb} f_a f_{LU} f_{RT} f_{LT} \\ &= \left(1900 \frac{\text{pc}}{\text{hrg-lane}}\right)(2 \text{ lanes})(0.967)(0.909)(1.010) \\ &\quad \times (1.000)(1.000)(0.90)(0.95)(1.000)(1.000) \\ &= 2884 \text{ pcphg} \end{aligned}$$

16. WARRANTS FOR INTERSECTION SIGNALING

As recommended by the MUTCD, four-way traffic signaling should be considered when one or more of the following justifying conditions (known as *warrants*) is present. Whereas warrants 1 and 2 have historically been used to justify most signal installations, these two warrants impose arbitrary numerical cut-offs that have little scientific basis. Warrants 9 through 11 recognize the desirability of basing signalization on only one- and four-hour analysis periods. These warrants may eventually eliminate the need for warrants 1 and 2. Additional warrants may be used when based on reasonable engineering judgment (e.g., to accommodate elderly or physically challenged individuals). The following summaries do not include the full-warrant requirements.

- *Warrant 1, Minimum vehicular volume:* For *major streets*, high traffic volume is more than 500 vph (one lane of approaching traffic) or 600 vph (two or more lanes of approaching traffic), counted over both directions and all lanes, for 8 hr. For *minor streets*, high traffic volume is more than 150 vph (200 vph for two lanes of approaching traffic) counted over one direction, all lanes.
- *Warrant 2, Interruption of continuous traffic:* Cross-street traffic cannot enter or cross the main traffic flow. For major streets with one lane of approaching traffic, volume is more than 750 vph for 8 hr. For minor streets with one lane of approaching traffic, volume is more than 75 vph for 8 hr. Different standards are applied for two or more lanes of approaching traffic. (Reduce volumes by 30% for rural locations.)
- *Warrant 3, Minimum pedestrian volume:* Volume is more than 100 pedestrians per hour over any 4 hr period, or more than 190 pedestrians during any 1 hr, with additional traffic volume requirements and reductions for slow-moving pedestrians.
- *Warrant 4, School crossing:* There are fewer gaps in the traffic stream during the crossing period than there are minutes in the crossing period.
- *Warrant 5, Progressive movement:* There is a need to regulate speed of cars and prevent platooning of flow.
- *Warrant 6, Accident experience:* The number of accidents or their value in a 12-month period exceeds maximum values.
- *Warrant 7, Systems warrant:* It is desirable to encourage concentration and organization of traffic flow networks.
- *Warrant 8, Combination of warrants:* No single warrant is satisfied, but warrants 1 and 2 are 80% satisfied.
- *Warrant 9, Four hour volumes:* For each of any 4 hr in an average day, the traffic on both the major and minor streets exceeds a cut-off volume. (Specific cut-off volumes are determined graphically.)
- *Warrant 10, Peak hour delay:* Undue delay by minor-street (side street) traffic in entering or crossing the main street is experienced during 1 hr of the day. Additional volume criteria are also met.
- *Warrant 11, Peak hour volume:* Minor-street (side street) traffic experiences high volume during 1 hr of the day. (Specific cut-off volumes are determined graphically.)

17. FIXED-TIME CYCLES

Fixed-time controllers are the least expensive and simplest to use. They are most efficient only where traffic can be accurately predicted. Fixed-time controllers are necessary if sequential intersections or intersections spaced less than ½ mi (0.8 km) apart are to be coordinated.

In general, the fixed signal cycle length should be between 35 and 120 sec. Green cycle lengths with fixed-time controllers should be chosen to clear all waiting traffic in 95% of the cycles. Usually, the 85th percentile speed is used in preliminary studies. Since the green

cycle must handle peak loads, level of service is sacrificed during the rest of the day, unless the cycle length is changed during the day with *multi-dial controllers*.

Amber time is usually 3 to 6 sec. Six sec may be used for higher speed roadways. A short all-red clearance interval may be provided after the amber signal to clear the intersection. It is also necessary to check that pedestrians can cross the intersection in the available walk time. (See Sec. 21.) A short all-red clearance interval is suggested after the green walk signal terminates.

Determining cycle lengths of signalized intersections is covered in the HCM, Ch. 9. Queuing models and simulation can also be used to determine or check cycle lengths in complex situations.

18. TIME-SPACE DIAGRAMS

To minimize the frustration of drivers who might otherwise have to stop at every traffic signal encountered while traveling in a corridor, it is desirable to coordinate adjacent fixed-time signals. With *alternate mode operation*, every other signal will be green at the same time. By the time a vehicle moving at a specific speed has traveled the distance between two adjoining signals, the signal being approached will turn green. For *double-alternate mode operation*, two adjacent pairs of signals will have the same color (i.e., red or green), while the following two adjacent signals will have the opposite color. Alternate mode is preferred. Unless all of the signals are equidistant, it is unlikely that all inconvenience will be eliminated from the traffic stream.

Signal coordination is essentially achieved by setting the controller's *offset*. *Offset* is the time from the end of one controller's green cycle to the end of the next controller's green cycle. The following graphical procedure can be used to establish the offset by drawing *time-space diagrams* (*space-time diagrams*). The horizontal axis represents distance (typical scales are 1 in:100 ft or 1 in:200 ft), and the vertical axis represents time (usually in seconds).

step 1: Draw the main and intersecting streets to scale along the horizontal scale. When signals are separated by short distances, the cross-street widths should be drawn accurately.

step 2: Assume or obtain the actual average travel speed along the main street. (This is rarely the posted speed limit.) Starting at the lower left corner, draw a diagonal line representing the average speed.

step 3: Make an initial assumption for the cycle length. For a two-way street, the cycle length should be either two times (alternate mode) or four times (double-alternate mode) the travel time at the average speed between intersections of average separation. The *effective green time* includes that portion (e.g., half) of the amber time that vehicles will continue to move through the intersection. Similarly, the *effective red time* includes the remainder of the amber time. The general timing guidelines of 35 sec minimum and 120 sec maximum apply.

step 4: Minimize the conflict between effective green and effective red periods at adjacent intersections. This can be done heuristically by cutting strips of paper for each intersection and marking off green and red periods according to the time scale. The strips are placed on the time-space diagram with offsets determined by the average speed and average intersection separation.

step 5: Check to see if the assumed cycle can accommodate the heaviest traveled intersection.

Figure 74.7 shows a time-space diagram with diagonal lines drawn between green cycle limits. (The two sets of diagonal lines represent the traffic flows in the two opposing directions.) The vertical distance between the diagonal lines indicates the green "window" of travel, known as the *bandwidth*. The *platoon length* is the horizontal distance between diagonal lines. The signal *offset* is the time difference (measured in the vertical direction) between the start of successive signals' green periods.

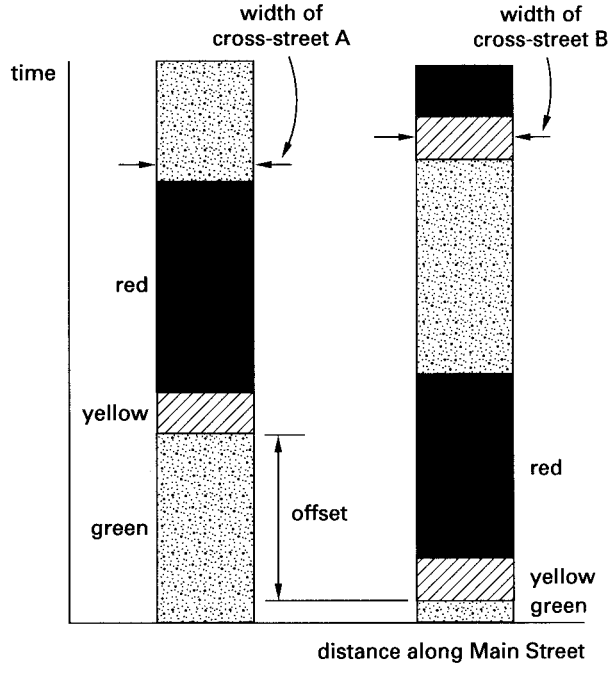

Figure 74.6 *Time-Space Diagram Construction*

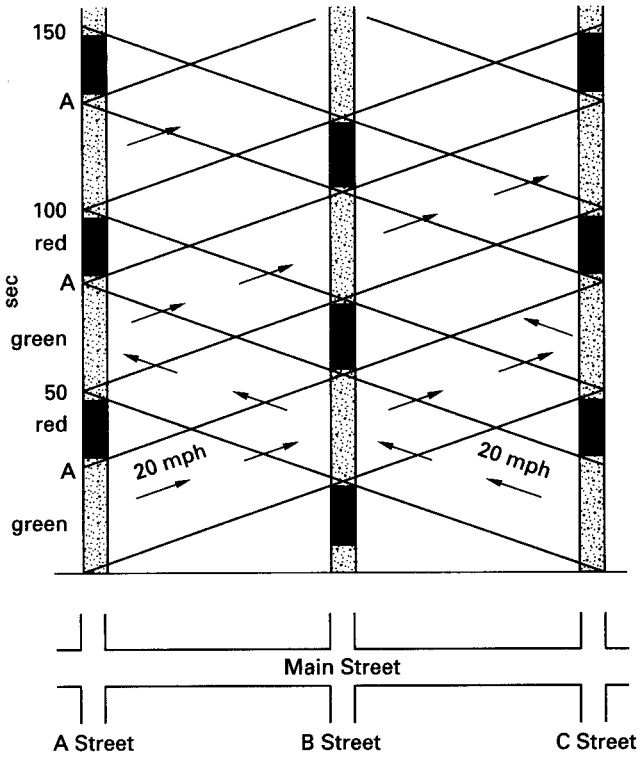

Figure 74.7 *Time-Space Diagram Bandwidth*

19. ON-DEMAND TIMING

On-demand controllers (*traffic-activated controllers* or *activated controllers*) are initially more expensive than fixed-time controllers. However, activated controllers do a better job of controlling flow, and they are better accepted by drivers.

Since cycle changes with on-demand controllers depend on the arriving traffic volume, ideally traffic counts are not needed. Four parameters must be specified to completely define the timing sequence: initial period, vehicle time period, maximum time period, and clearance allowance.

- *Initial period:* The initial period must allow enough time for traffic stopped between the stop line and the detector to begin moving. The number of cars between the stop line and the detector is calculated from Eq. 74.27.

$$\text{no. of cars in initial period} = \frac{\text{distance between line and detector}}{\text{car length}} \qquad 74.27$$

The first car can be assumed to cross the stop line approximately 5 sec after the green signal appears. The next car will require 3 sec more. Subsequent cars between the detector and stop line require $2\frac{1}{4}$ sec. Studies have shown the average start-up lot time and average arrival headway to be approximately half of these values. However, these values accommodate the slowest of drivers.

- *Vehicle period:* The vehicle period must be long enough to allow a car crossing the detector (moving at the slowest reasonable speed) to get to the intersection before the amber signal appears. It is not necessary to have the vehicle get entirely through the intersection during the green, since the amber period will provide additional time. In a 30 mph (50 km/h) zone, a speed of approximately 20 mph (30 km/h) into the intersection is reasonable.
- *Maximum period:* The maximum period is the maximum delay that the opposing traffic can tolerate. For a main street 60 sec is typical, and 30 to 40 sec is appropriate for a side street. The period should never exceed 120 sec.
- *Amber period:* The amber clearance period can be determined from the time required to perceive the light, brake, and stop the vehicle, plus the assumed average speed into the intersection. Amber periods of 3 to 6 sec are typical.
- *Green period:* The green period is the smaller of the sum of initial and vehicle periods and the maximum period.

20. WALKWAYS

(Capacity analysis of pedestrians in walkways and crosswalks is covered in the HCM, Ch. 13.)

The level of service (LOS) for pedestrians in walkways (i.e., sidewalks) and queuing areas is categorized in much the same way as for freeway and highway vehicles. Table 74.10 relates important parameters to the level of service. The primary criterion for determining pedestrian level of service is *space* (the inverse of density) per pedestrian. This, in turn, affects the speed at which pedestrians can walk. Mean speed and flow rate are supplementary criteria.

Pedestrian speed, S, is the average pedestrian walking speed (ft/sec). Pedestrian *flow rate*, v, is the number of pedestrians passing a point per unit time (ped/min or ped/15 min). *Unit width flow* is the average flow of pedestrian per unit width of walkway (ped/min-ft). Pedestrian *density* is the average number of pedestrians per unit area (ped/ft^2 or ped/m^2). Pedestrian *space*, M, is the average area per pedestrian (ft^2/ped or m^2/ped), and is the inverse of density.

$$v = SD = S/M \qquad 74.28$$

Maximum pedestrian *capacity* in walkways is 25 ped/min-ft, pedestrians per minute per foot of walkway width (82 ped/min-m). This occurs when the space is approximately 5 to 9 ft^2/ped (0.47 to 0.84 m^2/ped). Capacity drops significantly as space decreases, and movement effectively stops when space is reduced to 2 to

4 ft^2/ped (0.19 to 0.37 m^2/ped). The *effective walkway width*, W_E, is determined by subtracting any unusable width, including perceived "buffer zones" from adjacent features, from the total walkway width. (Refer to HCM Fig. 13.5.) The average *pedestrian unit flow rate* is

$$v = \frac{v_{p,15}}{15W_E} \qquad 74.29$$

A *platoon* is a group of pedestrians walking together in a group. When all units are expressed in ped/min-ft, the rate of flow within platoons, v_p, is

$$v_p = v + 4 \quad \text{[U.S. only]} \qquad 74.30$$

Table 74.10 *Pedestrian Level of Service on Walkways*

LOS	pedestrian space in ft^2/ped (m^2/ped)	average speed in ft/min (m/min)	flow rate in ped/min-ft[a] (ped/min-m)	volume-capacity (v/c) ratio
A	$\geq$ 130 (12)	$\geq$ 260 (79)	$\leq$ 2 (7)	$\leq$ 0.08
B	$\geq$ 40 (3.7)	$\geq$ 250 (76)	$\leq$ 7 (23.0)	$\leq$ 0.28
C	$\geq$ 24 (2.2)	$\geq$ 240 (73)	$\leq$ 10 (33)	$\leq$ 0.40
D	$\geq$ 15 (1.4)	$\geq$ 225 (68.7)	$\leq$ 15 (49.0)	$\leq$ 0.60
E	$\leq$ 6 (0.6)	$\geq$ 150 (45.7)	$\leq$ 25 (82)	$\leq$ 1.00
F	$<$ 6 (0.6)	$<$ 150 (45.7)	variable	variable

(Multiply ft^2/ped by 0.0929 to obtain m^2/ped.)
(Multiply ft/min by 0.3048 to obtain m/min.)
(Multiply ped/min-ft by 3.28 to obtain ped/min·m.)
[a]pedestrians per minute per foot (meter) width of walkway

21. CROSSWALKS

Analysis of pedestrians in *crosswalks* is slightly different than in pure walkways. Walking is affected by signaling, turning vehicles, platooning, and interception of the platoon of pedestrians coming from the opposite side. The HCM recommends using an average walking speed of 4.5 ft/sec (1.35 m/s) and a 3 sec starting delay. However, some people can walk as fast as 6 ft/sec (1.8 m/s), and 30 to 40% walk slower than 4 ft/sec (1.2 m/s). If a significant portion of walkway users are elderly, it may be appropriate to use a design speed of 3 ft/sec (0.9 m/s) and a 5 sec starting delay. Physically challenged individuals require additional consideration.

22. PARKING

The minimum parallel street parking *stall width* is commonly taken as 8 ft (2.4 m). This width accommodates the vehicle and its separation from the curb. Seven ft (2.1 m) wide stalls are substandard and should be limited to residential areas and attendant-parked lots. Widths larger than 9 ft (2.7 m) are appropriate in shopping areas where package-loading is expected. If the width is specified as 10 to 12 ft (3.0 to 3.7 m), the street parking corridor can be used for delivery trucks or subsequently converted to an extra traffic lane or bicycle path. The minimum length of a parallel street parking stall is 18 ft (5.4 m). In order to accommodate most cars, longer lengths, 20 to 26 ft (6.0 to 7.8 m), may be used.

Figure 74.8 illustrates parallel street parking near an intersection as recommended by the Green Book. The 15 to 20 ft (4.6 to 6.0 m) clearance from the last stall to the intersection is required for crosswalks and turning movements of long buses and tandem trucks. The exact distance will depend on the dimensions of the vehicles expected.

Adapted from Green Book (1994), Fig. IV-31.

Figure 74.8 *Parallel Parking Design*

Tandem parking (also known as *travers tandem parking* and *double-alternate parking*) provides two shortened stalls placed end to end with a single maneuver zone available for each of the two stalls. A parking vehicle pulls into the stall space and maneuver zone. The vehicle is removed from the traffic stream in about 4 sec. (With the traditional parallel parking procedure, traffic may halt for as much as 30 sec or more while a vehicle attempts to back into the parking space.) The original (1970) tandem design required 56 ft (17.1 m): two 20 ft (6.1 m) stalls and a 16 ft (4.9 m) maneuver zone. With modern smaller cars, the required space can be reduced to 45 to 50 ft (13.7 to 15.3 m): two 18 ft (5.5 m) stalls and a 9 to 14 ft (2.7 to 4.3 m) maneuver zone. Other dimensions may work. Typical parallel curb parking geometry is given in Fig. 74.9.

Diagonal parking (*angle parking*) street parking can be specified with angles to the curb of 45°, 60°, 75°, and 90°. The effects of diagonal parking on lane width can be determined from trigonometry. The significant disadvantage of impaired vision when backing up should be considered when designing angle parking.

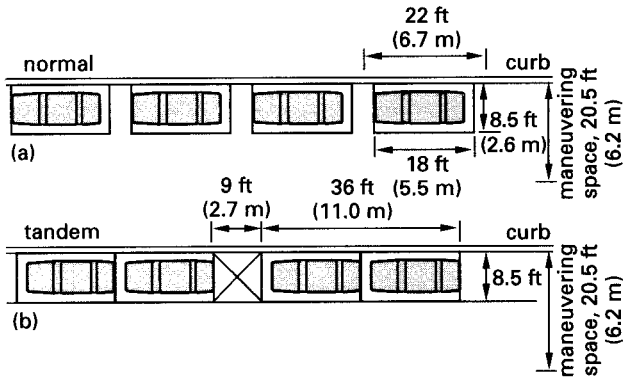

Figure 74.9 *Typical Curb Parking Geometry*

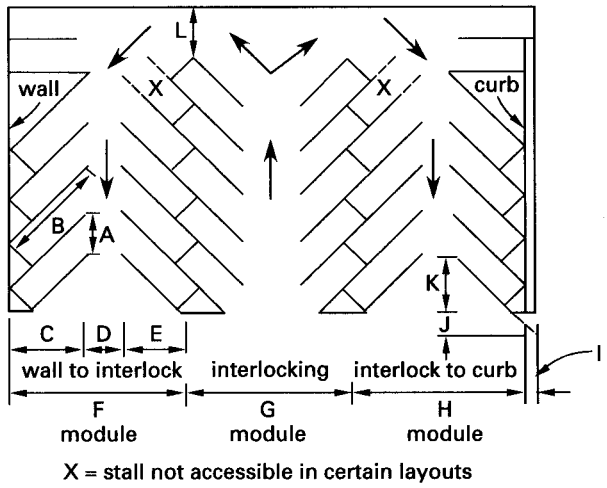

Figure 74.10 *Parking Lot Layout*

In designing *parking lots*, an area of 320 to 380 ft^2 (29.7 to 35.3 m^2) per car will allow for access lanes through lots. The maximum capacity of a parking lot can be calculated by dividing the gross lot area by the minimum area (e.g., 320 ft^2 or 29.7 m^2) per car. Knowledge of the typical vehicle is important in determining the size of the parking stalls. Designs may be based on a "standard" vehicle, although maximum space efficiency will be achieved only by using a range of stall sizes accommodating different vehicle classes. The stall requirement can range from 7 × 15 ft (2.1 × 4.5 m) for compacts to 9 × 19 ft (2.7 × 5.7 m) for campers and vans. If only one type of stall size is chosen, that size should be closer to the larger requirement. Table 74.11 and Fig. 74.10 refer to a parking lot based on a nominal 9 × 18.5 ft (2.7 × 5.6 m) parking area and angled stalls. It has been shown that the optimal parking angle is 60°.

Table 74.11 *Parking Lot Dimensions (9 × 18.5 ft stall)*

dimension	on diagram[a]	angle 45°	60°	75°	90°
stall width, parallel to aisle	A	12.7	10.4	9.3	9.0
stall length of line	B	25.0	22.0	20.0	18.5
stall depth to wall	C	17.5	19.0	19.5	18.5
aisle width between stall lines	D	12.0	16.0	23.0	26.0
stall depth, interlock	E	15.3	17.5	18.8	18.5
module, wall to interlock	F	44.8	52.5	61.3	63.0
module, interlocking	G	42.6	51.0	61.0	63.0
module, interlock to curb face	H	42.8	50.2	58.8	60.5
bumper overhang (typical)	I	2.0	2.3	2.5	2.5
offset	J	6.3	2.7	0.5	0.0
setback	K	11.0	8.3	5.0	0.0
cross aisle, one-way	L	14.0	14.0	14.0	14.0
cross aisle, two-way	–	24.0	24.0	24.0	24.0

(Multiply ft by 0.3048 to obtain m.)

[a]See Fig. 74.10.

The stall angle affects other characteristics. The required width of the traffic aisles is directly related to the chosen stall angle. A wider aisle is needed to enter a 90° stall than to enter a 60° stall. The use of one-way aisles and stall overlaps saves space and facilities.

ADA (Americans with Disabilities Act) *accessible parking spaces* (i.e., "handicapped parking") are required in all parking lots for visitors, customers, and employees. The total number of accessible spaces is given in Table 74.12. The number of designated van-accessible spaces is obtained by dividing the total number of accessible spaces by eight and rounding up, with no less than one van-accessible space. All remaining spaces can be car accessible.

Table 74.12 *Minimum Number of Accessible Parking Spaces[a]*

total number of parking spaces in lot	total minimum number of car- and van-accessible[b] parking spaces
1–25	1
26–50	2
51–75	3

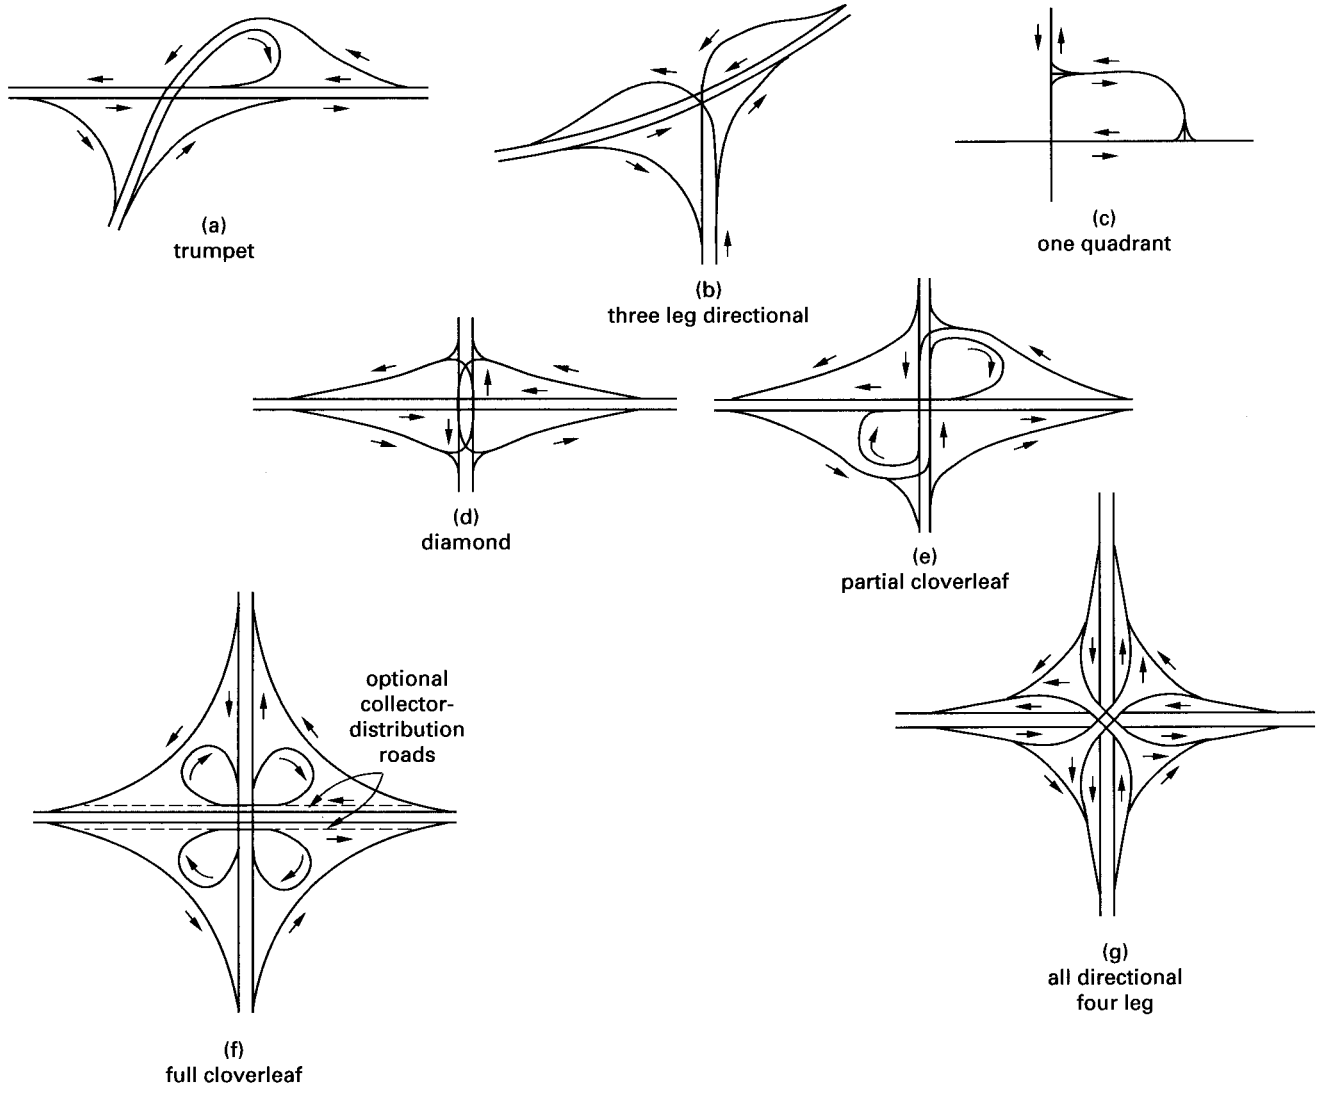
501–1000	2% of total
> 1000	20 plus 1 for each 100 over 1000

[a]Subject to changes in ongoing legislation

[b]One-eighth of total minimum accessible spaces must be van accessible.

Source: ADA Standards for Accessible Design 4.1.2(5)

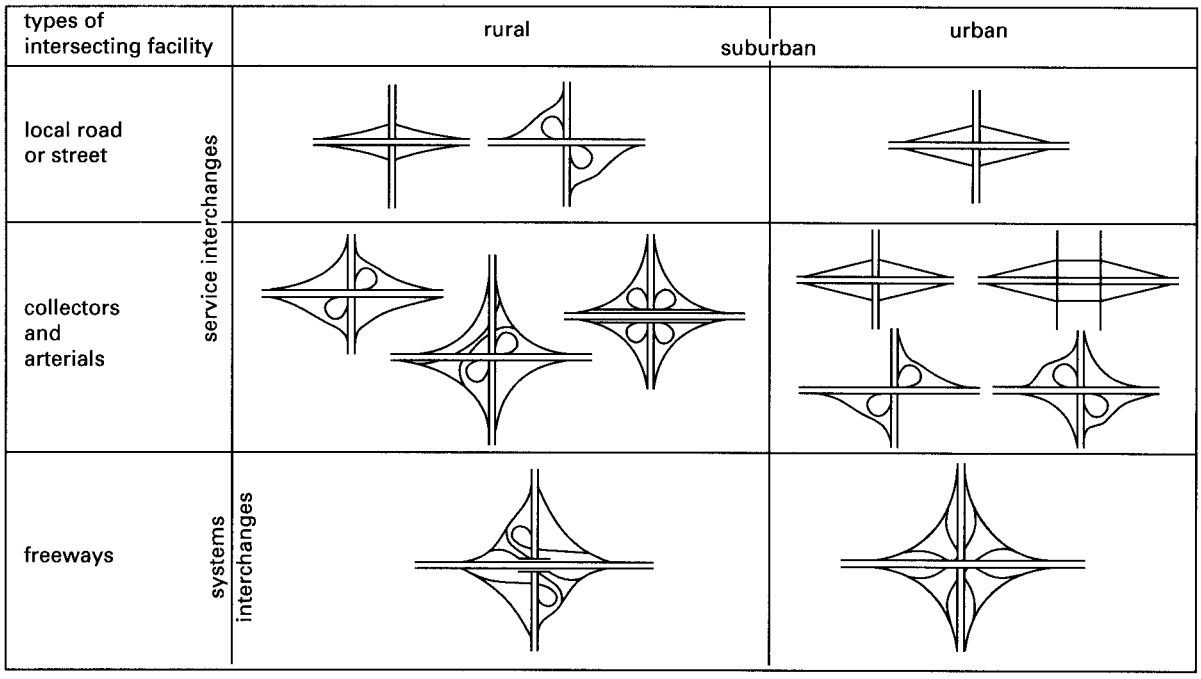
Accessible spaces may be dispersed among multiple lots with accessible entrances. Spaces should be located closest to accessible building entrances. An accessible



curb cut is required from the parking lot to the general walkway. The accessible route must be at least 3 ft (0.9 m) wide. The slope along the accessible route should not be greater than 1:12 in the direction of travel.

Car-accessible spaces should be 8 ft (2.4 m) wide, with a 5 ft (1.5 m) accessible aisle alongside. Two adjacent accessible spaces can share one aisle. Van-accessible spaces should be 8 ft (2.4 m) wide, with an 8 ft (2.4 m) access aisle. Vans with lifts generally exit on the passenger side.) Van-accessible spaces also require a 98 in (2490 mm) minimum height clearance. All surfaces must be stable and slip-resistant, and have a maximum cross slope of 2%. Signage with the accessibility symbol must be provided. Special van-accessible signage is required for appropriate spaces.

Other facts that must be considered when designing a parking lot include the location of driveways, lighting, landscaping, sidewalks, and entry/exit systems (i.e., gates, doors, ticketing, etc.). Only after these factors have been specified can the layout be designed to maximize the number of parking places.



23. HIGHWAY INTERCHANGES

Highway interchanges allow traffic to enter or leave a highway. Interchange locations are affected by the volume of traffic expected on the interchange, convenience, and required land area. The frequency of interchanges along a route should be sufficient to allow weaving between the interchanging traffic. Factors affecting the

Figure 74.12 *Adaptability of Interchanges on Freeways as Related to Types of Intersecting Facilities*

type of interchange chosen include cost, available land, total flow volume, volume of left turns, and volume of weaving movement. Except in extreme cases, several different designs may be capable of satisfying the design requirements.

Diamond interchanges are suitable for major-road–minor-road intersections. Diamond interchanges can handle fairly large volume roadways and can accommodate some left turns at grade. Left turns must be made directly on the minor highway. They lend themselves to staged construction. The frontage roads and/or ramps can be constructed, leaving the freeway lanes to be built at a later date. The right-of-way costs are low, since little additional area around the freeway is required.

Diamond interchanges force traffic using a ramp to substantially reduce its speed. Since the capacity per ramp is limited to approximately 1000 vph, diamond interchanges cannot be used for highway-to-highway intersections.

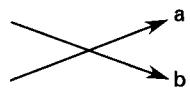
Cloverleaf interchanges incorporate loop connections and allow nonstop left turn movement. *Partial cloverleafs* provide for nonstop left turns along selected routes only, whereas *full cloverleafs* provide nonstop turning for all four traffic directions. (A *loop* or *loop ramp* is a 270° turn in the direction opposite the final direction of travel.) Cloverleafs provide for free flow by separating the traffic in both directions. However, they require large rights-of-way. Cloverleaf intersections slow traffic from the design speed and require short weaving distances. Turning traffic follows a circuitous route. The practical limit of capacity of loop ramps is approximately 800 to 1200 vph. Cloverleaf interchanges should not be used to connect two freeways since they cannot safely accommodate the large volumes of turning traffic.

Both diamond and cloverleaf intersections can be improved by various means, including by the use of a third level and collector-distributor roads to increase the speed and volume of weaving sections.

Directional interchanges (*all-directional interchanges*) allow direct or semidirect connections for left turn movements. The design speeds of connections normally are near the design speed of the through lanes, and large traffic volumes can be handled without significant weaving. However, large rights-of-way are required. Directional interchanges are expensive because of the structures provided. Directional interchanges may contain three or four layers or be of *rotary bridge* design.

When there are only three approach legs, T-, Y-, or *trumpet interchanges* can be used.

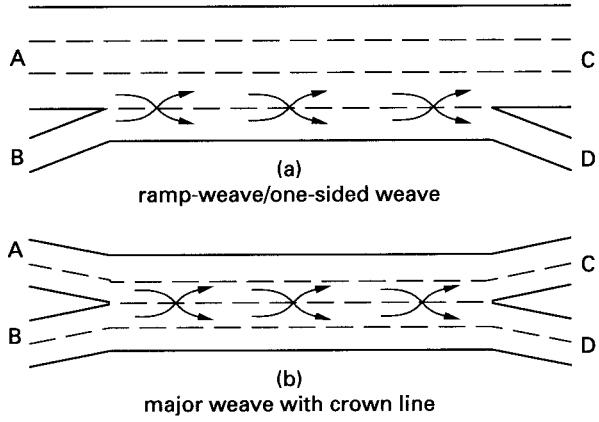
24. WEAVING AREAS



(Analysis and design procedures for weaving areas are covered in the HCM, Ch. 4.)

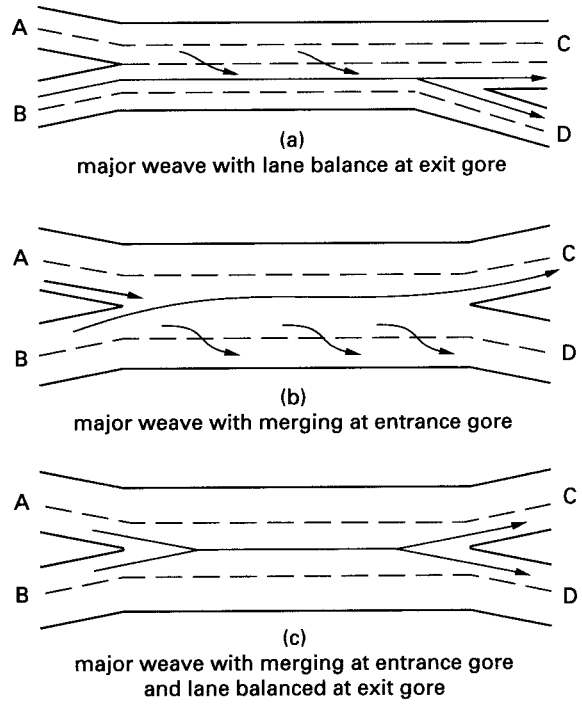
Weaving is the crossing of at least two traffic streams traveling in the same general direction along a length of highway without traffic control. Weaving is an issue that must be considered in interchange selection, and interchanges without weaving are favored over

interchanges with weaving. Weaving areas require increased lane-change maneuvers and result in increased traffic turbulence. The length of weaving area is measured from the *merge gore area* at a point where the right edge of the freeway shoulder lane and the left edge of the merging lane(s) are 2 ft (0.6 m) apart to a point at the *diverge gore area* where the two edges are 12 ft (3.7 m) apart.



Weaving configuration refers to the relative placement and number of entry lanes and exit lanes for a roadway section. The configuration can have a major impact on how much lane changing is required. Configuration is based on the number of required lane changes that must be performed by the two weaving flows in the section. The HCM illustrates three configuration types, and criteria for each are listed in Table 74.13. Figures 74.13, 74.14, and 74.15 illustrate type A, B, and C weaving areas.

Table 74.13 *Configuration Type Versus Minimum Number of Required Lane Changes*



minimum number of required lane changes for merging into mainline traffic (movement a)	minimum number of required lane changes for weaving out of mainline traffic (movement b)

25. TRAFFIC CALMING

Although traditional designs based on the HCM and the Green Book have intended to maximize the flow of traffic, *traffic calming* features are introduced to slow

the flow. Such features include traffic circles, narrow streets, curb extensions, and textured crosswalks. These features, which generally are contrary to traditional design guidelines in the Green Book, are in response to a new urbanism that encourages consideration of historical, community, and aesthetic factors.

26. ECONOMIC EVALUATION

Road user costs include fuel, tires, oil, repairs, time, and accidents. Such costs affect design decisions where there are delays due to congestion, stops, turning, and so on. A reduction in road-user costs can be used to economically justify (i.e., as an economic warrant) interchanges and other features. Reductions in road-user costs are generally far greater than the increased cost of travel times that interchanges cause (compared to at-grade intersections).

Generally, public projects (such as interchanges) are justified using a benefit-cost ratio of annual benefits to annual capital costs. *Annual benefits* is the difference in road-user costs between the existing and improved conditions. *Annual capital costs* is the sum of interest and the amortization of the cost of the improvement. When staged construction is anticipated, incremental costs must be used to justify the construction of future subsequent stages.

Much can be done to improve the safety of some roadway sections. Features such as breakaway poles, cushioned barriers, barriers separating two directions of traffic, and direction channeling away from abutments are common. These features must be economically justified, particularly where they are to be retrofitted to existing highways. The justification is usually the value of personal injury and property damage avoided by the installation of such features.

There are three general classifications of accidents: those with property damage only, those with injury combined with property damage, and those involving death with property damage. The cost of each element (i.e., death, injury, and property damage) can be evaluated from insurance records, court awards, state disability records, and police records. Actuaries may be able to prepare estimates of remaining potential earnings. Also, federal agencies such as the U.S. National Safety Council and OSHA are active in monitoring and maintaining similar statistics.

27. CONGESTION PRICING

Congestion pricing (CP) is the charging of higher tolls (on toll roads and bridges) during peak traffic hours. CP limits the use of roadways during peak periods by providing an economic disincentive. The disincentive can be a toll (also called a *cordon charge* or *road-access charge*) on an otherwise free road. It can also be a fuel tax, or even a car purchase and ownership taxation. On toll facilities, tolls can be raised only during peak hours. Alternatively, additional lanes can be constructed to collect tolls from single-occupancy vehicles.

Congestion pricing is a politically sensitive concept. It has not met with significant success before the 1990s. However, political and environmental issues are making it easier for decision makers to embrace the concept.

28. QUEUING MODELS

A *queue* is a waiting line. Time spent in a system (i.e., the *system time*) includes the *waiting time* (time spent waiting to be served) and the *service time*. *Queuing theory* can be used to predict the system time, W, the time spent in the queue, W_q, the average queue length, L_q, and the probability that a given number of customers will be in the queue, $p\{n\}$.

Over the years, many different queuing models have been developed to accommodate different service policies and populations. For example, some multiserver processes (e.g., tellers drawing from a line of banking customers) draw from a single queue. Other processes (e.g., bridge tolltakers) have their own queues. Most models predict performance only for steady-state operation, which means that the service facility has been open and in operation for some time. Start-up performance often must be evaluated by simulation.

The following basic relationships are valid for all queuing models predicting steady-state performance. $1/\lambda$ is the average time between arrivals, and $1/\mu$ is the average service time per server. For a system to be viable, λ must be less than μs, where s is the number of servers. The *utilization factor*, ρ, is defined as the ratio λ/μ.

$$L = \lambda W \qquad 74.31$$

$$L_q = \lambda W_q \qquad 74.32$$

$$W = W_q + \frac{1}{\mu} \qquad 74.33$$

Most queuing models are mathematically complex and fairly specialized. However, two models are important because they adequately predict the performance of simple queuing processes drawing from typical populations. These are the M/M/1 single-server model and the M/M/s multi-server model.

29. M/M/1 SINGLE-SERVER MODEL

In the M/M/1 single-server model, a single server ($s = 1$) draws from an infinite calling population. The service times are exponentially distributed with mean μ. The specific service time distribution is defined by Eq. 74.34.

$$f(t) = \mu e^{-\mu t} \qquad 74.34$$

As a consequence of using the exponential distribution, the probability of a customer's remaining service time exceeding h (after already spending time with the server)

is given by Eq. 74.35. The probability is not affected by the time a customer has already spent with the server.

$$P\{t > h\} = e^{-\mu h} \qquad 74.35$$

Arrival rates are described by a Poisson distribution with mean λ. The probability of x customers arriving in any period is

$$p\{x\} = \frac{e^{-\lambda}\lambda^x}{x!} \qquad 74.36$$

The following relationships describe an M/M/1 model.

$$p\{0\} = 1 - \rho \qquad 74.37$$

$$p\{n\} = p\{0\}\rho^n \qquad 74.38$$

$$W = \frac{1}{\mu - \lambda} = W_q + \frac{1}{\mu} = \frac{L}{\lambda} \qquad 74.39$$

$$W_q = \frac{\rho}{\mu - \lambda} = \frac{L_q}{\lambda} \qquad 74.40$$

$$L = \frac{\lambda}{\mu - \lambda} = L_q + \rho \qquad 74.41$$

$$L_q = \frac{\rho\lambda}{\mu - \lambda} \qquad 74.42$$

Example 74.7

A state's truck weigh station has the ability to handle an average of 20 trucks per hour. Trucks arrive at the average rate of 12 per hour. Performance is described by an M/M/1 model. Find the steady-state values of (a) the time spent waiting to be weighed, (b) the time spent in the queue, (c) the number of trucks waiting to be weighed, (d) the number of trucks in the queue, and (e) the probability that there will be 5 trucks waiting to be weighed at any time.

Solution

$$\rho = \frac{\lambda}{\mu} = \frac{12\ \frac{\text{trucks}}{\text{hr}}}{20\ \frac{\text{trucks}}{\text{hr}}} = 0.6$$

(a)
$$W = \frac{1}{\mu - \lambda} = \frac{1}{20\ \frac{\text{trucks}}{\text{hr}} - 12\ \frac{\text{trucks}}{\text{hr}}} = 0.125\ \text{hr/truck}$$

(b)
$$W_q = \frac{\rho}{\mu - \lambda} = \frac{0.6}{20\ \frac{\text{trucks}}{\text{hr}} - 12\ \frac{\text{trucks}}{\text{hr}}} = 0.075\ \text{hr/truck}$$

(c)
$$L = \frac{\lambda}{\mu - \lambda} = \frac{12\ \frac{\text{trucks}}{\text{hr}}}{20\ \frac{\text{trucks}}{\text{hr}} - 12\ \frac{\text{trucks}}{\text{hr}}} = 1.5$$

(d)
$$L_q = \frac{\rho\lambda}{\mu - \lambda} = \frac{(0.6)\left(12\ \frac{\text{trucks}}{\text{hr}}\right)}{20\ \frac{\text{trucks}}{\text{hr}} - 12\ \frac{\text{trucks}}{\text{hr}}} = 0.9$$

(e)
$$p\{0\} = 1 - \rho = 1 - 0.6 = 0.4$$
$$p\{5\} = p\{0\}\rho^5 = (0.4)(0.6)^5 = 0.031$$

30. M/M/*s* MULTI-SERVER MODEL

Similar assumptions are made for the M/M/s model as for the M/M/1 model, except that there are s servers instead of 1. Each server has an average service rate of μ and draws from a single common calling line. Therefore, the first person in line goes to the first server that is available. Each server does not have its own line. (This model can be used to predict the performance of a multiple-server system where each server has its own line if customers are allowed to change lines so that they go to any available server.) The following equations describe the steady-state performance of an M/M/s system.

$$W = W_q + \frac{1}{\mu} \qquad 74.43$$

$$W_q = \frac{L_q}{\lambda} \qquad 74.44$$

$$L_q = \frac{p\{0\}\rho^{s+1}}{s!(1-\rho)^2} \qquad 74.45$$

$$L = L_q + \rho \qquad 74.46$$

$$p\{0\} = \frac{1}{\frac{\rho^s}{s!\left(1 - \frac{\rho}{s}\right)} + \sum_{j=0}^{s-1} \frac{\rho^j}{j!}} \qquad 74.47$$

$$p\{n\} = \frac{p\{0\}\rho^n}{n!} \quad [n \le s] \qquad 74.48$$

$$p\{n\} = \frac{p\{0\}\rho^n}{s!s^{n-s}} \quad [n > s] \qquad 74.49$$

31. AIRPORT RUNWAY DESIGNATION

Analysis of airport capacity is based on traffic counts and determination of a "design aircraft." The Federal Aviation Administration (FAA) has prepared Federal

Advisory Circulars outlining the requirements for each airplane design group and airport or runway designation.

Runways are usually designated based on the *magnetic azimuth* of the runway centerline. A designation will consist of a number and, in the case of parallel runways, a letter. (Single-digit runway designation numbers are not preceded by zeros.) On single runways, dual parallel runways, and triple parallel runways, the designation number will be the whole number nearest one-tenth of the magnetic azimuth when viewed from the direction of the approach. For example, if the magnetic azimuth was 192°, the runway designation marking would be 19. For a magnetic azimuth of 57°, the runway designation would be 6. For a magnetic azimuth ending with the number 5, such as 135°, the runway designation can be either 13 or 14. In the case of parallel runways, each runway designation number is supplemented by a letter (i.e., L for left and R for right) when viewed from the direction of approach (e.g., 18L or 18R).

32. DETOURS

(Geometric design of detours and other traffic controls in areas of construction, maintenance, and emergencies is covered in Part VI of MUTCD.)

Signs announcing detours and construction should be placed 1500 ft (450 m) in advance of the beginning of rechannelization. (Warning distance is not measured from the site of construction or other features.) On expressways and limited-access facilities, the advance warning distance should be increased by one half mile or more. After the initial sign, a series of additional signs should be spaced every 500 ft (150 m).

When traffic is detoured, the most important geometric element is the length of the *channelization taper*. The basic taper length is given by Eqs. 74.50 and 74.51, in which L is the taper length in ft, W is the width of the lateral offset (the lane width in lane shifts) in ft, and S is the posted speed or off-peak 85th percentile speed in mph.

$$L = \frac{WS^2}{60} \quad [v \leq 40 \text{ mph; U.S. only}] \qquad 74.50$$

$$L = WS \quad [v > 40 \text{ mph; U.S. only}] \qquad 74.51$$

Merging tapers (where two lanes merge) are longer than other nonmerging tapers and require the full taper length. When more than one lane must be closed, merged traffic should be permitted to travel approximate $2L$ before the second lane is merged. *Shifting tapers* (where traffic is moved to an entirely different travel path) require a minimum length of $L/2$, and *shoulder tapers* (preceding shoulder construction on an untraveled improved shoulder with a minimum width of 8 ft (2.4 m)) require a minimum length of $L/3$. When two-directional traffic on a two-way road is slowed, stopped, and alternately channeled into a single lane by a flagger, a *two-way traffic taper* with a maximum length of 100 ft (30 m) is used. *Downstream tapers* are optional and, where used, have lengths of 100 ft per lane.

Tapers are marked by *channelization devices* (e.g., cones) having an approximate maximum spacing in feet equal to the speed limit in mph.

Warning and taper lengths are generally not included in the length of the detour.

PRACTICE PROBLEMS

Design Speeds/Volume Parameters

1. *(Time limit: one hour)* Commuter trains travel between stations spaced 1.0 mi apart. A train arrives every 5 min, and the trains can attain a maximum speed of 80 mph. Each train has 5 cars, with a maximum capacity of 220 people per car. When the train stops, it must wait 1.0 min to allow for passenger movement. The uniform acceleration of the train is 5.5 ft/sec^2. Deceleration is 4.4 ft/sec^2. (a) What is the top speed of the train? (b) What is the maximum capacity of the line in people per hour? (c) What is the average train speed? (d) What is the average running speed? (e) In regard to the answer in part (d), explain whether the basis is time or spacing. (f) How much time would be saved between stations if the maximum speed was increased to 100 mph?

Answers: (a) 15.3 mph; (b) 13,200 passengers/hr; (c) 15 mph; (d) 12 mph; (e) time; (f) no savings

2. *(Time limit: one hour)* A rural two-lane highway passing through rolling terrain has a design speed of 60 mph. The traffic distribution is 5% trucks, 15% buses, and 80% cars, with 70% going uphill during the design hour. One particular segment of the highway is a 3% uphill grade lasting for 2 mi with 40% of that length unavailable for passing. The lane width is 11 ft, and shoulders are 6 ft wide on one side and 2 ft wide on the other. (a) What service flow rate of traffic can be carried at level of service D? (b) What service flow rate of traffic can be carried at level of service B, if level of service B is possible? (c) What treatments might be made to improve the level of service? (d) Interpolating from the results of parts (a) and (b) (i.e., without calculating service flow at other speeds or levels of service), estimate the capacity of that segment.

Answers: (a) 1523 vph; (b) 601 vph; (d) 1755 vph

3. *(Time limit: one hour)* One lane of a two-lane highway was observed for an hour during the day. The following data were gathered.

average distance between front bumpers of successive cars	80 ft
average mean speed during the study	30 mph
space mean speed	29 mph

Transportation

(a) What is the average headway? (b) What is the density in vehicles per mile? (c) What is the traffic volume in vehicles per hour? (d) What is the maximum (ideal) capacity in both directions? (e) Sketch a graph of the relationship between speed and density. (f) Sketch the relationship between speed and volume. Label the axes and indicate the region of unstable flow. (g) Sketch a graph of the relationship between volume and density. Label the axes and indicate jam density. (h) Which is a more accurate parameter of traffic capacity: volume or density? Why? (i) What is the maximum (ideal) capacity of one lane of a four-lane freeway?

Answers: (a) 1.88 sec/veh; (b) 66 vpm; (c) 1914 vph; (d) 2800 pcph; (h) volume; (i) 2200 vph

Intersection Design

4. The intersection of First Street and Main Street, located in a suburb with negligible pedestrian activity, is being investigated. The peak-hour factor on all approaches is 0.85. The signal cycle is 60 sec, two-phase. On Main Street, there is one 20 ft lane in each direction, and parking is prohibited. First Street is one-way westbound with two 11 ft lanes and parking lanes on both sides. Traffic travels equally in the two lanes of First Street. Turning on red is prohibited. All of the amber time is considered to be lost. Find the maximum service flow on First Street for level of service E.

parameter	First (westbound)	Main (northbound)	Main (southbound)
green time	27 sec	27 sec	27 sec
amber time	3 sec	3 sec	3 sec
trucks	4%	5%	5%
buses	0	0	0
left turns	10%	10%	0
right turns	10%	0	10%

Answer: 1261 vph

5. Two streets in a town of 25,000 people intersect at a stop sign: a 36 ft side street and a 44 ft arterial. There have been many complaints from the side street users that traffic signals are needed at the intersection. (a) What factors would you take into consideration when deciding whether to signalize the intersection? (b) Give a logical, step-by-step description of how you would investigate the problem. (c) Discuss how you would arrive at your recommendations. (d) If a signal is required, specify fixed timing or on-demand type decision criteria.

Economic Justification of Highway Safety Features

6. A benefit/cost analysis is to be performed to justify the installation of safety-related road improvements, such as flexible barriers and breakaway poles. What records could you use to obtain an economic value for property damage prevented and human lives saved by the safety improvements?

1. VEHICLE DYNAMICS

A moving surface vehicle (e.g., car, truck, or bus) is retarded by five major forms of resistance: inertia, grade, rolling, curve, and air resistance. The *inertia resistance* (*inertial resisting force*) is calculated from the vehicle mass and acceleration.

$$F_i = ma \quad \text{[SI]} \qquad 75.1(a)$$

$$F_i = \frac{ma}{g_c} = \frac{wa}{g} \quad \text{[U.S.]} \qquad 75.1(b)$$

For a vehicle ascending a constant incline ϕ, the *grade resistance* is the component of the vehicle weight, w, acting parallel and down a frictionless inclined surface. The *grade* or *gradient*, G, is the slope in the direction of roadway. Grade is usually specified in percent. For example, a roadway with a 6% grade would increase in elevation 6 ft for every 100 ft of travel. For grades commonly encountered in road and highway design, there is essentially no difference in the road length and the horizontal measurement.

$$F_g = w \sin\phi \approx w \tan\phi = \frac{wG\%}{100} \qquad 75.2$$

The *rolling resistance* can be calculated theoretically as presented in Ch. 73. For analysis of vehicle dynamics, the coefficient of rolling friction, f_r, used in Eq. 75.3 is

Transportation

generally considered to be constant.[1] For modern vehicles, it is reported as approximately 0.010 to 0.015 and is approximately constant at 13.5 lbf per 1000 lbm of mass (130 N per kg) for all speeds up to 60 mph (97 kph). For higher speeds, it should be increased 10% for every 10% increase in speed above 60 mph (97 kph). Rolling resistance is even higher for gravel roads and roads in poor condition.

$$\begin{aligned} F_r &= f_r w \cos\phi \\ &\approx f_r w \end{aligned} \qquad 75.3$$

Curve resistance is the force exerted on the vehicle by its front wheels when the direction of travel is changing. Components of the curve resistance also impede the vehicle's forward motion, decreasing the fuel economy. As with centrifugal force, it is a function of the curve radius and vehicle speed. Curve resistance is generally obtained experimentally or from a table of typical values. When the vehicle is traveling in a straight direction, the curve resistance is zero.

Air resistance is the drag force given by Eq. 75.4, where A is the frontal cross-sectional area.

$$F_D = \frac{C_D A \rho \mathrm{v}^2}{2} \qquad \text{[SI]} \qquad 75.4(a)$$

$$F_D = \frac{C_D A \rho \mathrm{v}^2}{2 g_c} \qquad \text{[U.S.]} \qquad 75.4(b)$$

In the absence of any information about the drag coefficient and/or air density, the average air resistance for modern cars can be approximated by

$$F_D \approx 0.0011 A_{\mathrm{m}^2} \mathrm{v}^2_{\mathrm{km/h}} \qquad \text{[SI]} \qquad 75.5(a)$$

$$F_D \approx 0.0006 A_{\mathrm{ft}^2} \mathrm{v}^2_{\mathrm{mi/hr}} \qquad \text{[U.S.]} \qquad 75.5(b)$$

The *propulsion power* (excluding the power used by power steering, air conditioner, and other accessories) is given by Eq. 75.6, where the sum of all resistances may be referred to as the *tractive force* or *tractive effort*. (Appropriate conversions can be made to horsepower and kilowatts.) For a typical vehicle, only about 50% of the nominal engine horsepower (brake power) rating is available at the flywheel for propulsion (i.e., after accessories). If the power is known, Eq. 75.6 can be solved for the maximum acceleration or velocity. Since the velocity also appears in the expression for drag force, a trial and error solution may be needed.

$$P = (F_i + F_g + F_r + F_c + F_D)\mathrm{v} \qquad 75.6$$

Regardless of how much power a vehicle's engine may be capable of developing, there is a point beyond which the use of additional power will merely result in spinning the driving tires. (The maximum tractive force is $f_s w$.) Beyond that point, no additional tractive effort can be generated to overcome resistance. The maximum *tractive force* as limited by wheel spinning is found by summing moments about some point on the vehicle, typically the tire-roadway contact point for the non-driven wheels. The moment from the unknown tractive force balances the moments from all of the resistance forces.[2]

Analysis of performance under acceleration and deceleration is the same as for any body under uniform acceleration. A vehicle's instantaneous forward velocity and tangential velocity of the tires are the same.

$$\mathrm{v}_{\mathrm{vehicle}} = \mathrm{v}_{t,\mathrm{tire}} = \pi d_{\mathrm{tire}} n_{\mathrm{tire}} \qquad 75.7$$

The engine-wheel speed ratio depends on the transmission and differential gear ratios. The *transmission gear ratio* is the ratio of the engine speed to the driveshaft speed. Unless there is an *overdrive gear*, the typical transmission gear ratio used for highest speeds is approximately 1:1. The differential gear ratio (typically 2.5:1 to 4:1) is the ratio of driveshaft to tire speeds.

$$n_{\mathrm{wheel}} = \frac{n_{\mathrm{engine}}}{R_{\mathrm{transmission}} R_{\mathrm{differential}}} \qquad 75.8$$

$$R_{\mathrm{transmission}} = \frac{n_{\mathrm{engine}}}{n_{\mathrm{driveshaft}}} \qquad 75.9$$

$$R_{\mathrm{differential}} = \frac{n_{\mathrm{driveshaft}}}{n_{\mathrm{wheel}}} \qquad 75.10$$

The relationship between brake power and engine-generated torque is

$$P_{\mathrm{kW}} = \frac{T_{\mathrm{N\cdot m}} n_{\mathrm{rpm}}}{9549} \qquad \text{[SI]} \qquad 75.11(a)$$

$$P_{\mathrm{hp}} = \frac{T_{\mathrm{in\text{-}lbf}} n_{\mathrm{rpm}}}{63{,}025} \qquad \text{[U.S.]} \qquad 75.11(b)$$

Only 75 to 90% of the engine power or torque reaches the rear wheels. This represents the mechanical efficiency, η_m. The remainder is lost in the transmission, differential, and other gear-reduction devices. The engine-generated tractive effort reaching the driving wheels is

$$F_{\mathrm{tractive}} = \frac{\eta_m T R_{\mathrm{transmission}} R_{\mathrm{differential}}}{r_{\mathrm{tire}}} \qquad 75.12$$

Equation 75.13 gives the relationship between vehicle speed and engine speed. The loss fraction, i, is typically 0.02 to 0.05 and primarily accounts for slippage in the clutch and automatic transmission.

$$\mathrm{v} = \frac{2\pi n_{\mathrm{rev/sec}}(1-i)}{R_{\mathrm{transmission}} R_{\mathrm{differential}}} \qquad 75.13$$

[1] An approximate relationship between speed and coefficient of rolling resistance for vehicles operating on typical paved roads was reported in 1957 by Taborek as

$$f_r = 0.01\left(1 + \frac{\mathrm{v}_{\mathrm{ft/sec}}}{147}\right)$$

[2] Unless specific information is known about the location of the vehicle's center of gravity and other properties, assumptions may need to be made about the point of application of the resistance forces.

The mass and volumetric rates of fuel consumption can be found from the horsepower and brake specific fuel consumption.

$$\dot{m}_{\text{fuel,kg/h}} = P_{\text{brake,kW}}(\text{BSFC}_{\text{kg/kW·h}}) \quad \text{[SI]} \quad 75.14(a)$$

$$\dot{m}_{\text{fuel,lbm/hr}} = P_{\text{brake,hp}}(\text{BSFC}_{\text{lbm/hp-hr}}) \quad \text{[U.S.]} \quad 75.14(b)$$

$$\dot{Q}_{\text{fuel,L/h}} = \frac{\dot{m}_{\text{fuel,kg/h}}\left(1000\ \frac{\text{L}}{\text{m}^3}\right)}{\rho_{\text{kg/m}^3}} \quad \text{[SI]} \quad 75.15(a)$$

$$\dot{Q}_{\text{fuel,gal/hr}} = \frac{\dot{m}_{\text{fuel,lbm/hr}}\left(7.48\ \frac{\text{gal}}{\text{ft}^3}\right)}{\rho_{\text{lbm/ft}^3}} \quad \text{[U.S.]} \quad 75.15(b)$$

The distance traveled per volume of fuel (also known as *fuel economy*), s', is

$$s'_{\text{fuel,km/L}} = \frac{v_{\text{km/h}}}{\dot{Q}_{\text{fuel,L/h}}} \quad \text{[SI]} \quad 75.16(a)$$

$$s'_{\text{fuel,mi/gal}} = \frac{v_{\text{mi/hr}}}{\dot{Q}_{\text{fuel,gal/hr}}} \quad \text{[U.S.]} \quad 75.16(b)$$

Example 75.1

A 2500 lbm (1100 kg) offroad utility vehicle has a frontal area of 22 ft^2 (2.0 m^2). At 30 mph (50 km/h), the vehicle has a maximum tractive force of 320 lbf (1400 N). While traveling offroad over gravel in still air, the rolling resistance is 50 lbf per ton of vehicle weight (0.25 N/kg). The air resistance coefficient, K, is 0.002 lbf-hr^2/ft^2-mi^2 (0.04 N·hr^2/m^2·km^2). What straight gravel grade can the vehicle climb while maintaining a constant forward velocity of 30 mph (50 km/h)?

SI Solution

Since the grade is straight, there is no curve resistance. Since the speed is constant, there is no inertial resistance. Since the air resistance coefficient has units, it is not a coefficient of drag. The air resistance is

$$F_D = KAv^2 = \left(\frac{0.04\ \text{N·h}^2}{\text{m}^2\text{·km}^2}\right)(2.0\ \text{m}^2)\left(50\ \frac{\text{km}}{\text{h}}\right)^2$$
$$= 200\ \text{N}$$

The rolling resistance is

$$F_r = \left(0.25\ \frac{\text{N}}{\text{kg}}\right)(1100\ \text{kg})$$
$$= 275\ \text{N}$$

The grade resistance is

$$F_g = F_{\text{tractive}} - F_D - F_r = 1400\ \text{N} - 200\ \text{N} - 275\ \text{N}$$
$$= 925\ \text{N}$$

The maximum grade is given by Eq. 75.2.

$$G = \frac{F_g}{w} = \frac{F_g}{mg} = \frac{925\ \text{N}}{(1100\ \text{kg})\left(9.81\ \frac{\text{m}}{\text{s}^2}\right)}$$
$$= 0.0857\ \ (8.6\%)$$

Customary U.S. Solution

Since the grade is straight, there is no curve resistance. Since the speed is constant, there is no inertial resistance. Since the air resistance coefficient has units, it is not a coefficient of drag. The air resistance is

$$F_D = KAv^2 = \left(0.002\ \frac{\text{lbf-hr}^2}{\text{ft}^2\text{-mi}^2}\right)(22\ \text{ft}^2)\left(30\ \frac{\text{mi}}{\text{hr}}\right)^2$$
$$= 39.6\ \text{lbf}$$

A vehicle with a mass of 2500 lbm has a weight of 2500 lbf in standard gravity. The rolling resistance is

$$F_r = \frac{\left(50\ \frac{\text{lbf}}{\text{ton}}\right)(2500\ \text{lbf})}{2000\ \frac{\text{lbf}}{\text{ton}}}$$
$$= 62.5\ \text{lbf}$$

The grade resistance is

$$F_g = F_{\text{tractive}} - F_D - F_r = 320\ \text{lbf} - 39.6\ \text{lbf} - 62.5\ \text{lbf}$$
$$= 217.9\ \text{lbf}$$

The maximum grade is given by Eq. 75.2.

$$G = \frac{F_g}{w} = \frac{217.9\ \text{lbf}}{2500\ \text{lbf}}$$
$$= 0.08716\ \ (8.7\%)$$

2. DYNAMICS OF STEEL-WHEELED RAILROAD ROLLING STOCK

The kinematic analysis of rail rolling stock is similar to that of vehicles, though different variables and terminology are used. The *drawbar pull*, DBP, is the net tractive force (behind the locomotive) and is the force available for hauling cars. Drawbar pull is calculated from the *car resistance*, CR; *accelerating force*, AF; *tractive force at the driving axles*, TFDA; and *locomotive resistance*, LR. The *tonnage rating* is the DBP divided by the total resistance per ton for an average car. The *ruling gradient* is the maximum grade that occurs along the route and that requires the full DBP for an extended period of time. Ruling grades limit the weight (length) of a train that can be accommodated with a single locomotive.

$$\text{DBP} = \text{TFDA} - \text{LR}$$
$$= \text{CR} + \text{AF} \quad 75.17$$

Transportation

The approximate tractive effort at the driving axles of a *diesel-electric locomotive unit* is given by Eq. 75.18. Typical efficiencies, η_{drive}, of diesel-electric drive systems vary from 0.82 to 0.93, with 0.82 being typically used. The efficiency of diesel-electric locomotives is essentially constant throughout the speed range.

$$F_{\text{tractive},N} = \frac{175 P_{\text{kW,rated}} \eta_{\text{drive}}}{\text{v}_{\text{km/h}}} \quad \text{[SI]} \qquad 75.18(a)$$

$$F_{\text{tractive,lbf}} = \frac{375 P_{\text{hp,rated}} \eta_{\text{drive}}}{\text{v}_{\text{mph}}} \quad \text{[U.S.]} \qquad 75.18(b)$$

The approximate frontal area of a locomotive or passenger rail car is 100 to 120 ft^2 (9.0 to 11 m^2). Freight cars have 85 to 90 ft^2 (7.7 to 8.1 m^2) of frontal area, though this value varies greatly with the nature of the load. Incorporating the frontal area term, the air resistance coefficient, K, has representative values of 0.094 lbf-hr^2-ton/mi^2 for containers on flat cars, 0.16 lbf-hr^2-ton/mi^2 for trucks and trailers on flat cars, and 0.07 lbf-hr^2-ton/mi^2 for all other standard rail units.

The *modified Davis equation*, applicable to modern, large, streamlined rolling stock moving at fast speeds, gives the *level tangent resistance*, R. w is the average loading per axle, and wn is the total weight calculated as the average axle load times the number of axles.

$$R_{\text{lbf/ton}} = 0.6 + \frac{20}{w_{\text{tons}}} + 0.01\text{v}_{\text{mph}} + \frac{K\text{v}_{\text{mph}}^2}{w_{\text{tons}} n} \quad \text{[US only]} \qquad 75.19$$

The *incidental resistances* include effects due to grade, curvature, and wind. The *grade resistance* is 20 lbf per ton for each percentage grade (i.e., essentially the weight times the grade). The *curve resistance* is approximately 0.8 lbf/ton (0.004 N/kg) per degree of curvature. Railroad curve resistance is considered equivalent to a grade resistance of 0.04% per degree of curvature. When the grade is "compensated," the compensated grade resistance includes the curve resistance, and curve resistance can be disregarded when calculating power requirements.

3. COEFFICIENT OF FRICTION

In most cases, a vehicle's braking system is able to provide more braking force than can be transmitted to the pavement. Therefore, the maximum deceleration is limited by the coefficient of friction between the tires and pavement.

The *coefficient of friction*, f, between a vehicle and the supporting roadway is the frictional force, F_f, divided by the normal force, N. The *normal force* is essentially the total weight of the vehicle, w, on all but the most extreme grades. The coefficient of friction is dependent on the condition of the vehicle's tires, the type and condition of the pavement, and the weather conditions.

$$f = \frac{F_f}{N} \qquad 75.20$$

There are two coefficients of friction: static and dynamic (kinetic). (The coefficients of friction may also be referred to as *coefficients of road adhesion.*) The *coefficient of static friction* is larger than the coefficient of dynamic (kinetic) friction. While a vehicle's tires are rotating, the relative velocity between a point of contact on the tire and roadway is zero and the coefficient of static friction controls.

Once a vehicle enters a skid, however, the *coefficient of dynamic friction* controls. Therefore, a vehicle held to its maximum braking deceleration without entering a skid (i.e., the skid is impending) will take less distance to come to a complete stop than if the vehicle locks up its tires and skids to a stop.

The coefficient of friction is not constant throughout the braking maneuver, but varies inversely with speed. This level of sophistication is not normally considered, and an average value that is representative of the speed and conditions is used.

Table 75.1 *Typical Coefficients of Skidding Friction*

speed in mph (km/h)		type of pavement[a] AC	SA	RA	PCC	wet
vehicles with new tires						
11	(18)	0.74	0.75	0.78	0.76	–
20	(30)	0.76	0.75	0.76	0.73	0.40
30	(50)	0.79	0.79	0.74	0.78	0.36
40	(65)	0.75	0.75	0.74	0.76	0.33
50	(80)					0.31
60	(100)					0.30
70	(115)					0.29
vehicles with badly worn tires						
11	(18)	0.61	0.66	0.73	0.68	–
20	(30)	0.60	0.57	0.65	0.50	0.40
30	(50)	0.57	0.48	0.59	0.47	0.36
40	(65)	0.48	0.39	0.50	0.33	0.33
50	(80)					0.31
60	(100)					0.30
70	(115)					0.29

(Multiply mph by 1.609 to obtain km/h.)
[a]AC—asphalt concrete, dry; SA—sand asphalt, dry; RA—rock asphalt, dry; PCC—portland cement concrete, dry; wet—all wet pavements.

Table compiled from a variety of sources; values vary widely.

4. ANTILOCK BRAKES

When a vehicle begins to skid, the driver becomes unable to steer. An *antilock (antiskid) braking system* (ABS), also known as a *brake assist system* (BAS), detects an impending skid and alternately removes and applies hydraulic pressure from the hydraulic brake system. This is equivalent to the driver rapidly "pumping" the brakes, a common antiskid strategy. The application of the hydraulic pressure pulses is approximately

18 times per second. The effect is to allow the tires to rotate slightly, preventing the skid and allowing the driver to steer. There are no skid marks with antilock brakes.

On wet pavement and ice, ABS will generally bring the vehicle to a stop in a shorter distance than if the vehicle were to go into a skid. Since the static coefficient of friction in a "skid-impending" braking maneuver is greater than the dynamic coefficient, the ABS braking distance on dry pavement should also be less. However, inasmuch as the average driver is unable to apply "just the right amount" of braking to achieve the maximum deceleration, the braking distance is essentially unchanged, and the primary benefit is being able to steer. On gravel and snow-covered roads, ABS braking distances can be greater than distances without ABS, since the tires of a skidding vehicle will dig through the upper layers of loose gravel or snow to find a solid layer with a greater coefficient of friction.

While ABS is active, a loud grating sound is heard and the brake pedal rapidly pulsates. This alarms some drivers and causes them to pump their brakes or remove pressure entirely from the brake pedal, eliminating the benefits of the ABS system. Also, some drivers tend to jerk the steering wheel during an ABS-assisted stop, causing the vehicle to go off course, often into an opposing lane. Because of these problems, many car insurance companies no longer offer discounts for ABS-equipped vehicles.

5. STOPPING DISTANCE

Stopping distance includes the distance traveled before the brakes are applied as well as the distance during the braking maneuver. The *braking perception-reaction time*, t_p, is also referred to as the *PIEV time*, using an acronym for perception, identification, emotion, and volition. PIEV time varies widely from person to person. Though the median value is approximately 0.90 sec for unexpected (unanticipated) events, individuals with slow reaction times may require up to 2.7 sec. 2.5 sec is the value used by AASHTO for determining the minimum *stopping sight distances*, the value that is appropriate for approximately 90% of the population [AASHTO *Green Book*, Chap. III]. For determining *passing sight distances*, PIEV time is approximately 3.5 to 4.5 sec, depending on the speed [AASHTO *Green Book*, Table III-4].

$$s_{\text{stopping}} = \text{v}t_p + s_b \qquad 75.21$$

6. BRAKING AND DECELERATION RATE

The maximum deceleration that can be developed in dry weather by a vehicle with tires and brakes in good condition is about 25 ft/sec^2 (7.5 m/s^2). (Acceleration and deceleration are sometimes specified in miles per hour per second, mphps, or kilometers per hour per second, kphps. Multiply mphps by 1.467 to obtain ft/sec^2, and multiply kphps by 0.278 to obtain m/s^2.) However, decelerations of 14 ft/sec^2 (4.2 m/s^2) are experienced by occupants as uncomfortable and alarming. 11 ft/sec^2 (3.3 m/s^2) is the approximate upper limit of desirable decelerations, and approximately 9 ft/sec^2 (2.7 m/s^2) is the maximum comfortable deceleration from high-speed travel.

If a vehicle locks its brakes and begins to skid on level ground, the deceleration rate will be $f_{\text{dynamic}}g$.

$$a = fg = f\left(9.81\ \frac{\text{m}}{\text{s}^2}\right) \qquad \text{[SI]} \quad 75.22(a)$$

$$a = fg = f\left(32.2\ \frac{\text{ft}}{\text{sec}^2}\right) \qquad \text{[U.S.]} \quad 75.22(b)$$

7. BRAKING AND SKIDDING DISTANCE

The braking/skidding distance required to come to a complete stop depends on friction and grade and can be calculated from Eq. 75.23. This distance is exclusive of the time traveled during PIEV time.

$$s_b = \left(\frac{\text{v}^2}{2g}\right)(f\cos\theta + \sin\theta) \qquad 75.23$$

The incline angle, θ, is small, so $\cos\theta \approx 1.0$, and $\sin\theta \approx \tan\theta = G$. The decimal grade, G, is positive when the skid is uphill and negative when the skid is downhill.

$$s_b = \frac{\text{v}^2}{2g(f+G)} = \frac{\text{v}_{\text{km/h}}^2}{254(f+G)} \qquad \text{[SI]} \quad 75.24(a)$$

$$s_b = \frac{\text{v}^2}{2g(f+G)} = \frac{\text{v}_{\text{mph}}^2}{30(f+G)} \qquad \text{[U.S.]} \quad 75.24(b)$$

Equations 75.23 and 75.24 do not apply directly to situations where the vehicle is brought to an abrupt stop by a collision or when the driver stops braking during the skid and continues on at a slower speed. In such cases, the actual skid length can be calculated as the difference in skidding distance to come to a complete stop from the initial speed and the skidding distance to come to complete stop from the final speed (i.e., the impact speed in the case of collisions).

Example 75.2

A 4000 lbm (1800 kg) car traveling at 80 mph (130 km/h) locks up its wheels, decelerates at a constant rate, and slides 580 ft (175 m) along a level road before stopping. (a) How much time does it take to stop?

(b) What is the acceleration? (c) What is the retarding force? (d) What is the coefficient of friction between the tires and the road?

SI Solution

(a) This is a case of uniform acceleration. The initial velocity is

$$v_o = \frac{\left(130\ \frac{\text{km}}{\text{h}}\right)\left(1000\ \frac{\text{m}}{\text{km}}\right)}{3600\ \frac{\text{s}}{\text{h}}} = 36.1\ \text{m/s}$$

The stopping distance, s, is 175 m. The final velocity, v, is 0.

$$t = \frac{2s}{v_o + v} = \frac{(2)(175\ \text{m})}{36.1\ \frac{\text{m}}{\text{s}} + 0} = 9.69\ \text{s}$$

(b) Use the uniform acceleration formulas.

$$a = \frac{v - v_o}{t} = \frac{0 - 36.1\ \frac{\text{m}}{\text{s}}}{9.69\ \text{s}} = -3.7\ \text{m/s}^2$$

(c) $$F_f = ma = (1800\ \text{kg})\left(3.7\ \frac{\text{m}}{\text{s}^2}\right) = 6660\ \text{N}$$

(d) $$f = \frac{F_f}{N} = \frac{F_f}{mg} = \frac{6660\ \text{N}}{(1800\ \text{kg})\left(9.81\ \frac{\text{m}}{\text{s}^2}\right)} = 0.38$$

Customary U.S. Solution

(a) This is a case of uniform acceleration. The initial velocity is

$$v_o = \frac{\left(80\ \frac{\text{mi}}{\text{hr}}\right)\left(5280\ \frac{\text{ft}}{\text{mi}}\right)}{3600\ \frac{\text{sec}}{\text{hr}}} = 117.3\ \text{ft/sec}$$

The stopping distance, s, is 580 ft. The final velocity, v, is 0.

$$t = \frac{2s}{v_o + v} = \frac{(2)(580\ \text{ft})}{117.3\ \frac{\text{ft}}{\text{sec}} + 0} = 9.89\ \text{sec}$$

(b) Use the uniform acceleration formulas.

$$a = \frac{v - v_o}{t} = \frac{0 - 117.3\ \frac{\text{ft}}{\text{sec}}}{9.89\ \text{sec}} = -11.9\ \text{ft/sec}^2$$

(c) Use Eq. 75.1.

$$F_f = \left(\frac{m}{g_c}\right)a = \left(\frac{4000\ \text{lbm}}{32.2\ \frac{\text{ft-lbm}}{\text{lbf-sec}^2}}\right)\left(11.9\ \frac{\text{ft}}{\text{sec}^2}\right) = 1480\ \text{lbf}$$

(d) $$f = \frac{F_f}{N} = \frac{1480\ \text{lbf}}{4000\ \text{lbf}} = 0.37$$

Example 75.3

A car traveling at 80 mph (130 km/h) locks up its wheels and skids up a 3% incline before crashing into a stationary massive concrete pedestal and coming to a complete stop. The skid marks leading up to the pedestal are 300 ft (90 m) long. The coefficient of friction between the tires and road is 0.35. (a) How far would the car have skidded if it had not hit the pedestal? (b) What was the speed of the car at impact?

SI Solution

(a) Use Eq. 75.24. The grade is positive since the car skids uphill.

$$s_b = \frac{v_{\text{km/h}}^2}{254(f + G)} = \frac{\left(130\ \frac{\text{km}}{\text{h}}\right)^2}{(254)(0.35 + 0.03)} = 175.1\ \text{m}$$

(b) Since the skid marks were only 90 m long, the vehicle would have skidded 175.1 m − 90 m = 85.1 m further. Solve Eq. 75.24 for the speed.

$$85.1\ \text{m} = \frac{v_{\text{km/h}}^2}{254(f + G)} = \frac{v^2}{(254)(0.35 + 0.03)}$$

$$v = 90.6\ \text{km/h}$$

Customary U.S. Solution

(a) Use Eq. 75.24. The grade is positive since the car skids uphill.

$$s_b = \frac{v_{\text{mph}}^2}{30(f + G)} = \frac{\left(80\ \frac{\text{mi}}{\text{hr}}\right)^2}{(30)(0.35 + 0.03)} = 561.4\ \text{ft}$$

(b) Since the skid marks were only 300 ft long, the vehicle would have skidded 561.4 ft − 300 ft = 261.4 ft further. Solve Eq. 75.24 for the speed.

$$261.4 \text{ ft} = \frac{v_{mph}^2}{30(f+G)} = \frac{v^2}{(30)(0.35+0.03)}$$

$$v = 54.6 \text{ mph}$$

8. SPEED DEGRADATION ON UPHILL GRADES

Most modern passenger cars traveling on highways are capable of negotiating uphill grades of 4 to 5% without speed decreases below their initial level-highway speeds. (Older cars with high mass-to-power ratios and some smaller-sized "economy" vehicles may experience speed decreases.)

Heavy trucks experience greater speed degradations than passenger cars. The primary variables affecting actual speed decreases are the grade steepness, the grade length, and the truck's mass-to-power ratio. *Mass-to-power ratios* are commonly stated in pounds per horsepower (lbm/hp) and kilograms per kilowatt (kg/kW). (Multiply lbm/hp by 0.6083 to obtain kg/kW.) Chapter III of AASHTO's *Green Book* contains simple graphs of speed decreases for "heavy trucks" with mass-to-power ratios of 300 lbm/hp (180 kg/kW) and recreational vehicles entering ascending grades at 55 mph (90 km/h).

9. ANALYSIS OF ACCIDENT DATA

Accident data are compiled and evaluated to identify hazardous features and locations, set priorities for safety improvements, support economic analyses, and identify patterns, causes (i.e., driver, highway, or vehicle), and possible countermeasures.

Accidents are classified into three *severity categories*, depending on whether there is (a) property damage only (referred to as *PDO accidents*), (b) personal injury, or (c) fatalities. The *severity ratio* is defined as the ratio of the number of injury and fatal accidents divided by the total number of all accidents (including PDO accidents.)

It is common to prioritize intersections according to the *accident rate*, R. The accident rate may be determined for PDO, personal injury, and fatal accidents, or the total thereof. The accident ratio is the ratio of the number of accidents per year to the average daily traffic, ADT. The rate is reported as an RMEV (i.e., rate per million entering vehicles).

$$R = \frac{(\text{no. of accidents})(10^6)}{(\text{ADT})(\text{no. of years})\left(365 \dfrac{\text{days}}{\text{yr}}\right)} \qquad 75.25$$

Routes (segments or links) between points are prioritized according to the accident rate per mile (per kilometer), calculated as the ratio of the number of accidents per year to the ADT per mile (kilometer) of length, counting traffic from all directions in the intersection. For convenience, the rate may be calculated per 100 million vehicle miles (HMVM).

$$R = \frac{(\text{no. of accidents})(10^8)}{(\text{ADT})(\text{no. of years})\left(365 \dfrac{\text{days}}{\text{yr}}\right) L_{\text{mi}}} \qquad 75.26$$

To identify the most dangerous features, it is necessary to determine what the accidents at an intersection or along a route had in common. This can be done in a number of ways, one of which is by drawing a collision diagram. A *collision diagram* is essentially a true-scale cumulative drawing of the intersection showing details of all of the accidents in the study. Dates, times, weather conditions, types of maneuvers, directions, severity, types of accidents, and approximate locations are recorded on the diagram.

Common *accident-type* categories include: rear-end, right-angle, left-turn, fixed-object, sideswipe, parked-vehicle, run off road, head-on, bicycle-related, and pedestrian-related.

Hypothesis testing can be used to determine if installed countermeasures are being effective. The *null hypothesis* is that the highway improvements have brought no significant decrease in accident rate. The counterhypothesis is that the highway improvements have brought significant decreases. A chi-squared test with a 5% confidence level is used to evaluate the two hypotheses.

10. ROAD SAFETY FEATURES

(Economic justification of road safety features is covered in Chap. 74.)

Road safety features are installed to protect public life and property and to reduce traffic-related lawsuits against highway and transportation departments. The most common actions include the installation of illumination, guardrails, and impact attenuators, as well as the relocation of dangerous facilities.

Guardrails are used on roadways where there is a severe slope or vertical dropoff to the side of the road, ditches, permanent bodies of water, embankments, and roadside obstacles (e.g., boulders, retaining walls, and sign and signal supports). Guardrails with turned-down ends are now prohibited in new installations and should be upgraded. Such guardrails, rather than protecting motorists from a fixed impact or spearing, often cause *vaulting* (also known as *launching* or *ramping*) and subsequent rollover.

Impact attenuators are used to provide crash protection at bridge pillars, center piers, gore areas, butterfly signs, light posts, and ends of concrete median barriers. These are mainly of the *crash cushion* variety (sand barrel, water barrel, and Hi-Dro® water-tube arrays), sandwich-type units, and crushable cartridges (including the G-R-E-A-T® "Guard Rail Energy Absorbing

Terminal" manufactured by Energy Absorption Systems, Chicago, IL, which uses crushable Hex-Foam® units surrounded by a framework of triple-corrugated steel guardrail).

Slip- and breakaway- (frangible coupling) bases are used on poles of roadside luminaires and signs to prevent vehicles from "wrapping around" the poles. Hinged and weakened bases for high-voltage power poles, however, may violate other codes (e.g., the *National Electric Code*) designed to prevent high-voltage wires from dropping on the public below. Other solutions, such as placing utility lines underground, increasing lateral offset or longitudinal pole spacing, or dividing the load over multiple poles, should be considered.

PRACTICE PROBLEMS

Collisions

1. Two cars are moving at 60 mph in the same direction and in the same lane. The cars are separated by 20 ft for each 10 mph of their speed. The coefficient of friction (skidding) between the tires and the roadway is 0.6. The reaction time is assumed to be 0.5 sec. (a) If the lead car hits a parked truck, what is the speed of the second car when it hits the first (stationary) car? (b) At what speed does the rule of thumb of one car length (i.e., 20 ft) per 10 mph become unsafe? (c) At 60 mph, what should the rule actually be?

Answers: (a) 69.3 ft/sec (47.3 mph); (b) 33.4 ft/sec (22.7 mph); (c) approximately two car lengths for every 10 mph

2. You have been hired by the owner of a damaged house to investigate the car crash that caused the damage. From the police report, you learn that the car was traveling down a 3% grade at an unknown speed. The skid marks are 185 ft (56 m) long, and the pavement was dry at the time of the accident. The police report estimates that the initial speed of the car was 25 mph (40 km/h). From an inspection, you know that the car's tires were new. The house owner does not believe the estimate of initial speed. You have the following data from tests performed on level roadways.

initial speed in mph (km/h):	30 (50)	40 (60)	50 (80)	60 (100)
coefficient of friction:	0.59	0.51	0.45	0.35

(a) Find the minimum initial speed of the car. (b) If the police report was mistaken in assuming the road surface was dry, what was the minimum initial speed of the car?

Answers: (a) 49 mph; (b) 41 mph

3. *(Time limit: one hour)* You are hired as a consultant to give expert evidence in a court action arising from a vehicle collision. The two vehicles collided head-on while traveling on a curve tangent with a 4% grade. Vehicle A skidded 195 ft downhill before colliding with vehicle B. Vehicle B skidded 142 ft. The police report estimates that both vehicles were traveling at 25 mph prior to the collision, based on vehicle deformation. (a) What were the respective speeds of the two vehicles prior to the application of brakes if the coefficient of friction is assumed to be 0.48? (b) Which of your assumptions (impact speed or coefficient of friction) produces the greatest possible error in your initial speed calculations?

Answers: (a) vehicle A: 56.6 mph, vehicle B: 53.3 mph; (b) The coefficient of friction is more sensitive to error.

Accident Data Analysis

4. *(Time limit: one hour)* Four intersections and five segments of highway have been evaluated using prior years' accident data. (a) Calculate the number of accidents per million vehicles for each intersection. Rank the intersections in order of highest to lowest need for improvement. (b) For the highway segments, calculate the number of accidents per year per million vehicle miles. Rank the segments in order of highest to lowest need for improvement. (c) Explain why calculations in (a) and (b) should be done. (d) Assume that the intersections varied in terms of the fractions of accidents that were fatal, injury, and property damage only. How would you compare the safety needs at those intersections?

intersection	ADT	accidents/year
A	820	4
B	1200	5
C	1070	7
D	1400	6

highway segment	ADT	accidents/year	length, mi (km)
1	1900	1	1.50 (2.41)
2	2000	14	1.35 (2.17)
3	5500	18	4.50 (7.24)
4	3000	11	0.53 (0.85)
5	4000	30	2.48 (4.00)

Answers: (a) C, A, D, B; (b) 4, 2, 5, 3, 1; (c) to rank improvement priorities; (d) weight by cost (i.e., value) of accident

1. ASPHALT CONCRETE PAVEMENT

Hot mix asphalt (HMA), commonly referred to as *asphalt concrete* (AC), *bituminous mix* (BM), and sometimes *hot mix asphaltic concrete* (HMAC), is a mixture

of *asphalt cement* (*asphalt binder*) and well-graded, high-quality aggregate. The mixture is heated and compacted by a paving machine into a uniform dense mass.

AC pavement is used in the construction of traffic lanes, auxiliary lanes, ramps, parking areas, frontage roads, and shoulders. AC pavement adjusts to limited amounts of differential settlement. It is easily repaired, and additional thicknesses can be placed at any time to withstand increased usage and loading. Over time, its nonskid properties do not significantly deteriorate. However, as the asphalt oxidizes, it loses some of its flexibility and cohesion, often requiring resurfacing sooner than would be needed with portland cement concrete. Asphalt concrete is not normally chosen where water is expected to permeate the surface layer.

Most AC pavement is usually applied over several other structural layers, not all of which are necessarily AC layers. A *full-depth asphalt pavement* consists of asphalt mixtures in all courses above the subgrade. Since asphalt and asphalt-treated bases are stronger than untreated granular bases, the surface pavement can be thinner. Other advantages of full-depth pavements include a potential decrease in trapped water within the pavement, a decrease in the moisture content of the subgrade, and little or no reduction in subgrade strength.

If the asphalt layer is thicker than approximately 4 in (102 mm) and is placed all in one lift, or if lift layers are thicker than 4 in (102 mm), the construction is said to be *deep strength asphalt pavement*. Using deep lifts to place layers of hot-mix asphalt concrete is advantageous for several reasons. (a) Thicker layers hold heat longer, making it easier to roll the layer to the required density. (b) Lifts can be placed in cooler weather. (c) One lift of a given thickness is more economical to place than multiple lifts equaling the same thickness. (d) Placing one lift is faster than placing several lifts. (e) Less distortion of the asphalt course will result than if thin lifts are rolled.

Modern advances in asphalt concrete paving include *Superpave* (Sec. 24) and *stone matrix asphalt* (Sec. 25). Both of these are outgrowths of the U.S. Strategic Highway Research Program (SHRP).

2. OTHER ASPHALT APPLICATIONS

Other types of asphalt products used in paving include *emulsified asphalts*, both anionic and cationic (depending on the charge of the emulsifying agent), and *cutback asphalts*, which are graded based on the speed at which the volatile substance used to liquefy the asphalt cement evaporates. Cutback asphalts may be referred to as RC, MC, and SC, referring to *rapid cure*, *medium cure*, and *slow cure* agents, respectively. Other applications of asphalt cement in construction include cold-mix asphalt mixtures, recycled road mixtures (both hot and cold), and surface treatments, which include seal coats, chip seals, slurry seals, and fog-coats.

3. ASPHALT GRADES

Asphalt varies significantly in its properties. In general, softer grades are used in colder climates to resist the expansion and contraction of the asphalt concrete caused by thermal changes. Harder grades of asphalt are specified in warmer climates to protect against rutting.

In the past, asphalt cement has been graded by *viscosity grading* and *penetration grading* methods. *Penetration grading* is based upon the penetration of a standard-sized needle loaded with a mass of 100 g in 5 sec at 77°F (25°C). A penetration of 40 to 50 (in units of mm) is graded as hard, and a penetration of 200 to 300 is soft. Intermediate ranges of 60 to 70, 85 to 100, and 120 to 150 have also been established. A penetration-graded asphalt is identified by its range and the word "pen" (e.g., "120 to 150 pen").

Viscosity grading is based on a measure of the absolute viscosity (tendency to flow) at 140°F (60°C). A viscosity measurement of AC-40 is graded as hard, and a measurement of AC-2.5 is soft. Intermediate ranges of AC-5, AC-10, and AC-20 have been established.

To meet the minimum specified viscosity requirements, oil suppliers have typically added more "light ends" (liquid petroleum distillates) to soften asphalt, regardless of the effects that such additions might have on structural characteristics. Concerns about the effects of such additions include oily buildup in mixing plant baghouses, light-end evaporation during pavement life, and possible reduced roadway performance.

Most state transportation and highway departments have stopped using penetration grading and have switched to performance grading. The *performance grading* (PG) system, which is used in Superpave™ and other designs, eliminates the structural concerns by specifying other characteristics. PG grading is specified by two numbers, such as PG 64-22. These two numbers represent the high and low (seven-day average) pavement temperature in degrees Celsius that the project location will likely experience in its lifetime. Both high and low temperature ratings have been established in 6° increments.

PG ratings can be achieved with or without polymers, at the supplier's preference. However, the "rule of 90" says that if the sum of the absolute values of the two PG numbers is 90 or greater, then a polymer-modified asphalt is needed. Asphalts without polymers can be manufactured "straight-run."

The use of *recycled asphalt pavement* (RAP) in the mixture has an effect on the asphalt grade specified. However, specifying less than 15 to 25% RAP generally does not require a different asphalt cement grade to be used.

Table 76.1 Superpave™ Binder Grades[a] (°C)

high-temperature grades	low-temperature grades
PG 46	-34, -40, -46
PG 52	-10, -16, -22, -28, -34, -40, -46
PG 58	-16, -22, -28, -34, -40
PG 64	-10, -16, -22, -28, -34, -40
PG 70	-10, -16, -22, -28, -34, -40
PG 76	-10, -16, -22, -28, -34
PG 82	-10, -16, -22, -28, -34

[a]For example, PG 52-16 would be applicable in the range of 52°C down to −16°C.

4. AGGREGATE

The *mineral aggregate* component of the asphalt mixture comprises 90 to 95% of the weight and 75 to 85% of the mix volume. Mineral aggregate consists of sand, gravel, or crushed stone. The size and grading of the aggregate is important, as the minimum lift thickness depends on the maximum aggregate size. Generally, the minimum lift thickness should be at least three times the nominal maximum aggegate size. However, compaction is not an issue with open-graded mixes, since it is intended that the final result be very open. Therefore, the maximum-size aggregate can be as much as 80% of the lift thickness.

Generally, *coarse aggregate* is material retained on a no. 8 sieve (2.36 mm openings), *fine aggregate* is material passing through a no. 8 sieve (2.36 mm), and *mineral filler* is fine aggregate for which at least 70% passes through a no. 200 sieve (75 m openings). The fine aggregate should not contain organic materials.

Aggregate size grading is done by sieving. Results may be expressed as either the percent passing through the sieve or the percent retained on the sieve, where the percent passing and the percent retained add up to 100%.

The maximum size of the aggregate is determined from the smallest sieve through which 100% of the aggregate passes. The *nominal maximum size* is designated as the largest sieve that retains some (but not more than 10%) of the aggregate.

An *asphalt mix* is specified by its nominal size and a range of acceptable passing percentages for each relevant sieve size, such as is presented in Table 76.2. The properties of the final mixture are greatly affected by the grading of aggregate. Aggregate grading can be affected by stockpile handling, cold-feed proportioning, degradation at impact points (more of an issue with batch plants), dust collection, and the addition of baghouse fines to the mix. Aggregates not only can become segregated; they also can be contaminated with other materials in adjacent stockpile.

Dense-graded mixtures contain enough fine, small, and medium particles to fill the majority of void space between the largest particles without preventing direct contact between all of the largest particles. Aggregate for most HMA pavement is *open graded*, which means that insufficient fines and sand are available to fill all of the volume between the aggregate. Asphalt cement is expected to fill such voids. *Gap-graded mixtures* (as used in stone matrix asphalt and Superpave™) are mixtures where two sizes (very large and very small) predominate.

Open-graded friction courses (OGFCs) have experienced problems with asphalt stripping, drain down, and raveling. Properly formulated, mixes perform reasonably well, though they are susceptible to problems when the voids become plugged, retain moisture, or become oxidized.

5. PAVEMENT PROPERTIES

Several properties are desirable in an asphalt mixture, including stability, durability, flexibility, fatigue resistance, skid resistance, impermeability, and workability. *Stability* refers to the ability to resist permanent deformation, usually at high temperatures over a long time period. It depends on the amount of internal friction present in the mixture, which is in turn dependent on aggregate shape and surface texture, mix density, and asphalt viscosity. Lack of stability results in rutting in wheel paths, shoving at intersections, bleeding or flushing, and difficulty in compaction.

Durability refers to the ability of a mixture to resist disintegration by weathering. A mixture's durability is enhanced by a high asphalt content, dense aggregate gradation, and high density. Lack of durability results in raveling, early aging of the asphalt cement, and stripping.

A mixture's *flexibility* refers to its ability to conform to the gradual movement due to temperature changes or settlement of the underlying pavement layers. Flexibility is enhanced by a high asphalt content, open gradation, and low asphalt viscosity. A lack of flexibility can result in transverse or block cracking and shear failure cracking.

Fatigue resistance refers to the ability to withstand repeated wheel loads. A mixture's fatigue resistance can be enhanced with the presence of dense aggregate gradation and high asphalt content. Lack of fatigue resistance will result in fatigue or alligator cracking.

Skid resistance refers to the ability to resist tire slipping or skidding. An asphalt mixture with the optimum asphalt content, angular surface aggregates, and hard, durable aggregates will provide adequate skid resistance. The *polishing characteristics* of the aggregate need to be determined before use, either by lab polishing, insoluble residue tests, or previous service records. ASTM procedure C131, "Resistance to Degradation of Small-Size Coarse Aggregate by Abrasion and Impact in

Table 76.2 *Typical Composition of Asphalt Concrete*

		mix designation and nominal maximum size of aggregate				
		1½ in (37.5 mm)	1 in (25.0 mm)	¾ in (19.0 mm)	½ in (12.5 mm)	⅜ in (9.5 mm)

no. 200[b]	(0.075 mm)	0 to 5	1 to 7	2 to 8	2 to 10	2 to 10
asphalt cement weight percent of total mixture[c]		3 to 8	3 to 9	4 to 10	4 to 11	5 to 12
		suggested coarse aggregate size numbers				
		4 and 67 or 4 and 68	5 and 7 or 57	67 or 68 or 6 and 8	7 or 78	8

[a]In considering the total grading characteristics of an asphalt paving mixture, the amount passing the no. 8 (2.36 mm) sieve is a significant and convenient field control point between fine and coarse aggregate. Gradings approaching the maximum amount permitted to pass the no. 8 (2.36 mm) sieve will result in pavement surfaces having a comparatively fine texture, while gradings approaching the minimum amount passing the no. 8 (2.36 mm) sieve will result in surfaces with a comparatively coarse texture.

[b]The material passing the no. 200 (0.075 mm) sieve may consist of fine particles of the aggregates or mineral filler, or both. It shall be free from organic matter and clay particles and have a plasticity index not greater than 4 when tested in accordance with ASTM Method D 423 and Method D 424.

[c]The quantity of asphalt cement is given in terms of weight percent of the total mixture. The wide difference in the specific gravity of various aggregates, as well as a considerable difference in absorption, results in a comparatively wide range in the limiting amount of asphalt cement specified. The amount of asphalt required for a given mixture should be determined by appropriate laboratory testing or on the basis of past experience with similar mixtures, or by a combination of both.

Reprinted with permission of the Asphalt Institute from *The Alphalt Handbook, Manual Series No. 4 (MS-4)*, 1989 ed., Fig. 3.6, copyright © 1989.

Los Angeles Machine," known as the *Los Angeles Abrasion Test* and the *Los Angeles Rattler Test*, is used to determine the durability of the aggregate and quality of long-term skid resistance. Prepared aggregate is placed in a drum with steel balls. The drum is rotated a specific number of times (e.g., 500), and the mass loss is measured.

A mixture's *impermeability* refers to its resistance to the passage of water and air. Impermeability is enhanced with a dense aggregate gradation, high asphalt content, and increased compaction. Permeable mixtures may result in stripping, raveling, and early hardening.

Workability refers to the ease of placement and compaction. A mixture's workability is enhanced by a proper asphalt content, smaller-size coarse aggregates, and proper mixing and compacting temperatures.

6. PROBLEMS AND DEFECTS

Various terms are used to describe the problems and defects associated with the mixing, placing, and functionality of HMA pavements.

- *alligator cracks:* interconnected cracks forming a series of small blocks resembling the marking on alligator skin or chicken wire

- *bleeding:* forming a thin layer of asphalt that has migrated upward to the surface (same as "flushing")
- *blowing:* see "pumping"
- *blow-up:* a disintegration of the pavement in a limited area
- *channeling:* see "rutting"
- *cold-cracking:* separation of pavement caused by temperature extremes, usually observed as cracks running perpendicular to the road's centerline
- *corrugations:* plastic deformation characterized by ripples across the pavement
- *cracking:* separation of pavement caused by loading, temperature extremes, and fatigue
- *disintegration:* breakup of pavement into small, loose pieces
- *drain-down:* liquid asphalt draining through the aggregate in a molten stage
- *faulting:* a difference in the elevations of the edges of two adjacent slabs
- *flushing:* see "bleeding"
- *lateral spreading cracking:* longitudinal cracking that occurs when the two edges of a road embankment supporting a pavement move away from the center
- *placement problems:* tender mixes
- *plastic instability:* excessive displacement under traffic
- *polishing:* aggregate surfaces becoming smooth and rounded (and subsequently, slippery) under the action of traffic
- *pothole:* a bowl-shaped hole in the pavement
- *pumping:* a bellows-like movement of the pavement, causing trapped water to be forced or ejected through cracks and joints
- *raveling:* a gradual, progressive loss of surface material caused by the loss of fine and increasingly larger aggregate from the surface, leaving a pockmarked surface
- *reflective cracking (crack reflection):* cracking in asphalt overlays that follow the crack or joint pattern of layers underneath
- *rutting:* channelized depressions that occur in the normal paths of wheel travel
- *scaling:* the peeling away of an upper layer
- *shoving:* pushing the pavement around during heavy loading, resulting in bulging where the pavement abuts an immobile edge
- *slippage cracking:* cracks in the pavement surface, sometimes crescent-shaped, that point in the direction of the wheel forces
- *spalling:* breaking or chipping of the pavement at joints, cracks, and edges
- *streaking:* alternating areas (longitudinal or transverse) of asphalt caused by uneven spraying
- *stripping:* asphalt not sticking to aggregate, water susceptibility
- *upheaving:* a local upward displacement of the pavement due to swelling of layers below
- *washboarding:* see "corrugations"

7. ASPHALT MODIFIERS

By itself, asphalt performance cannot be predicted with a good degree of confidence, particularly in the modern mixtures (e.g., Superpave™) that place greater demands on asphalt. *Asphalt modifiers* are added to improve the characteristics and reliability of the asphalt binder, improve the performance of the HMA, and reduce cost. Table 76.3 lists some of the types of modifiers.

Table 76.3 *Types of Asphalt Modifiers*

category	examples
mineral fillers	dust, lime, portland cement, and carbon black
extenders	sulfur and lignin
rubbers	natural latex, synthetic latex (styrene-butadiene), block copolymer (styrene-butadiene-styrene), and reclaimed rubber
plastics	polyethylene, polypropylene, ethylene-vinyl-acetate, and polyvinyl chloride
fibers	asbestos[a], rock wool, polypropylene, and polyester
oxidants	manganese and other mineral salts
antioxidants	lead compounds, carbon, and calcium salts
hydrocarbons	recycling oils and rejuvenating oils
antistrip materials	amines and lime

[a] Asbestos may be prohibited in current formulations.

One major type of modifier is *polymers*, which come in two varieties: rubber types and plastic types. Rubber-type "elastomers" (e.g., latexes, block copolymers, and reclaimed rubber) toughen asphalt, whereas plastic-type "plastomers" (polybutadiene and polyisoprene) stiffen it. *Polymer-modified asphalt* (PMA) is more resistant to rutting, cold-cracking, and other durability problems.

In hot-mix, dense-graded mixtures, *synthetic latex* is the most common additive, providing improved resistance to rutting, shoving, and thermal cracking; improved load-carrying ability; improved fracture resistance; improved durability; and water resistance. Synthetic latex is also the most common additive in chip seals, used to improve chip retention and resistance to bleeding and chip embedment.

Lime and other anti-strip commercial additives in HMA reduce pavement raveling and strength degradation in the presence of water. Antioxidant additives increase asphalt's tensile strength and stiffness.

8. ASPHALT MIXERS AND PLANTS

The earliest asphalt mixers were of the *batch mixer* variety. Aggregate was heated and dried in a rotating drum exposed to a burner flame. Mixing with asphalt cement took place in a separate pugmill.

The highest-quality asphalt concrete mixtures are produced in stationary mixing plants, and these are referred to as *plant mixes*.

In modern *drum mixers*, graded aggregate is dried and heated by a large burner flame at 2500 to 2800°F (1370 to 1540°C) at one end of a rotating drum. Aggregate and asphalt cement are added, and at some point, *recycled asphalt pavement* (RAP) can be added. In *parallel-flow mixers* (also known as *center-entry mixers*), virgin aggregate moves in the same direction as the burner flame. RAP is added farther into the drum, away from the main flame, so as not to burn off the RAP's asphalt cement. RAP must be heated essentially entirely by conduction. RAP cannot be added until the mixture temperature is down to about 800°F (430°C), otherwise the RAP asphalt cement will be burned off as "blue smoke."

Parallel flow mixers can make up to 50% of their mix from RAP, but not much more, since smaller quantities of virgin aggregate cannot transfer enough heat by conduction to the RAP to soften it. Also, if the virgin aggregate has a high moisture content, the RAP fraction must be decreased. Inasmuch as most paving specifications limit RAP to maximums of 25 to 40%, parallel-flow mixers can still be used effectively with recycled materials.

In modern *counterflow mixers*, graded virgin aggregate enters from the end and moves by rotation and gravity toward the burner flame. Counterflow uses fuel more efficiently, and it is easier to use with RAP. Emissions and air pollution rules are easier to satisfy.

Tough air pollution standards apply to asphalt plants. Applicable standards affect the release of carbon monoxide, total hydrocarbons, NOx gases, and particulates. Current technology, however, make "zero opacity" operations possible, without any visible emissions.

9. WEIGHT-VOLUME RELATIONSHIPS

The objectives of an asphalt mixture design are to provide enough asphalt cement to adequately coat, waterproof, and bind the aggregate; provide adequate stability for traffic demands; provide enough air voids to avoid bleeding and loss of stability; and produce a mixture with adequate workability to permit efficient placement and compaction.

Figure 76.1 illustrates the weight-volume relationships for asphalt concrete. The total weight of an asphalt

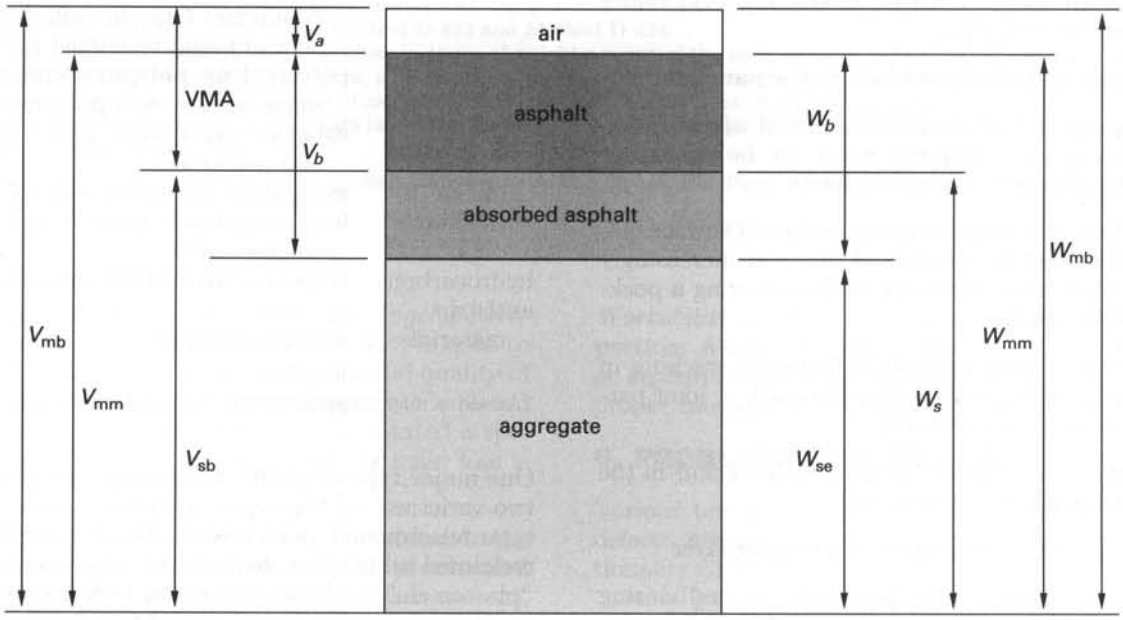

Figure 76.1 *Weight-Volume Relationships for Asphalt Mixtures*

mixture is the sum of the weight of the asphalt and the aggregate. The total volume is the sum of the volume of aggregate and the asphalt not absorbed by the aggregate, plus the air voids.

Although the specific gravity of the asphalt cement can vary widely, the percentage of the total mixture weight contributed by asphalt cement varies from 3 to 8% (by weight) for large nominal maximum sizes (e.g., 1½ in or 37.5 mm) and from 5 to 12% for small nominal maximum sizes (e.g., ⅜ in or 9.5 mm).

The *surface area method* can be used as a starting point in mix design for determining the percent of asphalt needed. The percentage of asphalt, P_b, is

$$\begin{aligned} P_b = {} & (100\%)(\text{aggregate surface area}) \\ & \times (\text{asphalt thickness}) \\ & \times (\text{specific weight of asphalt}) \end{aligned} \qquad 76.1$$

(The aggregate surface area is measured in units of ft^2/lbf or m^2/kg, the asphalt thickness is in in or mm, and the specific weight of asphalt is in lbf/ft^3 or kg/m^3.)

The aggregate surface area is obtained by multiplying the weight (mass) of the aggregate by a *surface area factor* (ft^2/lbf or m^2/kg). The factor must be known, as it is different for each type of aggregate and for each sieve size. In practice, each surface area factor is multiplied by the percent (converted to a decimal) passing each associated sieve, not by the actual aggregate weight, and the products are summed. The total is the surface area in ft^2/lbf (m^2/kg) for the aggregate mixture.

10. PLACEMENT AND PAVING EQUIPMENT

Paving machines consist of a loading hopper, distribution equipment, and an adjustable *screed*. Hot paving mix is brought from the plant in trucks and loaded directly from the trucks into the paving machine. *Low-lift loaders* are able to pick asphalt paving mix that has been dumped in windrows in front of the paver by trucks. Normally, a mixture *paving temperature* in the range of 250 to 285°F (120 to 140°C) is satisfactory. (Compaction must be completed before the mix cools below 185°F (85°C).)

Hydrostatic drive systems are the norm, eliminating mechanical shifting and keeping the operation smooth. One-pass paving is not generally possible, and roller compaction is required. However, *high-density screeds* are used to achieve densities as high as 92% of specification, about 10% more than with conventional screeds. A tamper bar before the screed also improves final density. High-density screeds are larger (i.e., more expensive) and require more power, or they must run at a slower speed. High-density screeds are preferred with cold-recycling since the rejuvenated mixtures tend to be stiffer than virgin materials.

Self-widening machines (*extending screeds*) enable a paving contractor to change paving widths "on the fly," without having to stop and add or remove parts. Extending screeds provide the same compaction as the main screen.

Paving machines can run on rubber tires or crawlers. Crawlers provide better traction on soft subgrades, but they must be loaded on lowboys to be moved any great distance. Rubber-tired pavers have greater mobility but less traction.

Large asphalt *paving machines* can place a layer, or *lift*, of asphalt concrete with a thickness of 1 to 10 in (25 to 250 mm) over a width of 6 to 32 ft (1.8 to 9.8 m) at a forward speed of 10 to 70 ft/min (3 to 21 m/min).

The asphalt pavement *linear yield*, also known as the *length of spread*, L, is calculated from the volumetric relationship of the layer being placed.

$$L_{\text{m/tonne}} = \frac{1000\ \frac{\text{kg}}{\text{tonne}}}{w_{\text{m}} t_{\text{m}} \rho_{\text{compacted,kg/m}^3}} \qquad \text{[SI]} \quad 76.2(a)$$

$$L_{\text{ft/ton}} = \frac{2000\ \frac{\text{lbf}}{\text{ton}}}{w_{\text{ft}} t_{\text{ft}} \gamma_{\text{compacted,lbf/ft}^3}} \qquad \text{[U.S.]} \quad 76.2(b)$$

Some paving is placed on the basis of weight per unit area and depends on the spreading rate, r.

$$L_{\text{m/tonne}} = \frac{1000\ \frac{\text{kg}}{\text{tonne}}}{r_{\text{kg/m}^2} w_{\text{m}}} \qquad \text{[SI]} \quad 76.3(a)$$

$$L_{\text{ft/ton}} = \frac{18{,}000\ \frac{\text{lbf-ft}^2}{\text{ton-yd}^2}}{r_{\text{lbf/yd}^2} w_{\text{ft}}} \qquad \text{[U.S.]} \quad 76.3(b)$$

The actual speed, v, will depend on many factors and should not exceed the value for which a quality pavement is produced. The forward speed should also coincide with the plant production rate, R_p, of asphalt concrete.

$$\begin{aligned} v_{\text{m/min}} &= \frac{R_{p,\text{tonne/h}} L_{\text{m/tonne}}}{60\ \frac{\text{min}}{\text{h}}} \\ &= \frac{R_{p,\text{tonne/h}} \left(1000\ \frac{\text{kg}}{\text{tonne}}\right) \left(1000\ \frac{\text{mm}}{\text{m}}\right)}{w_{\text{m}} t_{\text{mm}} \rho_{\text{kg/m}^3} \left(60\ \frac{\text{min}}{\text{hr}}\right)} \end{aligned} \qquad \text{[SI]} \quad 76.4(a)$$

$$\begin{aligned} v_{\text{ft/min}} &= \frac{R_{p,\text{ton/hr}} L_{\text{ft/ton}}}{60\ \frac{\text{min}}{\text{hr}}} \\ &= \frac{R_{p,\text{ton/hr}} \left(2000\ \frac{\text{lbf}}{\text{ton}}\right) \left(12\ \frac{\text{in}}{\text{ft}}\right)}{w_{\text{ft}} t_{\text{in}} \gamma_{\text{lbf/ft}^3} \left(60\ \frac{\text{min}}{\text{hr}}\right)} \end{aligned} \qquad \text{[U.S.]} \quad 76.4(b)$$

11. ROLLING EQUIPMENT

Most specifications now require 92 to 97% density, which means rolling is necessary even with high-density screeds. Roller forward speeds are usually between 1 and 2½ mph. Compaction must be completed before the mix cools below 185°F (85°C).

Production efficiency is higher with *vibratory rollers* than with *static rollers*, but consistency, noise, and control are sometimes issues. Because of this, many specifications still require a compaction train that includes static rollers. Modern technology is moving toward *density-on-the-run meters* attached to vibratory rollers. These gauges can determine density on the spot, allowing the operator to adjust vibration frequency and amplitude to maintain a consistent density.

Rubber-tired *pneumatic rollers* provide a kneading action in the finish roll. This is particularly important with chip-seal and other thin-surface treatments.

Lift thickness is dependent on the type of compaction equipment used. When static steel-wheeled rollers are used, the maximum lift thickness that can be compacted is about 3 in (75 mm). When pneumatic or vibratory rollers are used, the maximum thickness that can be compacted is almost unlimited. Generally, lift thickness is limited to 6 to 8 in (150 to 200 mm). Proper placement is problematic with greater thicknesses.

12. CHARACTERISTICS OF ASPHALT CONCRETE

(The following material is consistent with the methods presented in *The Asphalt Handbook, MS-4*, 1989 edition, Asphalt Institute, Lexington, KY).

There are three specific gravity terms used to describe aggregate. The *apparent specific gravity*, G_{sa}, of an aggregate (coarse or fine) is

$$G_{sa} = \frac{m}{V_{aggregate}\rho_{water}} \quad \text{[SI]} \qquad 76.5(a)$$

$$G_{sa} = \frac{W}{V_{aggregate}\gamma_{water}} \quad \text{[U.S.]} \qquad 76.5(b)$$

Each of the components, including the coarse aggregate, fine aggregate, and mineral filler, has its own specific gravity (G) and proportion (P) by weight in the total mixture. The *bulk specific gravity*, G_{sb}, of the combined aggregate is

$$G_{sb} = \frac{P_1 + P_2 + \ldots P_n}{\frac{P_1}{G_1} + \frac{P_2}{G_2} + \ldots + \frac{P_n}{G_n}} \qquad 76.6$$

ASTM procedure C127, "Specific Gravity and Absorption of Coarse Aggregate," is used to measure the specific gravity of coarse aggregate without having to measure its volume. In Eqs. 76.7 through 76.9, A represents the oven-dried weight, B is the weight at saturated-surface dry conditions, and C is the submerged weight of the aggregate in water.

$$G_{sa} = \frac{A}{A - C} \qquad 76.7$$

$$G_{sb} = \frac{A}{B - C} \qquad 76.8$$

$$\text{absorption} = \frac{(100\%)(B - A)}{A} \qquad 76.9$$

ASTM procedure C128, "Specific Gravity and Absorption of Fine Aggregate," is used for the fine aggregate. In Eqs. 76.10 through 76.12, A is the oven-dried weight, B represents the weight of a *pycnometer* filled with water, S is the weight of the soil sample (standardized as 500 g), and C is the weight of a pycnometer filled with the soil sample and water added to the calibration mark.

$$G_{sa} = \frac{A}{B + A - C} \qquad 76.10$$

$$G_{sb} = \frac{A}{B + S - C} \qquad 76.11$$

$$\text{absorption} = \frac{(100\%)(S - A)}{A} \qquad 76.12$$

The *bulk specific gravity*, G_{sb}, of the aggregate mixture is found from Eq. 76.11. The *apparent specific gravity* of the aggregate mixture, G_{sa}, is also calculated from Eq. 76.11, except that the apparent specific gravities are used in place of the bulk specific gravities.

The *effective specific gravity* of the aggregate, G_{se}, is calculated from the maximum specific gravity, the specific gravity of the asphalt, G_b, and the proportion of the asphalt in the total mixture, P_b, expressed as a percentage. The effective specific gravity is always between the bulk and apparent specific gravities.

$$G_{se} = \frac{100\% - P_b}{\frac{100\%}{G_{mm}} - \frac{P_b}{G_b}} \qquad 76.13$$

ASTM procedure D2041, "Theoretical Maximum Density (Rice Method)," is used to measure the *maximum specific gravity*, G_{mm}, of the paving mixture, which is the specific gravity if the mix had no air voids. However, in practice, some air voids always remain and this maximum specific gravity cannot be achieved.

The maximum specific gravity is calculated from the proportions of aggregate and asphalt, P_s and P_b, respectively, in percent, and the specific gravity of the asphalt, G_b.

$$G_{mm} = \frac{100\%}{\frac{P_s}{G_{se}} + \frac{P_b}{G_b}} \qquad 76.14$$

If ASTM D2041 is used to determine the maximum specific gravity, G_{mm}, Eq. 76.15 is used. A is the mass of an oven-dried sample, D is the mass of a container filled with water at 77°F (25°C), and E is the mass of the container filled with the sample and water at 77°F (25°C).

$$G_{mm} = \frac{A}{A + D - E} \qquad 76.15$$

By convention, the *absorbed asphalt*, P_{ba}, is expressed as a percentage by weight of the aggregate, not as a percentage of the total mixture.

$$P_{ba} = \frac{(100\%)G_b(G_{se} - G_{sb})}{G_{sb}G_{se}} \qquad 76.16$$

The *effective asphalt content* of the paving mixture, P_{be}, is the total percentage of asphalt in the mixture less the percentage of asphalt lost by absorption into the aggregate.

$$P_{be} = P_b - \frac{P_{ba}P_s}{100\%} \qquad 76.17$$

The *bulk specific gravity of the compacted mixture*, G_{mb}, is determined through testing according to ASTM procedure D2726, "Bulk Density of Cores (SSD)."

The *percent VMA* (*voids in mineral asphalt*) in the compacted paving mixture is

$$\text{VMA} = 100\% - \frac{G_{mb}P_s}{G_{sb}} \qquad 76.18$$

The percent *total air voids* in the compacted mixture represents the air spaces between coated aggregate particles. The total air voids in the compacted mixture should be 3 to 5%. With higher void percentages, voids can interconnect and allow air and moisture to permeature the pavement. If air voids are less than 3%, there will be inadequate room for expansion of the asphalt binder in hot weather. Below 2%, the asphalt becomes plastic and unstable.

$$P_a = \text{VTM} = \frac{(100\%)(G_{mm} - G_{mb})}{G_{mm}} \qquad 76.19$$

The *voids filled with asphalt*, VFA, indicates how much of the VMA contains asphalt and is found using Eq. 76.20.

$$\text{VFA} = \frac{(100\%)(\text{VMA} - \text{VTM})}{\text{VMA}} \qquad 76.20$$

Nondestructive *nuclear gauge testing* (with the gauge in the surface or backscatter position) can be used to determine actual relative density or percent air voids of new pavement. *Extraction methods* (which use dangerous and expensive chemicals) of determining density and air voids are now essentially outdated.

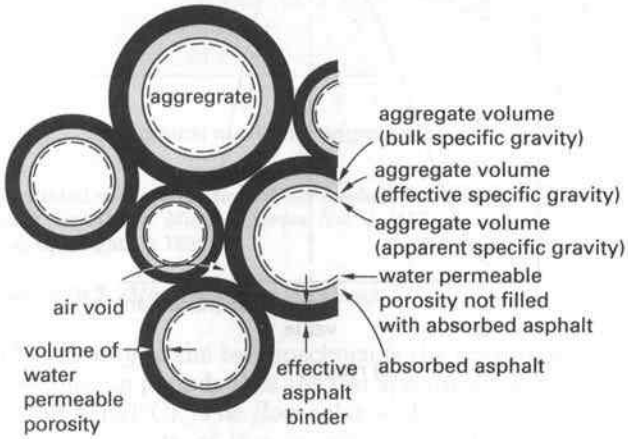

Figure 76.2 *VMA, Air Voids, and Effective Asphalt Content*

13. MARSHALL MIX TEST PROCEDURE

The *Marshall test method* is a density voids analysis and a stability-flow test of the compacted test specimen. The size of a test specimen for a Marshall test is 2.5 in by 4 in (64 mm by 102 mm) in diameter. Specimens are prepared using a specified procedure for heating, mixing, and compacting the asphalt aggregate mixtures. When preparing data for a Marshall mix design, the stability of the samples that are not 2.5 in (63.5 mm) high must be multiplied by the correlation ratios in Table 76.4.

Table 76.4 *Stability Correlation Factors*

specimen volume, cm^3 (in^3)	approximate specimen thickness, mm (in)	correlation ratio
406–420 (25.0–25.6)	50.8 (2.0)	1.47
421–431 (25.7–26.3)	52.4 (2.06)	1.39
432–443 (26.4–27.0)	54.0 (2.13)	1.32
444–456 (27.1–27.8)	55.6 (2.25)	1.25
457–470 (27.9–28.7)	57.2 (2.25)	1.19
471–482 (28.7–29.4)	58.7 (2.31)	1.14
483–495 (29.5–30.2)	60.3 (2.37)	1.09
496–508 (30.2–31.0)	61.9 (2.44)	1.04
509–522 (31.1–31.8)	63.5 (2.5)	1.00
523–535 (31.9–32.6)	64.0 (2.52)	0.96
536–546 (32.7–33.3)	65.1 (2.56)	0.93
547–559 (33.4–34.1)	66.7 (2.63)	0.89
560–573 (34.2–34.9)	68.3 (2.69)	0.86
574–585 (35.0–35.7)	71.4 (2.81)	0.83
586–598 (35.8–36.5)	73.0 (2.87)	0.81
599–610 (36.6–37.2)	74.6 (2.94)	0.78
611–625 (37.3–38.1)	76.2 (3.0)	0.76

(Multiply cm^3 by 0.061 to obtain in^3.)
(Multiply mm by 0.0394 to obtain in.)

The objective of a Marshall test is to find the optimum asphalt content for the blend or gradation of aggregates. To accomplish this, a series of test specimens is prepared for a range of different asphalt contents so that when plotted, the test data will show a well-defined optimum value. Tests are performed in ½% increments of asphalt contents, with at least two asphalt content samples above the optimum and at least two below.

After each sample is prepared, it is placed in a mold and compacted with 35, 50, or 75 hammer blows, as specified by the design traffic category. The compaction hammer is dropped from a height of 18 in (457 mm), and after compaction the sample is removed and subjected to the bulk specific gravity test, stability and flow test, and density and voids analysis. Results of these tests are plotted, a smooth curve giving the best fit is drawn for each set of data, and an optimum asphalt content determined that meets the criteria of (a) maximum stability and unit weight and (b) median of limits for percent air voids from Table 76.5.

Table 76.5 *Marshall Mix Design Criteria*

mix criteria	light traffic ESAL $< 10^4$ surface and base min–max	medium traffic $10^4 <$ ESAL $< 10^6$ surface and base min–max	heavy traffic ESAL $> 10^6$ surface and base min–max
compactive effort, no. of blows/face	35	50	75
stability, N (lbf)	3336 (750)–NA	5338 (1200)–NA	8006 (1800)–NA
flow, 0.25 mm (0.01 in)	8–18	8–16	8–14
air voids, %	3–5	3–5	3–5
VMA, %	(See Fig. 76.5.)		

(Multiply N by 0.225 to obtain lbf.)

Figure 76.5 *VMA Criterion for Mix Design*

The *stability* of the test specimen is the maximum load resistance in pounds that the test specimen will develop at 140°F (60°C). The *flow value* is the total movement (strain) in units of $^1/_{100}$ in occurring in the specimen between the points of no load and maximum load during the stability test.

The *optimum asphalt content* for the mix is the numerical average of the values for the asphalt content. This value represents the most economical asphalt content that will satisfactorily meet all of the established criteria.

Example 76.1

An asphalt mix uses an aggregate blend of 56% coarse aggregate (specific gravity of 2.72) and 44% fine aggregate (specific gravity of 2.60). The maximum aggregate size for the mixture is 3/4 in (19 mm). The resulting asphalt mixture is to have a specific gravity of 2.30. The asphalt content is to be selected on the basis of medium traffic and the following Marshall test data.

maximum content, % by weight of mix	Marshall stability, N	flow, 0.25 mm	theoretical density, kg/m³	asphalt specific gravity
4	4260	10.0	2300	2.42
5	4840	12.3	2330	2.44
6	5380	14.4	2340	2.44
7	5060	16.0	2314	2.40
8	3590	19.0	2250	2.30

Solution

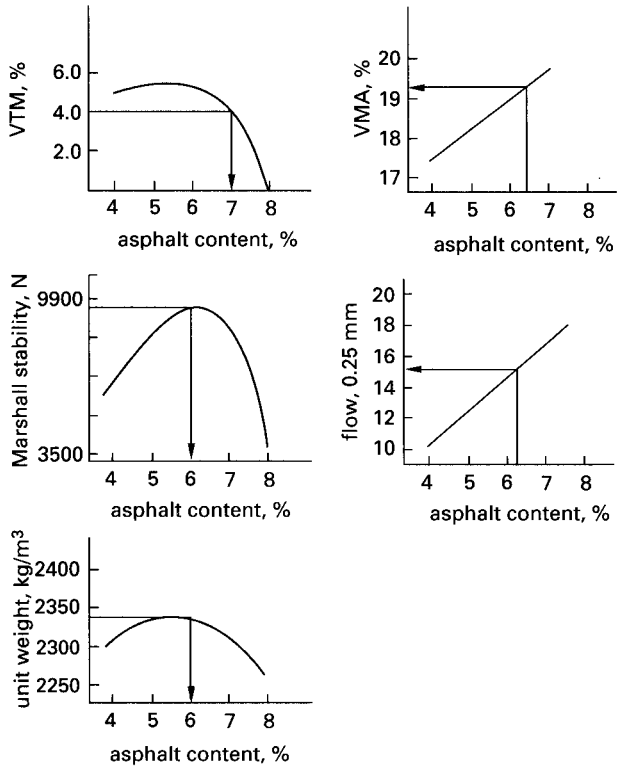
step 1: Calculate air voids for each asphalt content and graph these values versus asphalt content. For example, for the 4% asphalt mixture, using Eq. 76.19,

$$\mathrm{VTM}_{4\%} = \frac{(100\%)(G_{\mathrm{mm}} - G_{\mathrm{mb}})}{G_{\mathrm{mm}}}$$

$$= \frac{(100\%)(2.42 - 2.30)}{2.42} = 4.96\%$$

step 2: Calculate the voids in mineral aggregate for each asphalt content. Use Eq. 76.6.

$$G_{\mathrm{sb}} = \frac{100\%}{\dfrac{P_{\mathrm{ca}}}{G_{\mathrm{ca}}} + \dfrac{P_{\mathrm{fa}}}{G_{\mathrm{fa}}}}$$



$$= \frac{100\%}{\dfrac{56\%}{2.72} + \dfrac{44\%}{2.60}} = 2.67$$

Use Eq. 76.18.

$$\mathrm{VMA}_{4\%} = 100\% - \frac{G_{\mathrm{mb}} P_s}{G_{\mathrm{sb}}}$$

$$= 100\% - \frac{(2.30)(96\%)}{2.67} = 17.3\%$$

step 3: Graph the results.

step 4: Obtain asphalt contents for maximum stability, maximum unit weight and median air voids (4% from Table 76.5) from the graphs.

step 5: Determine the optimum AC content.

$$\text{optimum AC} = \frac{\text{AC}_{\text{stability}} + \text{AC}_{\text{unit weight}} + \text{AC}_{\text{4\% air voids}}}{3}$$

$$= \frac{6.0\% + 6.0\% + 7.0\%}{3}$$

$$= 6.33\%$$

step 6: Check against the criteria for medium traffic. Check VMA = 19.25 against Fig. 76.5. Check flow = 14.8 against Table 76.5.

14. TRAFFIC

(The information included in this section is consistent with the *AASHTO Guide for the Design of Pavement Structures* (*AASHTO Guide*), 1993.)

The AASHTO pavement design method requires that all traffic be converted into *equivalent single-axle loads* (ESALs). This is the number of 18,000 lbf single axles (with dual tires) on pavements of specified strength that would produce the same amount of traffic damage over the design life of the pavement.

Appendix D of the *AASHTO Guide* gives *load equivalency factors* (LEFs) for flexible pavements for various *terminal serviceability indices*, p_t. A p_t value of 2.5 is assumed unless other information is available.

$$\text{ESALs} = (\text{no. of axles})(\text{LEF}) \qquad 76.21$$

Since the structural number, SN, is not known until the design is complete, initial values of 3 and 5 are assumed for the structural number of low-volume roads and high-volume roads, respectively. Once the design is complete, the ESALs can be recomputed and the design verified.

15. TRUCK FACTORS

Truck factors, TFs, are the average LEF for a given class of vehicle and are computed using *loadometer data*. The truck factor is calculated as the total ESALs for all axles divided by the number of trucks.

$$\text{TF} = \frac{\text{ESALs}}{\text{no. of trucks}} \qquad 76.22$$

Example 76.2

Using the data given, calculate the truck factor for 165 total trucks with five or more axles, assuming SN = 5 and $p_t = 2.5$.

Solution

ESALs are obtained by multiplying the number of axles by the LEF for each entry. Obtain LEF values from Apps. 76.A through 76.C.

axle load, lbf	no. of axles	× LEF	= ESALs
	single axle		
<3000	0	0.0002	0.000
4000	1	0.002	0.002
8000	6	0.034	0.204
10,000	144	0.088	12.672
16,000	16	0.623	9.968
28,000	1	5.39	5.390
	tandem axles		
<6000	0	0.0003	0.000
10,000	14	0.007	0.098
16,000	21	0.047	0.987
22,000	44	0.180	7.920
27,000	42	0.430	18.039
30,000	44	0.658	28.952
32,000	21	0.857	17.997
34,000	101	1.09	110.090
36,000	43	1.38	59.340
		total ESALs for all axles:	271.659

The truck factor is

$$\text{TF} = \frac{\text{ESALs}}{\text{no. of trucks}} = \frac{271.659 \text{ ESALs}}{165 \text{ trucks}}$$

$$= 1.65 \text{ ESAL/truck}$$

16. DESIGN TRAFFIC

Once the truck factors are computed, the design ESALs can be computed from the distribution of vehicle classes in the AADT and the expected growth rate. If the 20 yr ESAL is to be predicted from the current (first) year ESAL and if a constant growth rate of $g\%$ per year is assumed, traffic *growth factors*, GFs (also known as *projection factors*), for growth rates, g, can be read as the $(F/A, g\%, 20)$ factors from economic analysis tables.

$$\text{ESAL}_{20} = (\text{ESAL}_{\text{first year}})(\text{GF}) \qquad 76.23$$

The *design traffic* is calculated as the product of the AADT, the fraction of AADT that represents truck traffic, the days in one year, and the growth factor over the design life. The ESAL is obtained by multiplying by the truck factor.

The *directional distribution factor*, D_D, is used to account for the differences in loading according to road direction. It is usually assumed to be 50%. Table 76.6 gives recommended values for *lane distribution factors*, D_L, on multilane facilities. The ESALs for the design lane are computed from Eq. 76.24.

$$w_{18} = D_D D_L \hat{w}_{18} \qquad 76.24$$

Table 76.6 *Lane Distribution Factors*

no. of lanes in each direction	percentage of ESALs in design lane, %
1	100
2	80–100
3	60–80
4	50–75

From *Guide for Design of Pavement and Structures*, p. II-9, copyright © 1993, by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

Example 76.3

Given the following traffic data in columns 1 through 3, as well as the truck factors, compute the design ESALs for a 20 yr period and a growth rate of 2%.

Solution

(vehicle type) [given]	(AADT) [given]	(fraction of AADT) [given]	$\left(\frac{\text{days}}{\text{yr}}\right)$	(GF)	(design traffic)	(design TF) [given]	=	ESAL
			single units					
2-axle, 4-tire	12,000	0.11	365	24.30	11,707,740	0.0122		142,834
2-axle, 6-tire	12,000	0.06	365	24.30	6,386,040	0.1890		1,206,962
3+ axles	12,000	0.04	365	24.30	4,257,360	0.1303		554,734
			tractor semi-trailers					
3-axle	12,000	0.02	365	24.30	2,128,680	0.8646		1,840,457
4-axle	12,000	0.02	365	24.30	2,128,680	0.6560		1,396,414
5-axle	12,000	0.15	365	24.30	15,965,100	2.3719		37,867,621
							total design ESALs:	43,009,022

Example 76.4

The traffic described in Ex. 76.3 has a directional traffic split of 60%/40%, and there are two lanes in each direction. What are the ESALs for the design lane?

Solution

From Table 76.6, $D_L \approx 0.9$.

From Eq. 76.24,

$$\begin{aligned} w_{18} &= D_D D_L \hat{w}_{18} \\ &= (0.6)(0.9)(43{,}009{,}022 \text{ ESALs}) \\ &= 23{,}224{,}872 \text{ ESALs} \end{aligned}$$

17. STANDARD VEHICLE CLASSIFICATIONS AND DESIGNATIONS

For the purposes of designing road geometry, AASHTO defines design vehicles according to the following categories: passenger car (P), single-unit truck (SU), single-unit bus (BUS), intermediate-length semitrailer (WB-40), large semitrailer (WB-50), and semitrailer/full trailer combination (WB-60). In the case of WB vehicles, the number represents the approximate wheelbase distance between the front (cab) axle and the last trailer axle.

Classification into axle types is also common. An axle may be defined as "single" or "tandem," and each axle may have single or dual tires. *Spread-tandem axles*, where two axles are separated by more than 96 in (2.2 m), generally are classified as two single axles. (All axles in a truck are included in the calculation of ESALs. For example, a typical tractor/trailer would contribute three quantities to the ESALs—one for the tractor front axle, one for the tractor tandem axle, and one for the trailer tandem axle.)

Except in theoretical stress studies, no attempt is made to account for the number of tires per axle. Although stresses at shallow depths are caused principally by individual wheels acting singly, stresses at greater depths are highest approximately midway between adjacent

Transportation

Table 76.7 *Standard Truck Loadings*
(All loads are axle loads in lbf (kg).)[a]

load designation	F_1	F_2	F_3	d_1^b, ft (m)	d_2^b, ft (m)
H20-44	8000 (3636)	32,000(14 545)	0	14(4)	
H15-44	6000 (2727)	24,000 (10 909)	0	14 (4)	
H10-44	4000 (1818)	16,000 (7273)	0	14 (4)	
HS20-44	8000 (3636)	32,000 (14 545)	32,000 (14 545)	14 (4)	14-30 (4-8.3)
HS15-44	6000 (2727)	24,000 (10 909)	24,000 (10 909)	14 (4)	14-30 (4-8.3)
P5	26,000 (11 793)	48,000 (21 772)	48,000 (21 772)	18 (5.4)	18 (5.4)
3	16,000 (7273)	17,000 (7273)	17,000 (7273)	15 (4.2)	4 (1.1)
3S2	(See Fig. 76.6.)				
3-3	(See Fig. 76.6.)				

[a]The mass, in lbm, supported per axle is numerically the same as the force, in lbf, experienced by the pavement.
[b]If the separation between axles is variable, the distance that produces the maximum stress in the section should be used.

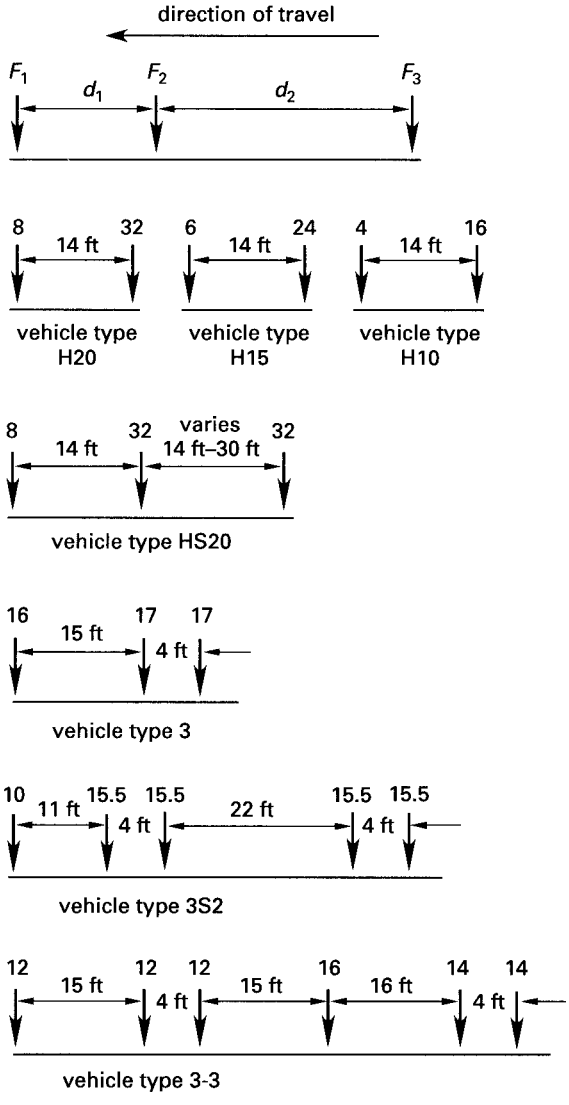


Figure 76.6 *Standard Truck Loadings*
(all loads in kips)

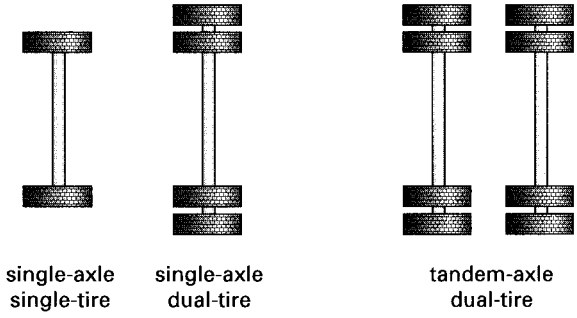

Figure 76.7 *Types of Axles and Axle Sets*

tires. Deep stresses due to dual-wheeled axles are approximately the same as for single-wheeled axles. Therefore, required pavement thickness is determined by the total axle load, not the number of tires.

Table 76.7 and Fig. 76.6 illustrate standard truck loads commonly used for design.

18. AASHTO METHOD OF FLEXIBLE PAVEMENT DESIGN

The 1993 *AASHTO Guide for the Design of Pavement Structures* (*AASHTO Guide*) is the basis of the conventional flexible pavement design method presented in this chapter. The *AASHTO Guide* is a conservative methodology, so average values can be used for all design variables. The design is based on four main design variables: time, traffic, reliability, and environment. Performance criteria, material properties, and pavement structural characteristics are also considered.

Time: The *analysis period* is the length of time that a given design strategy covers (the *design life* or *design period*). The *performance period* is the time that the initial pavement structure is expected to perform adequately before needing rehabilitation. For example, on a high-volume urban roadway, the analysis period

should be 30 to 50 yr, which may include the initial performance period and several *rehabilitation periods* following overlays or maintenance operations.

Traffic: The traffic counts are converted into standard 18 kip ESALs.

Reliability: Reliability considerations ensure that the structure will last for the designated design period. They take into consideration variations in traffic and performance predictions. Facilities that are considered to be more critical are designed using higher reliability factors. It is necessary to select an *overall standard deviation*, S_o, for reliability to account for traffic and pavement performance that is representative of local conditions. Based on historical information obtained during the AASHTO Road Test, appropriate standard deviations for flexible pavements are 0.4 to 0.5.

Table 76.8 *Suggested Levels of Reliability for Various Functional Classifications*

functional classification	recommended level of reliability (percent)	
	urban	rural
interstates and freeways	85–99.9	80–99.9
principal arterials	80–99	75–95
collectors	80–95	75–95
local	50–80	50–80

From *Guide for Design of Pavement and Structures*, Table 2.2, copyright © 1993 by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

19. PERFORMANCE CRITERIA

The *terminal serviceability index*, p_t, represents the lowest serviceability index that can be experienced before rehabilitation, resurfacing, or reconstruction is required. Suggested levels are between 2 and 3, with 2.5 recommended for major highways and 2.0 recommended for less important roads. If costs are to be kept low, the design traffic volume or design period should be reduced. Terminal serviceability should not be reduced, as small changes in it will result in large differences in pavement design.

The *actual initial serviceability*, p_o, represents the actual ride quality of the new roadway immediately after it is installed. This value is not usually known during the initial design, but it may be assumed to be between 4.2 and 4.5.

The *change in serviceability*, ΔPSI, is calculated as the difference between the initial serviceability and the terminal serviceability.

$$\Delta\text{PSI} = p_o - p_t \qquad 76.25$$

20. LAYER STRENGTHS

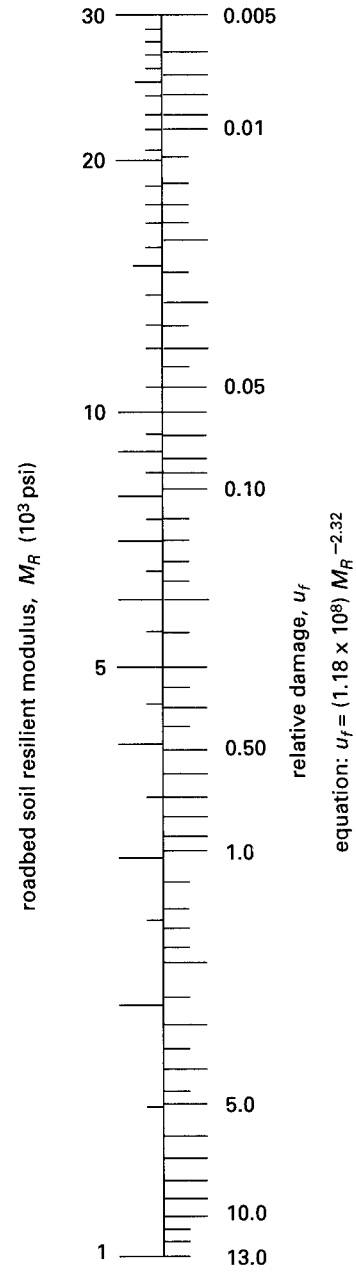
Prior to designing a flexible pavement, the strengths of the pavement layers and the underlying soil must be determined or assumed.

There may be a considerable range in the strength values of the underlying soil. If the range is small for a given area, the lowest value should be selected for design. If there are a few exceptionally low values that come from one area, it may be possible to specify replacing that area's soil with borrow soil to increase the localized weak spots. If there are changing geological formations along the route that modify the value, it may be necessary to design different pavement sections as appropriate.

The *effective roadbed soil resilient modulus*, M_R, must be determined. The resilient modulus can either be measured in the laboratory using the AASHTO T274 test procedure, or it can be predicted from correlations with nondestructive deflection measurements. For roadbed materials, laboratory resilient modulus tests should be performed on representative soils under different representative seasonal moisture conditions. The effective roadbed modulus represents the combined effect of all the seasonal modulus values. The *relative damage value*, u_f, is estimated using the vertical scale on the right side of Fig. 76.8 or by Eq. 76.26. All u_f values are then summed, and the total is divided by the number of seasons, giving the average u_f value. The corresponding effective subgrade modulus value is read from the vertical scale.

$$u_f = (1.18 \times 10^8) M_R^{-2.32} \qquad 76.26$$

The resilient modulus, M_R, is the same as the modulus of elasticity, E, of the soil. It is not the same as the *modulus of subgrade reaction*, k, used in rigid pavement design, although the two are related. For positive values of the resilient modulus, $M_R \approx 19.4k$.



Different state departments of transportation use different methods of classifying materials. The *California bearing ratio* (CBR) and *soil resistance value* (R-value) are widely used. It may be necessary to convert one known strength parameter to another for use with a particular design procedure. Appendices 76.A, 76.B, and 76.C and Eqs. 76.27 and 76.28 are used to make such conversions. However, correlations of the resilient modulus with other measured parameters, such as the R-value, are usually poor.

$$M_R = 1500(\text{CBR}) \quad [\textit{AASHTO Guide} \text{ Eq. } 1.5.1] \qquad 76.27$$

To convert from the R-value to the resilient modulus for fine-grained soils, use Eq. 76.28.

$$M_R = 1000 + 555R \quad \left[\begin{array}{c}\textit{AASHTO Guide} \text{ Eq. } 1.5.3 \\ R \leq 20\end{array}\right] \qquad 76.28$$

Transportation

21. PAVEMENT STRUCTURAL NUMBER

AASHTO combines pavement layer properties and thicknesses into one variable called the design *structural number*, SN. Once the structural number for a pavement is determined, a set of pavement layer thicknesses are chosen. When combined, these layer thicknesses must provide the load-carrying capacity corresponding to the design structural number.

Equation 76.29 is the AASHTO *layer-thickness equation*. D_1, D_2, and D_3 represent actual thicknesses (in inches) of surface, base, and subbase courses, respectively. (If a subbase layer is not used, the third term is omitted.) The a_i are the *layer coefficients*, also known as *strength coefficients*. m_2 and m_3 represent *drainage coefficients* for base and subbase layers, respectively. Typical values of drainage coefficients vary from 0.4 to 1.40, as recommended in Table 2.4 of the *AASHTO Guide*. Values greater than 1.0 are assigned to bases and subbases with good/excellent drainage and are seldom saturated [*AASHTO Guide* Table 2.4].

Theoretically, any combinations of thicknesses that satisfy Eq. 76.29 will work. However, minimum layer thicknesses result from construction techniques and strength requirements. The thickness of the flexible pavement layers should be rounded to the nearest 1/2 in (12 mm). When selecting layer thicknesses, cost effectiveness as well as placement and compaction issues must be considered to avoid impractical design.

$$\mathrm{SN} = D_1 a_1 + D_2 a_2 m_2 + D_3 a_3 m_3 \qquad 76.29$$

The layer coefficients, a_i, vary from material to material, but the values given in Table 76.10 can be used for general calculations. The *AASHTO Guide* contains correlations for all three layer coefficients as functions of the materials' elastic (resilient) moduli. Although the a_1 correlation is purely graphical (see *AASHTO Guide* Fig. 2.5, p. II-18), mathematical correlations are given for a_2 and a_3 for granular materials.

$$a_2 = 0.249(\log_{10} E_b) - 0.977 \qquad 76.30$$

[*AASHTO Guide* p. II-20]

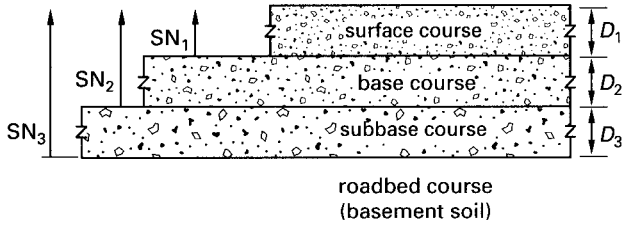
$$a_3 = 0.227(\log_{10} E_{\mathrm{sb}}) - 0.839 \qquad 76.31$$

[*AASHTO Guide* p. II-22]

Flexible pavements are layered systems and are designed accordingly. First, the required structural number over the native soil is determined, followed by the structural number over the subbase and base layers, using applicable strength values for each. The maximum allowable thickness of any layer can be computed from the differences between the computed structural numbers.

This method should not be used to determine the structural number required above subbase or base materials having moduli of resilience greater than 40,000 psi (275 MPa). Layer thicknesses for materials above high-strength subbases and bases should be based on cost effectiveness and minimum practical thickness considerations.

Table 76.9 *Minimum Thickness*[a]



traffic (ESAL)	asphalt concrete in (mm)	aggregate base[b] in (mm)
< 50,000	1.0 (25) (or, surface treatment)	4 (100)
50,001–150,000	2 (50)	4 (100)
150,001–500,000	2.5 (63)	4 (100)
500,001–2,000,000	3 (75)	6 (150)
2,000,001–7,000,000	3.5 (88)	6 (150)
> 7,000,000	4 (100)	6 (150)

(Multiply in by 25.4 to obtain mm.)

[a] Minimum thicknesses may also be specified by local agencies and by contract.

[b] Includes cement-, lime-, and asphalt-treated bases and subbases.

$$D_1^* \geq \frac{\mathrm{SN}_1}{a_1}$$

$$\mathrm{SN}_1^* = a_1 D_1^* \geq \mathrm{SN}_1$$

$$D_2^* \geq \frac{\mathrm{SN}_2 - \mathrm{SN}_1^*}{a_2 m_2}$$

$$\mathrm{SN}_1^* + \mathrm{SN}_2^* \geq \mathrm{SN}_2$$

$$D_3^* \geq \frac{\mathrm{SN}_3 - \left(\mathrm{SN}_1^* + \mathrm{SN}_2^*\right)}{a_3 m_3}$$

[a] Asterisks indicate values actually used, which must be equal to or greater than the required values.

Figure 76.10 *Procedure for Determining Thicknesses of Layers Using a Layered Analysis Approach*[a]

Example 76.5

Determine the pavement thicknesses for two pavement layers over subgrade that have a required structural number of 5. Layer 1 consists of asphalt concrete with a strength coefficient, a_1, of 0.44 and a minimum thickness of 3.00 in. Layer 2 is a granular base with a strength coefficient, a_2, of 0.13; a drainage coefficient, m_2, of 1.00; a minimum thickness of 6.00 in; and a maximum thickness of 25 in.

Table 76.10 *Typical Layer Strength Coefficients*[a] *(1/in)*

	value	range
subbase coefficient, a_3		
sandy gravel[b]	0.11	
sand, sandy clay		0.05–0.10
lime-treated soil	0.11	
lime-treated clay, gravel		0.14–0.18
base coefficient, a_2		
sandy gravel[b]	0.07	
crushed stone	0.14	0.08–0.14
cement treated base (CTB)	0.27	0.15–0.29
seven-day $f'_c > 650$ psi (4.5 MPa)	0.23	
400–650 psi (2.8–4.5 MPa)	0.20	
< 400 psi (2.8 MPa)	0.15	
bituminous treated base (BTB)		
coarse	0.34	
sand	0.30	
lime-treated base		0.15–0.30
soil cement	0.20	
lime/fly ash base		0.25–0.30
surface course coefficient, a_1		
plant mix[b]	0.44	
recycled AC,		
3 in or less	0.40	0.40–0.44
4 in or more	0.42	0.40–0.44
road mix	0.20	
sand-asphalt	0.40	

(Multiply 1/in by 0.0394 to obtain 1/mm.)
(Multiply psi by 6.89 to obtain kPa.)
[a]The AASHTO method correlates layer coefficients with resilient modulus.
[b]The average value for materials used in the original AASHTO road tests were:

asphaltic concrete surface course	0.44
crushed stone base course	0.14
sandy gravel subbase	0.11

Compiled from a variety of sources.

Solution

Trial 1: Try a 3 in thick bituminous pavement. Use Eq. 76.29.

$$SN_1 = \left(0.44\ \frac{1}{\text{in}}\right)(3.00\text{ in}) = 1.32$$

Determine the thickness of aggregate base required.

$$D_2 = \frac{SN_2 - SN_1}{a_2 m_2}$$

$$= \frac{5 - 1.32}{\left(0.13\ \frac{1}{\text{in}}\right)(1.00)}$$

$$= 28.3\text{ in} \quad [> 25\text{ in}]$$

Trial 2: Try a 5 in thick bituminous pavement.

$$SN_1 = \left(0.44\ \frac{1}{\text{in}}\right)(5.00\text{ in}) = 2.20$$

$$D_2 = \frac{SN_2 - SN_1}{a_2 m_2}$$

$$= \frac{5 - 2.20}{\left(0.13\ \frac{1}{\text{in}}\right)(1.00)}$$

$$= 21.5\text{ in} \quad [\text{OK}]$$

22. ASPHALT INSTITUTE METHOD OF FULL-DEPTH FLEXIBLE PAVEMENT DESIGN

(The Asphalt Handbook, MS-4, 1989 edition, is the source for the information in this section. The Asphalt Institute pavement design method was developed in 1981. It makes several assumptions regarding material properties, enabling the design to be read from a series of charts. Like the AASHTO method, it uses 18 kip ESALs as a measure of traffic loading.)

Two designs are considered: full-depth asphalt (asphalt concrete over asphalt subgrade) and asphalt concrete over untreated granular base. Environmental conditions are considered for the effects of temperature on asphalt stiffness and the effects of freezing and thawing on subgrade and untreated base materials.

The following steps constitute the design procedure.

step 1: Determine the 20 yr, 18 kip equivalent single-axle loading (ESAL) for the pavement.

step 2: The resilient modulus of the subgrade is the design parameter, and it is a function of traffic. Select a design subgrade percentile based on Table 76.12 and design ESALs.

Table 76.11 *Design Resilient Modulus Percentiles (highways)*

traffic, ESALs	design subgrade percentile
≤ 10,000	60
10,000–1,000,000	75
≥ 1,000,000	87.5

Reprinted with permission of the Asphalt Institute from *The Asphalt Handbook, Manual Series No. 4 (MS-4),* 1989 ed., Table 11.1, copyright © 1989.

Table 76.12 *Minimum Asphalt Concrete Surface Thickness*

traffic, ESALs	traffic conditions	min. asphalt concrete, in (mm)
≤ 10,000	light rural roads	1 (25)
10,000–1,000,000	medium truck traffic	1.5 (40)
≥ 1,000,000	heavy truck traffic	2.0 (50)

(Multiply in by 25.4 to obtain mm.)

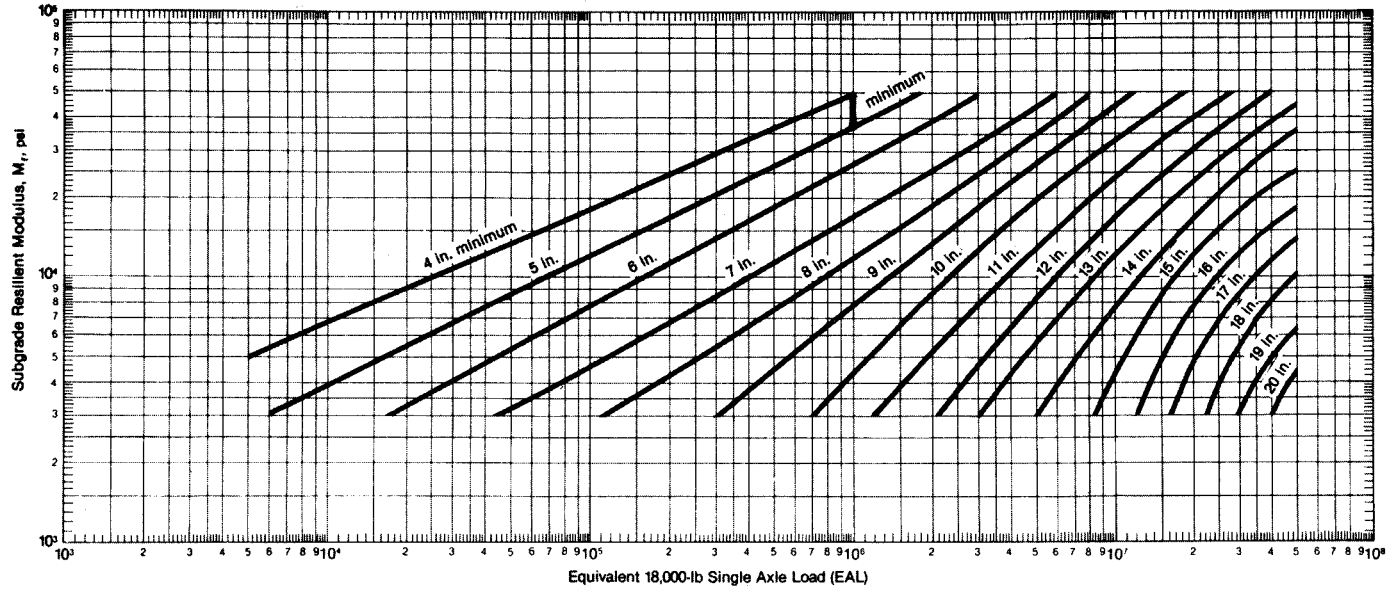
Transportation

step 3: For full-depth bituminous asphalt pavement, use Fig. 76.11 or 76.12 to determine minimum pavement thickness. For asphalt concrete over granular base, determine the minimum asphalt concrete surface thickness according to Table 76.12.



step 4: Select the aggregate base thickness as 6 or 12 in.

step 5: From Figs. 76.13 and 76.14, find the asphalt concrete thickness to be used over the corresponding base thickness.

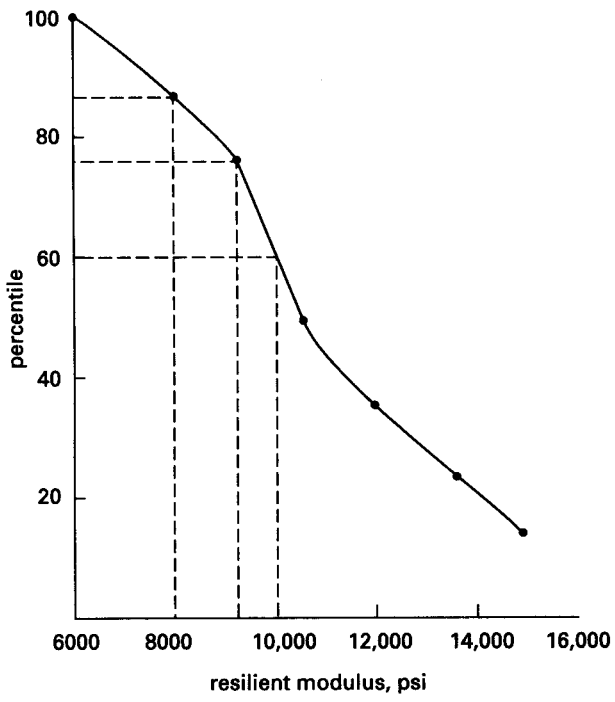
Figure 76.14 *Asphalt Concrete on Untreated Aggregate Base (U.S. customary units)*



Example 76.6

The following California bearing ratio (CBR) values were obtained from multiple tests on the base soil over a proposed roadway: 7, 6, 8, 4, 6, 9, 5, and 10. Determine the design resilient modulus, M_R, for a traffic level of 100,000.

Solution

CBR	M_R, psi	greater quantity	percentage
10	15,000	1	$(\frac{1}{8})(100\%) = 12.5\%$
9	13,500	2	25%
8	12,000	3	37.5%
7	10,500	4	50%
6	9000	6	75%
6	9000	6	75%
5	7500	7	87.5%
4	6000	8	100%

Plot the values. From the plot and Fig. 76.12, the required resilient modulus at 100,000 ESALs is M_R = 9000 psi.

Example 76.7

Design a full-depth asphalt pavement for a subgrade modulus of 6000 psi and 1,000,000 ESALs.

Solution

Use Fig. 76.12. At 1,000,000 ESALs, the full-depth pavement design is 9.5 in.

Example 76.8

Design an asphalt concrete pavement over a granular base for a subgrade modulus of 6000 psi and 1,000,000 ESALs.

Solution

Use Fig. 76.14. At 1,000,000 ESALs and a 6 in granular base, the required asphalt pavement thickness is 8.5 in.

23. ASPHALT PAVEMENT RECYCLING

There are a variety of processes that collectively comprise *recycled asphalt pavement* (RAP) technology. The primary benefit of recycling is cost effectiveness, although strength and reliability do not appear to be affected. *Full-depth reclamation* turns a roadway into the base material for a new surface. The original roadway pavement and some of the underlying material are removed, pulverized, and reused.

Profiling, also known as *surface recycling*, is a modification of the visible surface of the pavement. *Cold planing* is the removal of asphalt pavement by special pavement milling and planing machines (i.e., *profiling equipment*). The resulting pavement with long striations provides a good skid-resistant surface. Cold planing is used to restore a road to an even surface. The material removed is 95% aggregate and 5% asphalt cement. Conventional milling machines run at 5 to 10 ft/min (1.5 to 3 m/min) with a 1 to 2 in (25 to 50 mm) cut. High-capacity machines can run at up to 80 ft/min (24 m/min) with a 4 to 6 in (100 to 150 mm) cut (though half this speed is more typical).

Cold in-place recycling employs a *cold train* of equipment to mill 1 to 6 in (25 to 150 mm) of pavement, crush, size, add asphalt rejuvenating agents and/or light asphalt oil in a pug mill, and finally redeposit and recompact the mixture in a conventional manner. A cold-recycled mix will have at least 6% voids, requiring some type of seal or overlay to keep air and water from entering. The overlay can be a sand, slurry, or chip seal. To achieve the required density, roller compaction is required.

Hot in-place recycling, also known as *hot in-place remixing* and *surface-recycling*, begins by heating the pavement to above 250°F (120°C) with high-intensity indirect propane heaters. Then, a scarifier loosens and removes a layer of up to 2 in (50 mm) of softened asphalt concrete. The removed material is mixed with a rejuvenator in a traveling pugmill, augured out laterally, redistributed, and compressed by a screed and rollers. A petroleum-based agent may be subsequently applied to restore the asphalt cement's adhesive qualities, or up to 2 in (50 mm) of additional new hot-mix asphalt cement can be applied over the replaced surface. Alternatively, a heavier petroleum product can

be applied to help the recycled surface withstand direct traffic. The entire paving train runs at approximately 2 ft/min. The pavement can be used almost immediately.

Hot mix recycling is used in the majority of pavement rehabilitation projects. This process removes the existing asphalt pavement, hauls it to an offsite plant, and blends it with asphalt cement and virgin rock aggregate. Batch plants can blend 20 to 40% RAP with virgin material, though 10 to 20% is more typical. Drum mixers can blend as much as 50% RAP with virgin material.

Microwave asphalt recycling produces hot mix with 100% RAP. Warm air is first used to dry and preheat the reclaimed pavement. Microwave radiation is used to heat the stones in the mixture (since asphalt is not easily heated by microwaves) to approximately 300°F (150°C) without coking any hydrocarbons. Rejuvenating agents restore the pavement's original characteristics, or new aggregate can be used to improve performance.

24. SUPERPAVE™

Superior Performing Asphalt Pavement (Superpave™) is an outgrowth of the U.S. *Strategic Highway Research Program* completed in 1993. Superpave™ is one of several methods of greatly increasing the stone-on-stone contact in the pavement, thus improving its loadbearing capacity. Toward that end, Superpave™ mixtures pay close attention to voids in the mineral aggregate (VMA), air voids in the mix, and voids filled with asphalt (VFA). Specifications also are set for coarse aggregate angularity and flat-and-elongated particles. The use of sand with rounded edges is reduced.

Three elements make up the Superpave™ concept. Level 1 mix design includes specifying asphalts by a set of performance-based *binder specifications*. Specifications include stiffness, dynamic shear (stiffness at high and medium temperatures), bending (stiffness at low temperatures), and in some cases direct tension. The binder specifications relate laboratory tests to actual field performance. Level 1 mix design is currently used by most highway agencies and is replacing older methods of asphalt call-outs.

Level 2 mix design includes performance-based tests to measure primary mixture performance factors: fatigue cracking, permanent deformation, low-temperature (thermal) cracking, aging, and water sensitivity.

Level 3 mix design is a computer-aided volumetric mix design and analysis incorporating test results, geographical location, and climatological data as well as new mix-testing technology such as the Superpave™ *gyratory compactor*, SGC. The laboratory gyratory compactor replaces the Marshall hammer for compacting mixture specimens.

Use of RAP in Superpave™ pavements is more difficult to quantify since the source and characteristics of RAP are not known in advance.

25. STONE MATRIX ASPHALT

Stone matrix asphalt (SMA), also known as *split mastic, stone-filled asphalt* and *stone mastic asphalt*, is a design method that has been imported from Europe. SMA has withstood years of punishment under Europe's heavier axle loads and studded tires without undue deterioration or rutting.

SMA uses single-sized cubical stones, typically 100% crushed rock or stone, in close contact. In the United States, typically 100% of an SMA aggregate will pass through a 3/4 in sieve and 80 to 90% will pass through a 1/2 in sieve, but only 25 to 30% will pass through a no. 4 sieve. (By contrast, a conventional mix will pass about 55% through a no. 4 sieve.) A rich mortar of asphalt cement, fibers, and fine aggregate (i.e., sand) is used to fill the voids and prevent asphalt drain-down. The sand fraction contains a large amount of manufactured crushed sand that may be washed if it contains too many fine particles. The mortar provides durability.

SMA requires different aggregates, different mixing technology, and different paving methods. Because of this, it is a specialty tool for highways that carry the heaviest traffic.

SMA contains a higher fraction (6 to 8%) of hard, low-penetration grade asphalt cement. The mixture often incorporates cellulose fibers, mineral (rock wool) fibers, or, less frequently, polymers to stiffen the mix and improve toughness.

When placed, SMA compacts less than 1/8 in (3 mm) per inch of thickness, and very little at all under 240°F (115°C). Paving rates are lower because the mix is stiffer. Since SMA compacts less and sets up faster, rollers have to follow closely. Most contractors roll SMA with a team of three 10- or 12-ton rollers, one working right behind the other, all closely following the paver.

SMA is currently more expensive than conventional mixes, but the general consensus is that lower life-cycle costs and extended life more than offset the initial cost premium.

Although SMA can be (and has been) designed with the traditional 50- and 75-blow Marshall mix methods, cutting-edge efforts include using the PG grading system for specifying asphalt cements. Like Superpave™, SMA's strength comes from its stone-on-stone contact. SMA differs from Superpave™, however, in the methods used to specify the asphalt and to design and test the mixture. However, the differences are becoming less distinct.

26. ADVANCED, ALTERNATIVE, AND EXPERIMENTAL FLEXIBLE PAVEMENTS

Asphalt rubber (AR) is a general term referring to a wide range of paving products that combine virgin or reclaimed rubber with asphalt cement. *Rubber-modified asphalt*, also known as *crumb-rubber modified (CRM) asphalt*, is made from scrap rubber from tires.

In the "wet process" (*reacted asphalt process* or *asphalt hot rubber mix* (AHRM)), the rubber is blended into hot asphalt, creating an asphalt-rubber binder with 10 to 25% rubber by weight. The mixture is held at 375 to 400°F (190 to 205°C) and agitated for 20 to 60 min. In the "dry process" (*rubberized asphalt process*), *crumb rubber*, also known as *crumb rubber modifier* (CRM), in the form of pea-sized beads replaces about 3% of the stone aggregate.

Asphalt rubber has attracted considerable attention in recent years. Federal requirements mandating the use of crumb rubber have been eliminated, mainly out of concerns over the health effects on paving workers. But some states continue to require it. Concerns have been raised about recyclability and combustible roads catching fire. Experience in California seems to indicate that asphalt rubber may result in pavement sections half the thickness of conventional asphalt concrete pavement. Asphalt rubber also holds heat longer than conventional mixes, allowing night placement at temperatures as low as 50°F (10°C). Other preliminary tests are mixed, indicating higher costs without significant structural or durability benefits.

Fast-track pavement is a fast-setting (using type-III portland cement) concrete. Fast-track pavement is used for asphalt overlays, where quick restoration without significant traffic interruption is needed. 4 in (100 mm) layers typically set up in 12 hr and are ready for traffic in 18 hr.

White-topping (also known as *ultrathin white-topping*, UTW) is a rehabilitation method used for rutted asphalt. It creates an economic surface for high-use areas. The technique involves placing a thin (e.g., 75 to 100 mm) layer of fiber-reinforced, high-performance concrete over rutted asphalt. The process forms a highly durable bond (lasting 3 to 4 times longer than asphalt), and it does not need the regular milling or maintenance that asphalt does. The white-topping has the flexibility of asphalt and the loadbearing capacity of concrete. Although asphalt can be placed less expensively per volume than concrete, the life-cycle costs of white-topping repair appear to be lower.

Roller-compacted concrete (RCC) is a zero-slump mixture that is placed and compacted. RCC is good for pothole repair.

Trashphalt is asphalt paving using a wide variety of scrap and waste materials including glass, rubber tire scrap, fly ash, steel refining waste, porcelain from crushed plumbing fixtures, roofing shingles, concrete, and brick. Concern has been raised that such paving materials will probably preclude pavement recycling efforts in later years.

Coal-derived *synthetic asphalt* is a technology that has become less important than when it was first developed. As long as oil prices remain low, it is unlikely that synthetic asphalt will be used much.

Sulfur concrete (*sulfur-asphalt concrete, sulfur-extended concrete, sulphex*, etc.) is manufactured by heating sulfur (20 to 40% by weight) to approximately 280 to 290°F (138 to 143°C) until it is molten, combining with asphalt, and then adding mineral filler and aggregate. (Below 300°F (150°C), elemental sulfur is the primary vapor component. Above that, sulfur dioxide and hydrogen sulfide become the dominant pollutants. Therefore, molten sulfur must be kept below 300°F (150°C).) First-generation sulfur concrete using pure sulfur experienced early rutting. Second-generation sulfur concrete used sulfur that had been chemically modified to reduce brittleness, and it performs better. There is currently little incentive to perfect sulfur concrete.

27. SUBGRADE DRAINAGE

Subgrade drains are applicable whenever the following conditions exist: (a) high groundwater levels that reduce subgrade stability and provide a source of water for frost action, (b) subgrade soils of silts and very fine sands that become quick or spongy when saturated, (c) water seepage from underlying water-bearing strata, (d) drainage path of higher elevations intercepts sag curves with low-permeability subgrade soils below.

Figure 76.15 illustrates typical subgrade drain placement. In general, drains should not be located too close to the pavement (to prevent damage to one while the other is being worked on), and some provision should be made to prevent the infiltration of silt and fines into the drain. Roofing felt or geotextile sleeves can be placed around the drains for this purpose.

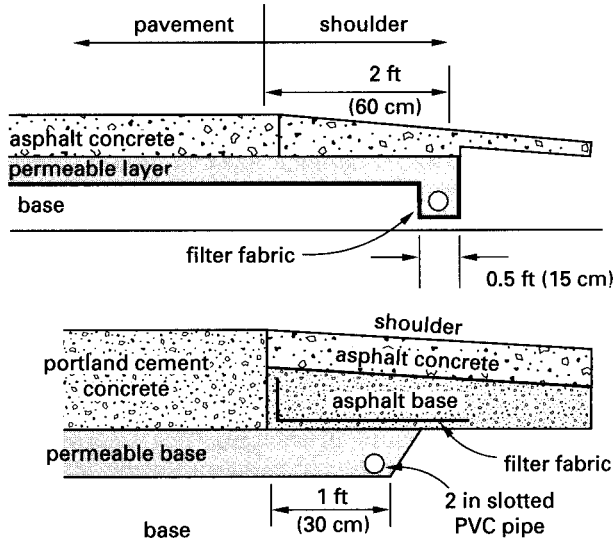


Figure 76.15 *Typical Subgrade Drain Details*

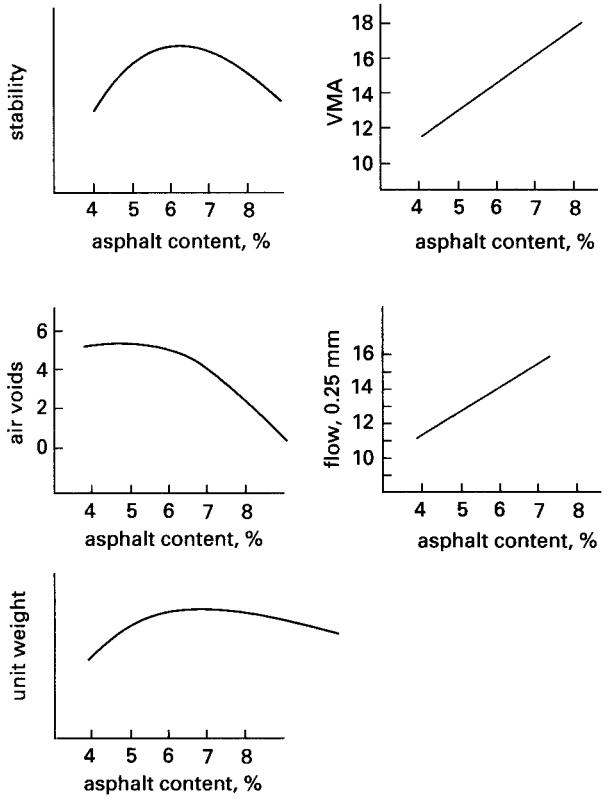
28. DAMAGE FROM FROST AND FREEZING



Frost heaving and reduced subgrade strength, along with the accompanying pumping during spring thaw, can quickly destroy a pavement. The following techniques can be used to reduce damage to a flexible

pavement in areas susceptible to frost: (a) constructing stronger and thicker pavement sections, (b) lowering the water table by use of subdrains and drainage ditches, (c) using layers of coarse sands or waterproof sheets beneath the pavement surface to reduce capillary action, (d) removing and replacing frost-susceptible materials to a level beneath the zone of frost penetration, and (e) using rigid foam sheets to insulate and reduce the depth of frost penetration.

PRACTICE PROBLEMS

Marshall Mixture Testing

1. Results of Marshall mix testing are shown. An asphalt pavement is to be designed for medium traffic using aggregate with a 3/4 in nominal size. What is the appropriate percentage of asphalt for the mix?

Answer: 6.8%

Mixture Properties

2. The mass of a core of asphalt concrete in air is 1150.0 g. The mass of the core in water is 498.3 g. What is the core's density in lbm/ft^3?

Answer: 144 lbm/ft^3

3. The specific gravity of a voidless mixture (i.e., the maximum theoretical specific gravity) of an asphalt concrete is 2.550. The components are specified as follows.

material	specific gravity	apparent specific gravity	by weight, %
asphalt cement	1.020	–	6.3
limestone dust	2.820	2.650	13.7
sand	2.650	2.905	30.4
gravel	2.650	2.873	49.6

(a) What is the air void content if the bulk specific gravity of the mixture is 2.340?

(A) 8.0%
(B) 8.2%
(C) 8.5%
(D) 8.6%

The answer is (B).

(b) What is the bulk specific gravity of the aggregate?

(A) 2.67
(B) 2.69
(C) 2.73
(D) 2.75

The answer is (A).

(c) What is the VMA of the mixture?

(A) 16%
(B) 17%
(C) 18%
(D) 19%

The answer is (C).

(d) What is the effective specific gravity of the aggregate?

(A) 2.80
(B) 2.82
(C) 2.84
(D) 2.86

The answer is (C).

(e) What is the asphalt absorption?

(A) 1.90%
(B) 2.05%
(C) 2.13%
(D) 2.18%

The answer is (D).

(f) What is the effective asphalt content of the mixture?

(A) 4.26%
(B) 4.50%
(C) 4.71%
(D) 5.03%

The answer is (A).

(g) What is the VFA of the mixture?
(A) 52.4%
(B) 53.8%
(C) 54.3%
(D) 54.6%

The answer is (C).

(h) What is the apparent specific gravity of the aggregate?
(A) 2.35
(B) 2.55
(C) 2.65
(D) 2.85

The answer is (D).

(i) How much would the percent air voids of the mixture change if the weight of the asphalt were increased by 2%?
(A) 0.05% decrease
(B) 0.14% decrease
(C) no change
(D) 0.14% increase

The answer is (B).

(j) How much would the VMA of the mixture change if the weight of the asphalt were increased by 2%?
(A) 0.1% decrease
(B) 0.2% decrease
(C) no change
(D) 0.1% increase

The answer is (D).

AASHTO Pavement Design

4. The following data apply to a particular road.

initial ADT	5000 vpd
growth rate	4%/yr
design period	20 yr

loadometer data

axle load (lbf)	number of axles out of 1250
single axles	
2000	800
5000	922
14,000	1851
19,000	37
double axles	
15,000	417
21,000	608
35,000	84

(a) What is the 18 kip equivalent axle load (EAL)?
(A) 1022
(B) 1044
(C) 1221
(D) 1387

The answer is (B).

(b) Calculate the 18 kip equivalent axle load per truck.
(A) 0.609
(B) 0.632
(C) 0.777
(D) 0.835

The answer is (D).

(c) Calculate the 20 yr ADT in one direction.
(A) 2700 vpd
(B) 3000 vpd
(C) 3500 vpd
(D) 3990 vpd

The answer is (D).

(d) Calculate the total number of trucks for the 20 yr design period.
(A) 5.2×10^6
(B) 6.0×10^6
(C) 6.7×10^6
(D) 7.3×10^6

The answer is (D).

(e) Calculate the total 18 kip single-axle load applications over the design period.
(A) 6.1×10^6
(B) 7.2×10^6
(C) 7.9×10^6
(D) 8.3×10^6

The answer is (A).

(f) Calculate the effective roadbed modulus for use in design, given the following data.

season	roadbed soil modulus (psi)
winter (Dec–Feb.)	16,000
spring (Mar–Apr.)	2000
summer (May–Sep.)	6000
fall (Oct–Nov.)	4000

(A) 2500 psi
(B) 2800 psi
(C) 3250 psi
(D) 3730 psi

The answer is (D).

(g) Using the AASHTO design charts, calculate the required structural number for a rural divided highway.

(A) 4.7
(B) 5.2
(C) 5.6
(D) 6.7

The answer is (C).

(h) If the minimum plant-mix asphalt layer thickness is 4 in, calculate the appropriate crushed-stone base layer thickness if it is placed directly on the subgrade. Use $m = 1$ for all drainage coefficients.

(A) 24 in
(B) 26 in
(C) 28 in
(D) 30 in

The answer is (C).

(i) For a 6 in plant-mix asphalt surface placed over an 8 in crushed stone base, calculate the required subbase thickness. Use $m = 1$ for all drainage coefficients.

(A) 23 in
(B) 25 in
(C) 27 in
(D) 31 in

The answer is (A).

(j) Given the following minimum thicknesses and unit costs, design the most economical pavement section.

material	minimum thickness	unit cost
asphalt plant mix	4 in	\$0.17/in
crushed stone base	6 in	\$0.04/in
granular subbase	–	\$0.01/in

(A) AC, 4 in; base, 6 in; subbase, 28 in
(B) AC, 4 in; base, 6 in; subbase, 38 in
(C) AC, 6 in; base, 6 in; subbase, 28 in
(D) AC, 4 in; base, 8 in; subbase, 30 in

The answer is (B).

1. RIGID PAVEMENT

Information for this chapter section is primarily derived from the *AASHTO Guide for the Design of Pavement Structures* ("*AASHTO Guide*"), 1993 edition. The Portland Cement Association (PCA) has also published a methodology for designing rigid pavements in its *Thickness Design for Concrete Highway and Street Pavements* ("*PCA Pavement Manual*"), 1984 edition.

Portland cement concrete (PCC) pavement is the most common form of *rigid pavement* because of its excellent durability and long service life. Its raw materials are readily available and reasonably inexpensive, it is easily formed, it withstands exposure to water without deterioration, and it is recyclable. The primary disadvantages of PCC pavement are that it can lose its original nonskid surface over time, it must be used with an even subgrade and only where uniform settling is expected, and it may rise and fall (i.e., fault) at transverse joints.

PCC pavement is placed with *slip-form construction* methods. A stiff concrete is placed in front of a paving train that distributes, vibrates, screeds, and finishes the layer. Shoulders are usually constructed of asphalt pavement later, since shoulder traffic is much lower.

PCC pavement may be reinforced or nonreinforced, and joints may or may not be included. The four main types of concrete pavement are *plain jointed concrete pavement* (JCP), *jointed reinforced concrete pavement* (JRCP), *continuously reinforced concrete pavement* (CRCP), and *prestressed concrete pavement* (PCP). *Construction joints* are required in both reinforced and nonreinforced pavement. (See Sec. 9.)

Use of *prestressed concrete pavement* (PCP) is rare in the United States. The major advantage of prestressing is a reduction (up to 50%) in thickness, making it more applicable to airfield pavements, which are thicker. Initial testing seems to indicate a superior, stronger, longer lasting pavement, but with added cost and complexity. Although the *AASHTO Guide* provides some

Transportation

design guidance, few state transportation departments, vendors, or contractors are available to teach the technology.

2. MIXTURE PROPORTIONING

The following steps constitute the Portland Cement Association's *absolute volume method* for proportioning a PCC mixture.

step 1: Select an appropriate slump from Table 77.1.

step 2: Select the maximum aggregate size to be smaller than one fifth of the narrowest form dimension, one third of the slab depth, and three fourths of the clear space between the rebar.

step 3: Select a trial water-cement ratio as the lower of the two values required for strength from Table 77.2, and for durability from Table 77.3.

step 4: Estimate the mixing water and air void contents from Table 77.4.

step 5: Calculate cement content by dividing the mixing water content by the water-cement ratio.

step 6: Estimate the coarse aggregate content from Table 77.5. This gives a ratio of the volume of coarse aggregate to the volume of concrete.

step 7: Estimate the fine aggregate content. Subtract the volumes of all other ingredients from the unit volume of the concrete to determine the unit volume of fine aggregate.

Table 77.1 *Recommended Slumps*

	slump (in)	
concrete construction	maximum[a]	minimum
pavements, slabs, reinforced foundations, walls, footings, caissons, and substructure walls	3	1
beams, reinforced walls, and building columns	4	1

Example 77.1

Design a concrete mixture for use in an exposed bridge pier. The bridge is located where exposure is severe, so air entrainment will be used. Specifications call for a 28 day compressive strength of 4000 lbf/in^2. The rebar has a clear spacing of 1 in. The fine aggregate has a fineness modulus of 2.60, and the coarse aggregate has a dry-rodded unit weight of 97 lbf/ft^3. The coarse aggregate bulk specific gravity is 2.65, and the fine aggregate bulk specific gravity is 2.63. Cement has a specific gravity of 3.15.

Solution

step 1: From Table 77.1, the recommended slump is 3 in.

step 2: The maximum aggregate size is 3/4 of the clear spacing between rebar.

$$\left(\tfrac{3}{4}\right)(1 \text{ in}) = 3/4 \text{ in}$$

step 3: Determine a trial water/cement ratio. From Table 77.2, $w/c = 0.40$. From Table 77.3, $w/c = 0.48$. Select the lower value of 0.40.

step 4: Select mixing water and air content. From Table 77.4, mixing water is 305 lbf/yd^3 of concrete. The volume of mixing water is

$$V_{\text{water}} = \frac{305\ \frac{\text{lbf}}{\text{yd}^3}}{62.4\ \frac{\text{lbf}}{\text{ft}^3}} = 4.89\ \text{ft}^3/\text{yd}^3$$

From Table 77.4, the air content is 6.0%. Therefore, the volume of air in a cubic yard of concrete is

$$V_{\text{air}} = \left(27\ \frac{\text{ft}^3}{\text{yd}^3}\right)(0.06) = 1.62\ \text{ft}^3/\text{yd}^3$$

Transportation

step 5: The mixing water per cubic yard of concrete is

$$W_{\text{water}} = \frac{V_{\text{mixing water}}}{\frac{w}{c}} = \frac{305\ \frac{\text{lbf}}{\text{yd}^3}}{0.40}$$
$$= 762.5\ \text{lbf/yd}^3$$

The volume of cement required is

$$V_{\text{cement}} = \frac{W_{\text{cement}}}{(\text{SG})\gamma_w}$$
$$= \frac{762.5\ \frac{\text{lbf}}{\text{yd}^3}}{(3.15)\left(62.4\ \frac{\text{lbf}}{\text{ft}^3}\right)} = 3.88\ \text{ft}^3/\text{yd}^3$$

step 6: Determine the coarse aggregate content. The volume fraction of dry-rodded coarse aggregate from Table 77.5 is 0.64. The dry-rodded volume of coarse aggregate per cubic yard is

$$V_{\text{coarse}} = (0.64)\left(27\ \frac{\text{ft}^3}{\text{yd}^3}\right) = 17.28\ \text{ft}^3/\text{yd}^3$$

The weight of coarse aggregate is

$$W_{\text{coarse}} = V\gamma_{\text{ca}} = \left(17.28\ \frac{\text{ft}^3}{\text{yd}^3}\right)\left(97\ \frac{\text{lbf}}{\text{ft}^3}\right)$$
$$= 1676.2\ \text{lbf/yd}^3$$

The volume of coarse aggregate is

$$V_{\text{coarse}} = \frac{W_{\text{ca}}}{(\text{SG})\gamma_w}$$
$$= \frac{1676.2\ \frac{\text{lbf}}{\text{yd}^3}}{(2.65)\left(62.4\ \frac{\text{lbf}}{\text{ft}^3}\right)}$$
$$= 10.14\ \text{ft}^3/\text{yd}^3$$

step 7: Determine the fine aggregate content. The fine aggregate takes up all space remaining after allowances have been made for the water, air, cement, and coarse aggregate.

$$V_{\text{fa}} = 27\ \frac{\text{ft}^3}{\text{yd}^3} - 4.89\ \frac{\text{ft}^3}{\text{yd}^3} - 1.62\ \frac{\text{ft}^3}{\text{yd}^3}$$
$$- 3.88\ \frac{\text{ft}^3}{\text{yd}^3} - 10.14\ \frac{\text{ft}^3}{\text{yd}^3}$$
$$= 6.47\ \text{ft}^3/\text{yd}^3$$

The weight of the fine aggregate is

$$W_{\text{fa}} = V_{\text{fa}}(\text{SG})\gamma_w$$
$$= \left(6.47\ \frac{\text{ft}^3}{\text{yd}^3}\right)(2.63)\left(62.4\ \frac{\text{lbf}}{\text{ft}^3}\right)$$
$$= 1061.8\ \text{lbf/yd}^3$$

3. AASHTO METHOD OF RIGID PAVEMENT DESIGN

All four types (see Sec. 1) of PCC rigid pavement may be designed using the AASHTO method. The AASHTO rigid pavement design concepts, terminology, and procedures are similar to those used by AASTHO for flexible pavement design. Similar and parallel concepts include the principal design variables (time, traffic, reliability and environment), serviceability, load equivalency factors, truck factors, growth factors, layer coefficients, structural number concept, lane and directional distribution factors, and ESAL loading.

The primary differences include using the soil modulus of subgrade reaction, k; concrete modulus of rupture, S'_c; drainage coefficient, C_D; joint J-value; frictional factor, F; and standard deviation, S_o.

Based on information obtained during the AASHTO Road Test, an appropriate overall standard deviation, S_o, for rigid pavements is 0.35. This is slightly different than for flexible pavements.

4. MATERIAL STRENGTHS

The material used for each pavement layer must be characterized. In the AASHTO method, the *modulus of subgrade reaction*, k (also known as the k-value, and essentially the modulus of elasticity), is the primary performance factor for the soil. The resilient modulus concept is not used, though the two moduli are linearly related. Correlations with other parameters are not generally exact, as Fig. 77.1 indicates.

$$k = \frac{M_R}{19.4} \qquad 77.1$$

The *effective k-value* incorporates the support abilities of all the layers. AASHTO and PCA (see Tables 77.6 and 77.7) have published methods for incorporating the strength of all the layers.

Concrete's average *modulus of rupture* (flexural strength), S'_c, is found using a *third-point loading flexure test* at 28 days, as specified by AASHTO T97 or ASTM C78. The construction specification modulus of rupture should not be used, as it is too conservative.

Concrete's *modulus of elasticity* is found using the ACI-318 relationship.

$$E_c = 57{,}000\sqrt{f'_c} \quad [E_c \text{ in lbf/in}^2] \qquad 77.2$$

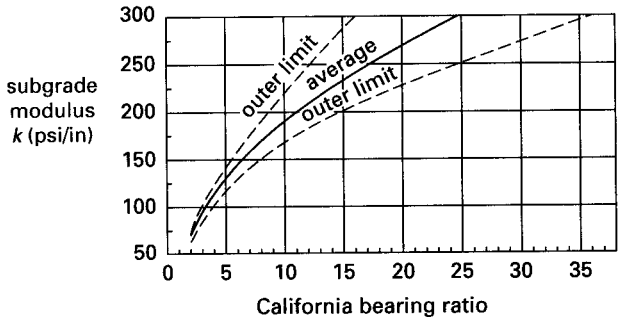

Figure 77.1 *Approximate Correlation Between CBR and Subgrade Modulus*

Table 77.6 *Effect of Untreated Subbase on k-Values*

Example 77.2

A subgrade has a California bearing ratio value of 10. A 6 in cement-treated subbase is to be used. What is the approximate effective k-value?

Solution

From Fig. 77.1, the subgrade k-value is 200 lbf/in^3. From Table 77.7, the effective k-value is 640 lbf/in^3.

5. PAVEMENT DRAINAGE

The *drainage coefficient*, C_d, is a function of the drainage quality and presence of moisture. If the ground is saturated much of the time or the drainage is poor, C_d may be as low as 0.70. If the pavement is well-drained and conditions are dry, C_d may be as high as 1.25. In cases where the conditions are not specific, $C_d = 1.00$ is assumed.

6. LOAD TRANSFER AND DOWELS

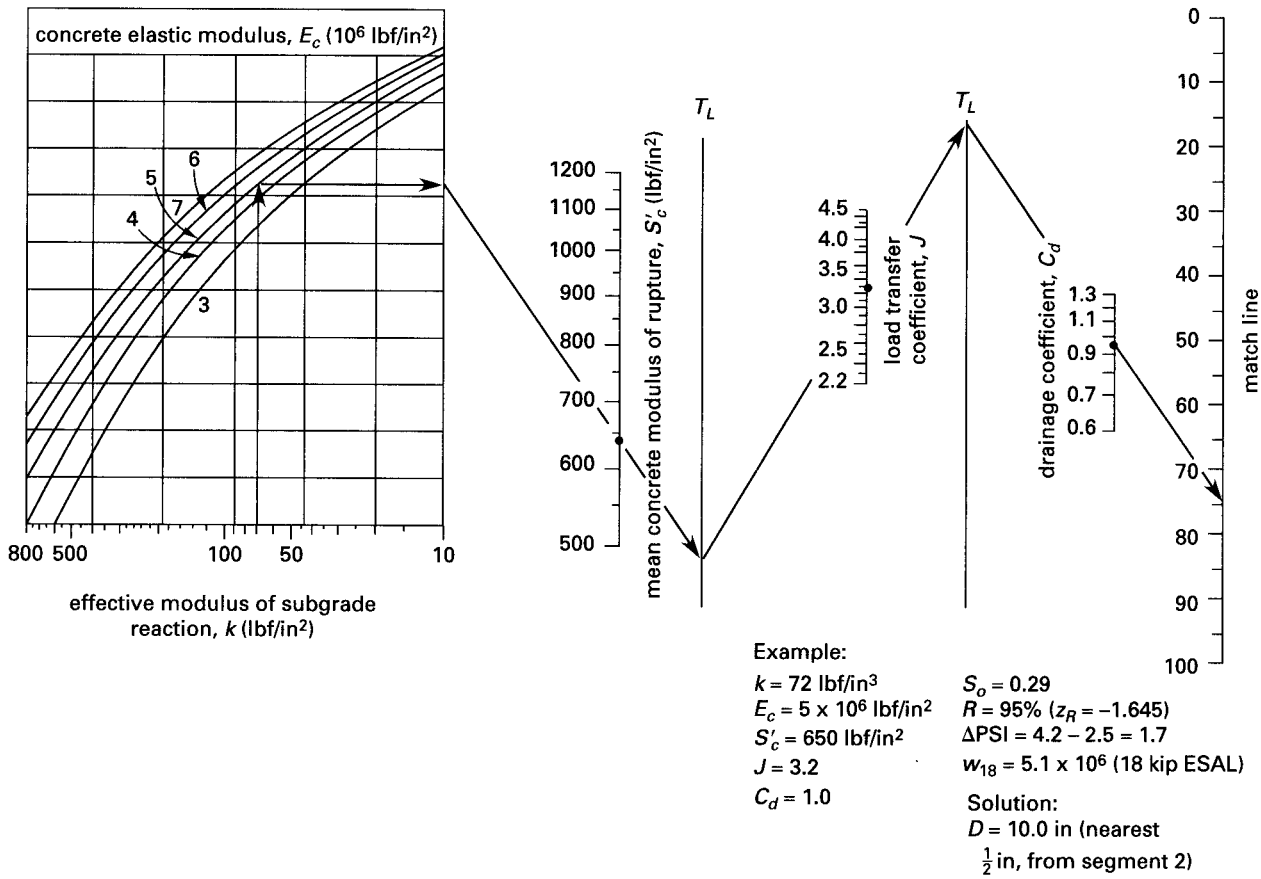
A *load transfer coefficient*, J (also known as the *J-value*), accounts for load distribution across joints and cracks. The J-value is affected by the use and placement of dowels, aggregate interlock, and tied shoulders. Approximate J-values for various conditions are given as

asphalt shoulders with dowels	$J = 3.2$
asphalt shoulders without dowels	$J = 4.0$
concrete shoulders with dowels	$J = 2.8$
concrete shoulders without dowels	$J = 3.8$

A rule of thumb for specifying the dowel diameter is the slab thickness divided by 8 and then rounded up to the nearest standard bar size. Typical dowel spacing is 12 in (305 mm), and typical dowel length is 18 in (457 mm).

7. PAVEMENT DESIGN METHODOLOGY

Slab thickness is determined from Fig. 77.2 for each k-value, and then rounded to the nearest 0.5 in (13 mm). To use Fig. 77.2 to determine the slab thickness, the following variables are required: (a) effective k-value; (b) estimated future traffic in ESALs using the rigid pavement equivalency factors; (c) reliability level, R; (d) overall standard deviation, S_o; (e) design serviceability loss, ΔPSI; (f) concrete modulus of elasticity, E_c; (g) concrete modulus of rupture, S'_c; (h) load transfer coefficient, J; and (i) drainage coefficient, C_d.

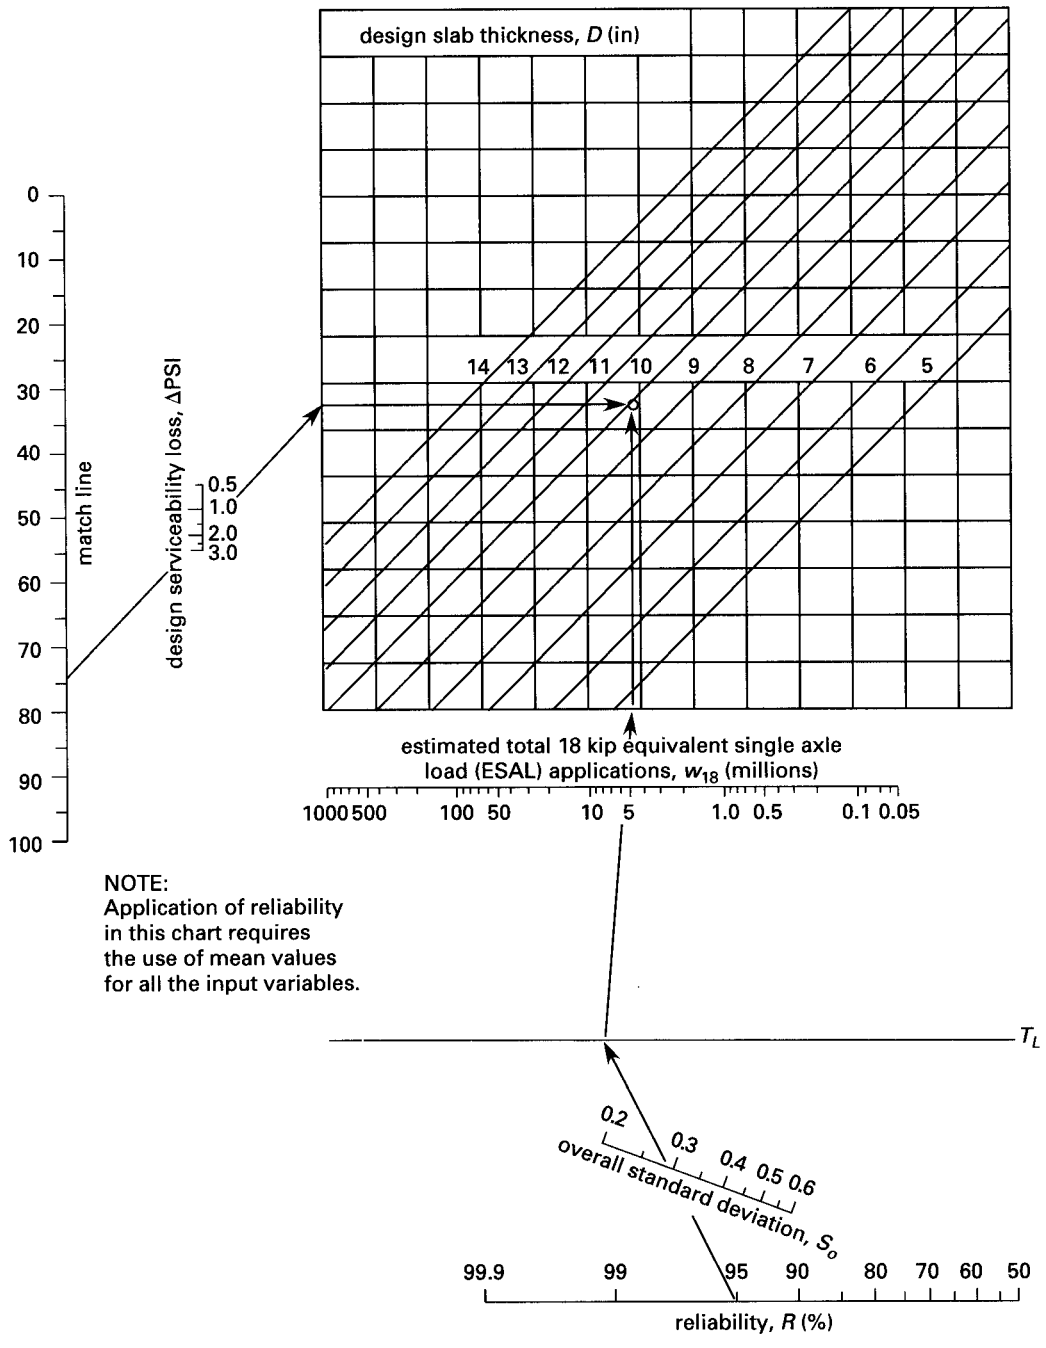


8. STEEL REINFORCING

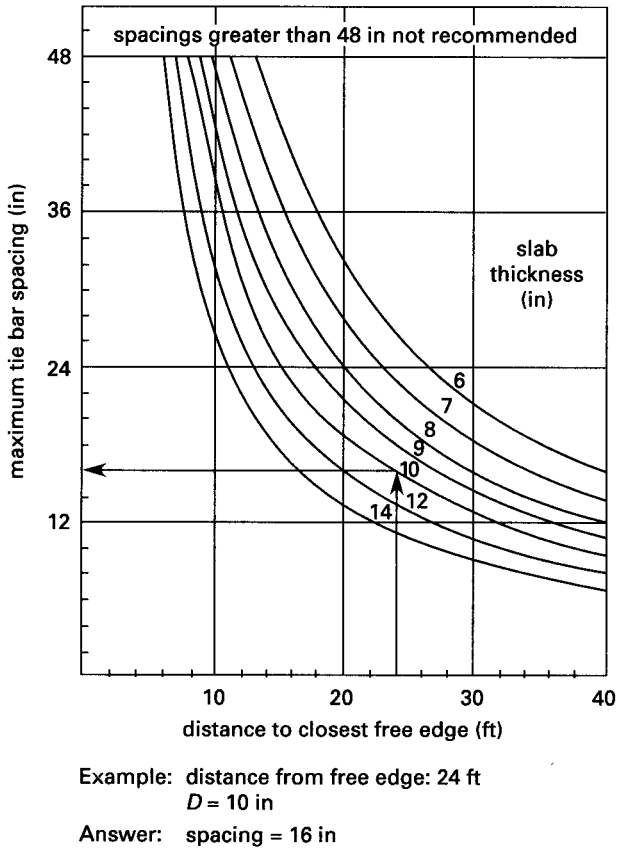
Reinforcing steel for rigid pavements may consist of deformed reinforcing bar, smooth wire mesh, or deformed wire fabric. The purpose of the steel is not to add structural strength, but to hold cracks tightly together and restrain their growth. As the slab contracts, the contraction is resisted by friction with underlying material. Restraint of contraction causes tensile stresses to be at a maximum at mid-slab. When tensile stresses exceed the tensile strength of the concrete, cracks develop. Because transverse cracking is not expected in slabs less than 15 ft (4.2 m) long, reinforcement is not used in short slabs.

Although AASHTO provides a nomograph ("Reinforcement Design Chart for Jointed Reinforced Concrete Pavement, *AASHTO Guide* Fig. 3.8, p. II-52), the percentage of reinforcing steel is easily calculated.

$$P_s = \frac{L_{ft} F(100\%)}{2 f_{s,lbf/in^2}} \qquad 77.3$$



Transportation



[a]Based on mean value of each variable.

Figure 77.4 *Recommended Maximum Tie Bar Spacing for PCC Pavement (5/8 in diameter tie bars, grade-40 steel, and subgrade friction factor of 1.5)*

The required reinforcement is expressed as a percentage, P_s, of the cross-sectional area. The *slab length*, L, represents the distance between the free, or untied, joints and has a substantial effect on the maximum concrete tensile stresses and the amount of steel required. *Steel working stress*, f_s, is assumed to be 75% of the steel yield strength. For example, grade-60 steel would be designed for 45 kips/in^2.

The *friction factor*, F, represents the frictional resistance between the bottom of the slab and the top of the subbase or subgrade. Typical values of F are 0.9 for natural subgrade, 1.5 for crushed stone or gravel, 1.8 for stabilized material, and 2.2 for placement on another surface treatment [*AASHTO Guide* Table 2.8].

To determine the amount of transverse reinforcement, Eq. 77.3 may still be used if L is taken as the side-to-side width of the slab. The transverse spacing between rebar, Y, is calculated from the cross-sectional area of the rebar, A_s; the percent of transverse steel, P_t; and the slab thickness, D.

$$P_t = \frac{A_s(100\%)}{YD} \qquad 77.4$$

Figures 77.3 and 77.4 give tie bar spacing for 1/2 in and 5/8 in diameter deformed bars. To use these figures, the closest distance to a free edge, defined as any joint not having tie bars or as the distance to the edge of pavement, must be known. Tie bar spacing increases with decreases in the distance to a free edge since the steel tensile stress is maximum at the center of the slab. Spacing also increases with a decrease in slab thickness.

Example 77.3

Design a jointed reinforced concrete pavement with a 60 ft slab length, two 12 ft lanes tied together, doweled joints, and asphalt shoulders. Assume the pavement is placed in a wet location with poor drainage. The subgrade is very weak clay with a California bearing ratio of 3. The friction factor, F, is 1.8. The design reliability is 90%. The concrete has a compressive strength of 4000 lbf/in^2 and a modulus of rupture of 650 lbf/in^2, both at 28 days. The traffic on the design lane is projected to be 20×10^6 ESALs. An 8 in cement-treated subbase will be used. Grade-40 steel reinforcement and 1/2 in diameter tie bars will be used.

Determine the (a) slab thickness, (b) length and spacing of dowel bars, (c) longitudinal and transverse reinforcement, and (d) tie bars for use in the longitudinal joints.

Solution

(a) From Fig. 77.1, the modulus of subgrade reaction is $k = 100$ lbf/in^3. From Table 77.7 with the subbase, the effective subgrade modulus is $k = 520$ lbf/in^3.

Use Eq. 77.2 to estimate E_c.

$$E_c = 57{,}000\sqrt{f'_c} = 57{,}000\sqrt{4000 \text{ lbf/in}^2}$$
$$= 3.6 \times 10^6 \text{ lbf/in}^2$$

From Sec. 6, the load transfer coefficient for asphalt shoulders with dowels is $J = 3.2$.

For poor draining, the drainage coefficient is $C_d = 0.7$.

Reliability, R, is given as 90%.

For PCC pavement, use an overall standard deviation, S_o, of 0.35.

Assume "normal" serviceability values of $p_o = 4.5$ and $p_t = 2.5$.

$$\Delta\text{PSI} = 4.5 - 2.5 = 2.0$$

From Fig. 77.2, the slab thickness is 12.5 in.

(b) Use the rule of thumb for dowel bars.

$$\text{diameter} = \frac{\text{thickness}}{8} = \frac{12.5 \text{ in}}{8}$$
$$= 1.56 \text{ in} \quad [\text{use } 1^5/_8 \text{ in}]$$

Use an average spacing of 12 in and a length of 18 in.

(c) Design the longitudinal and transverse reinforcement.

With grade-40 steel, the working stress is

$$0.75f_y = (0.75)\left(40 \frac{\text{kips}}{\text{in}^2}\right) = 30 \text{ kips/in}^2$$

The friction factor is given as $F = 1.8$.

The percentage of longitudinal steel is given by Eq. 77.3.

$$P_s = \frac{LF(100\%)}{2f_s}$$
$$= \frac{(60 \text{ ft})(1.8)(100\%)}{(2)\left(30{,}000 \frac{\text{lbf}}{\text{in}^2}\right)} = 0.18\%$$

Since the two lanes are tied together, both must be considered for horizontal steel. The width is 24 ft.

From Eq. 77.3, the area of transverse steel is

$$P_t = \frac{LF(100\%)}{2f_s}$$
$$= \frac{(24 \text{ ft})(1.8)(100\%)}{(2)\left(30{,}000 \frac{\text{lbf}}{\text{in}^2}\right)} = 0.072\%$$

(d) Since $^1/_2$ in diameter tie bars are used, Fig. 77.3 is applicable. The slab thickness is 12.5 in. The distance from a free edge is 12 ft. The tie bar spacing is read as approximately 24 in.

9. PAVEMENT JOINTS

Figure 77.4 shows the three standard forms of joints used on a concrete pavement. *Contraction joints (control joints, weakened plane joints, dummy joints)* are usually sawn into the pavement to a depth of one fourth (transverse joints) or one third (longitudinal joints) of the slab thickness, but they can also be hand-formed while the concrete is wet or formed by pouring around inserts. The purpose of the joint is to create a thinner pavement section in one location (a weak line to encourage shrinkage cracking along that line). Contraction joints also relieve tensile stresses in the pavement. The uneven crack joint provides for load transfer between the slab sections by aggregate interlock. To prevent deicing sand and water from infiltrating the joints, a hot pour or preformed joint sealer can be used in the joint.

With nonreinforced construction, contraction joints should be placed at regular intervals to allow for the shrinkage of the concrete during drying and in thermal changes. 24 times the thickness of the slab and a ratio of slab width to slab length ≤ 1.25 are typical rules of thumb used to select the distance between contraction joints for nonreinforced pavement.

Contraction joints can be placed at regular intervals and at 90° angles to the centerline. However, skewing the transverse joints and/or placing them at random intervals minimizes the amount of faulting as well as noise and impact from vehicular traffic. State highway departments have standard joint patterns for spacing and standard skew angles.

Hinge joints, also known as *warping joints*, are similar to control joints. However, hinge joints are longitudinal joints, generally placed along the centerline of a highway.

Construction joints are used transversely between construction periods and longitudinally between pavement lanes. Longitudinal joints are usually spaced to coincide with lane markings at 8 and 12 ft (SI) intervals, but spacing depends primarily on paver width. They are usually keyed, formed by attaching a metal or wooden keyway form at middepth. With slip-form pavers, the keyway is formed by the slipform as it advances. Dowels are not generally used with longitudinal joints.

Isolation joints (expansion joints) are used to relieve compressive (i.e., buckling) stresses in the pavement where it adjoins another structure. Expansion joints are placed where the pavement abuts bridges, at intersections, where concrete and asphalt pavements abut each other, and at end-of-day pours. Transverse joints are placed across the direction of roadway travel.

Use of *dowel bars* in transverse joints depends on the service conditions. They are not needed in residential or other low-traffic streets, but they may be needed with heavy truck traffic. If one end of a dowel is lubricated, the slab will slip over the dowel as the slab expands and contracts, providing a good transfer of load. However, most dowels are inserted dry. Dowel insertion can be done automatically with modern paving train equipment, or they can be inserted manually.

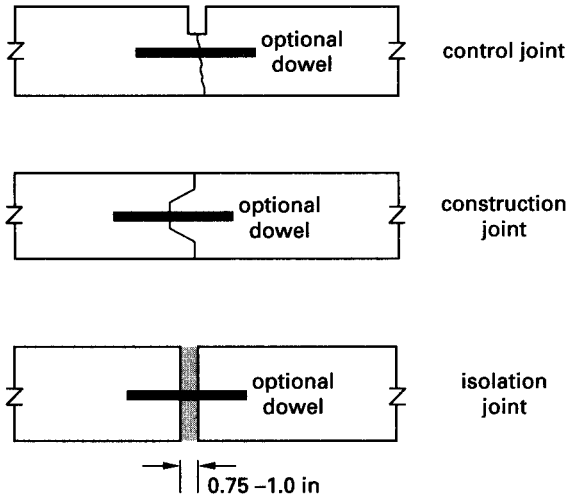

Figure 77.5 *Types of Concrete Pavement Joints*

10. SURFACE SEALING

Sealing of PCC surfaces is typically used to prevent chloride ions (from deicing salts) from penetrating the concrete and corroding reinforcing and supporting steel. Sealing is predominantly used to protect steel bridge decks. It is not commonly done on open roads.

In the past, natural linseed oil has traditionally been used. However, modern commercial formulations include silane/siloxane-type sealers and alkali silicate-type sealers. Silane/siloxane sealers are classified as "penetrating sealers," as they retain their properties after the upper surface layer of sealer has been worn away.

11. RECYCLING

Recycled PCC pavement material may be used as aggregate base, subbase, or aggregate for new pavement. Recycling is not only economically favorable; it also solves the problem of disposing of large amounts of PCC pavement. Recycled aggregate may actually be more durable than in the original state because it has already gone through multiple freeze-thaw cycles. Recycling can be used with lean concrete (*econocrete*) and slipform pavers.

In typical operation, diesel pile hammers, resonant pavement breakers, or drop hammers are used to break up the pre-existing concrete. A backhoe separates broken pavement and steel, and the steel is also recovered. The concrete is removed, crushed, screened, and reused. Most recycling is done on-site.

12. PAVEMENT GROOVING

Grooving is a method of increasing skid resistance and reducing hydroplaning on all types of pavements. Grooves permit the water to escape under tires and prevent buildup of water on the surface. The recommended groove is 1/4 in wide and 1/4 in deep (6 mm by 6 mm), with a center-to-center spacing of 1 1/4 in (32 mm). So that the grooving does not weaken the pavement surface, the minimum spacing is approximately 1 1/8 in (29 mm). To be effective in removing water, the maximum spacing is approximately 2 in (50 mm).

Grooving should be used only with structurally adequate pavements. If the pavement is in poor condition, it should be rehabilitated before grooving. Grooves should be continuous. In the case of special surfaces such as airfields where pavement widths exceed standard roadway widths, transverse rather than longitudinal grooves may be used.

13. ADVANCED, ALTERNATIVE, AND EXPERIMENTAL PAVEMENTS

Dual-layer pavements are claimed to yield quieter rides and reduced road noise. The paving machine lays down two layers of different concretes simultaneously—a lower, thicker layer containing large aggregate for economy, and an upper thinner layer made up of smaller stones. The upper stones are subsequently exposed by washing away cement paste before hardening.

Until recently, few *thin-overlay* options were available. Delamination problems have been experienced with thin, *grout-bonded concrete* placed over existing concrete surfaces. Epoxy-bonded overlays have been more successful. Thin 3/4 to 1 in (19 to 25 mm) *polymer concrete* overlays are successful and are becoming more common. Polyester-styrene polymer, a catalyst, aggregate smaller than 1/2 in, and sand are used. Good bonding is obtained by abrasive blasting (e.g., shotblasting) followed by vacuuming to clean and roughen the original surface. The overlay sets up in less than half an hour.

Flyash (class-C) modified concrete appears to be more susceptible to sulfate attack than normal concrete. When flyash concrete contains a high calcium content, the concrete is also more prone to alkali silica reactions. Adding flyash appears to decrease durability with no significant increase in strength.

Rubcrete, using ground-up rubber in place of some of the aggregate, is generally not applicable to structural applications, including upper pavement layers.

Various other innovations, including *latex-modified concrete* (LMC) and *steel fiber-reinforced* concrete, are available for special applications and adventurous contractors.

PRACTICE PROBLEMS

Concrete Paving Mixtures

1. *(Time limit: one hour)* A concrete mixture is made up of materials with the following properties.

material	absolute volume fraction	bulk specific gravity (oven dry)	absorption (%)
sand	0.25	2.60	1.0
gravel	0.50	2.70	1.5
cement	0.10	3.15	–
water	0.15	–	–

(a) What is the volumetric water-cement ratio?

(A) 1.2:1
(B) 1.4:1
(C) 1.5:1
(D) 1.7:1

The answer is (C).

(b) What is the gravimetric water-cement ratio?

(A) 0.3:1
(B) 0.5:1
(C) 0.7:1
(D) 0.9:1

The answer is (B).

(c) What is the water-cement ratio?

(A) 4.8 gal/sack
(B) 5.4 gal/sack
(C) 5.7 gal/sack
(D) 6.0 gal/sack

The answer is (B).

(d) If the moisture content of the sand is 3.0%, what is the weight of free water in the sand used for a 1 ft^3 batch?

(A) 0.7 lbf excess
(B) 0.8 lbf excess
(C) 0.9 lbf excess
(D) 0.8 lbf deficit

The answer is (B).

(e) If the moisture content is 0.5%, what is the weight of free water in the gravel for a 1 ft^3 batch?

(A) 0.7 lbf excess
(B) 0.8 lbf excess
(C) 0.9 lbf excess
(D) 0.8 lbf deficit

The answer is (D).

(f) Using the results from parts (d) and (e), calculate the weight of the "added water."

(A) 8.7 lbf
(B) 8.9 lbf
(C) 9.1 lbf
(D) 9.4 lbf

The answer is (D).

(g) What is the weight of the materials in 1 ft^3 of the mix?

(A) 144 lbf
(B) 148 lbf
(C) 155 lbf
(D) 161 lbf

The answer is (C).

(h) If 0.25 ft^3 of the mixture weighs 37 lbf, what percent air is in the mixture?

(A) 3.2%
(B) 4.5%
(C) 4.9%
(D) 5.3%

The answer is (C).

(i) Another concrete mixture has the proportions of cement to gravel of 1:2.5:3.5 by weight, and the water-cement ratio is 6 gal/sack. The specific gravities of the components are unchanged. What is the relative proportion by weight of water in the mixture?

(A) 0.5
(B) 0.7
(C) 0.9
(D) 1.1

The answer is (A).

(j) What is the volume of all ingredients in a one-sack batch of the mixture described in part (i)?

(A) 3.5 ft^3
(B) 3.8 ft^3
(C) 4.2 ft^3
(D) 4.7 ft^3

The answer is (D).

2. How much water must be added to the following materials to obtain 6 gal net of mixing water?

material	weight (lbf)	moisture content (%)	absorption capacity (%)
damp gravel	75.0	3.4	1.50
damp sand	46.0	4.5	0.90

Answer: 47.02 lbf

3. The batch weights for a concrete mixture include 1344 lbf damp sand with a moisture content of 4.24%, and 2260 lbf of damp gravel with a moisture content of

Transportation

2.10%. The absorption capacity of the sand is 0.90%, and the absorption capacity of the gravel is 1.50%. 220 lbf of water are added to the mixture. What is the net mixing water?

Answer: 276.3 lbf

Rigid Pavement Design

4. *(Time limit: one hour)* A jointed, reinforced concrete pavement using doweled joints and asphalt shoulders is being designed with the AASHTO rigid pavement procedure. A reliability of 90% has been estimated. The slab length is 60 ft. Two 12 ft lanes are tied together. The pavement is to be constructed in a wet environment with poor drainage. The subgrade is a very weak clay with a CBR of 3. The friction factor, F, is 1.8. At 28 days, the concrete has a compressive strength of 4000 psi with a modulus of rupture of 650 psi. The traffic in the design lane is projected to be 20×10^6 ESALs. An 8 in cement-treated subbase will be used. Grade-40 steel and ½ in tie bars will be used.

(a) What subgrade k-value would you use in the design?

(A) 50 lbf/in^3
(B) 80 lbf/in^3
(C) 100 lbf/in^3
(D) 120 lbf/in^3

The answer is (C).

(b) What is the effective k-value you would use in the design?

(A) 500 lbf/in^3
(B) 520 lbf/in^3
(C) 550 lbf/in^3
(D) 600 lbf/in^3

The answer is (B).

(c) Estimate the concrete modulus of elasticity, E_c, for use in the design.

(A) 3.0×10^6 lbf/in^2
(B) 3.2×10^6 lbf/in^2
(C) 3.6×10^6 lbf/in^2
(D) 3.8×10^6 lbf/in^2

The answer is (C).

(d) What is the required slab thickness?

(A) 11.5 in
(B) 11.8 in
(C) 12.0 in
(D) 12.5 in

The answer is (D).

(e) What size dowel bars are to be used?

(A) no. 8
(B) no. 10
(C) no. 12
(D) no. 13

The answer is (D).

(f) How much longitudinal steel is required, expressed in terms of percentage of area?

(A) 0.15%
(B) 0.18%
(C) 0.20%
(D) 0.24%

The answer is (B).

(g) How much transverse steel is required, expressed in terms of percentage of area?

(A) 0.05%
(B) 0.07%
(C) 0.10%
(D) 0.14%

The answer is (B).

(h) At what distance from the free edge should tie bars be placed?

(A) 6 ft
(B) 8 ft
(C) 10 ft
(D) 12 ft

The answer is (D).

(i) What is the required increase in slab thickness if traffic is increased by 20%?

(A) 0.5 in
(B) 1.0 in
(C) 1.5 in
(D) 2.0 in

The answer is (A).

(j) By how many inches could the pavement thickness be reduced if the subgrade is treated to increase its CBR value to 10?

(A) 0.5 in
(B) 1.0 in
(C) 1.5 in
(D) 2.0 in

The answer is (A).

1. ERROR ANALYSIS: MEASUREMENTS OF EQUAL WEIGHT

There are still many opportunities for errors in surveying, although calculators and modern equipment have significantly reduced the magnitudes of most errors. The purpose of error analysis is not to eliminate errors but rather to estimate their magnitudes. In some cases, it is also appropriate to assign the errors to the appropriate measurements.

The *expected value* of a measurement, also known as the *most likely value* or *probable value*, is the value that has the highest probability of being correct. If a series of k

measurements is taken, the most probable value, x_p, is the average (mean) of those measurements, as shown in Eq 78.1. For related measurements whose sum should equal some known quantity, the most probable values are the observed values corrected by an equal part of the total error.

$$x_p = \frac{x_1 + x_2 + \cdots + x_k}{k} \qquad 78.1$$

Measurements of a given quantity are assumed to be normally distributed. If a quantity has a mean μ and a sample standard deviation s, the probability is 50% that a measurement of that quantity will fall within the range of $\mu \pm 0.6745s$. The quantity $0.6745s$ is known as the *probable error.* The *probable ratio of precision* is $\mu/0.6745s$. The interval between the extremes is known as the 50% *confidence interval.* Other confidence limits are easily obtained from the normal tables. For example, for a 95% interval, replace 0.6745 with 1.96, and for a 99% interval, replace 0.6745 with 2.57.

The *probable error of the mean*, E_{mean}, of k observations is given by Eq. 78.2.

$$E_{\text{mean}} = \frac{0.6745s}{\sqrt{k}} = \frac{E_{\text{total},k \text{ measurements}}}{\sqrt{k}} \qquad 78.2$$

Example 78.1

The interior angles of a triangular traverse were measured as 63°, 77°, and 41°. Each measurement was made once, and all angles were measured with the same precision. What are the most probable interior angles?

Solution

The sum of angles in a triangle should equal 180°. The error in measurement is

$$(63° + 77° + 41°) - 180° = +1°$$

The correction required to make the sum total 180° is −1°, which is proportioned equally among the three angles. The most probable values are then

$$63° - \frac{+1°}{3} = 62.67°$$

$$77° - \frac{+1°}{3} = 76.67°$$

$$41° - \frac{+1°}{3} = 40.67°$$

Example 78.2

A critical distance was measured twelve times. The mean value was 423.7 ft with a sample standard deviation, s, of 0.31 ft. What are the 50% confidence limits for the distance?

Solution

From Eq. 78.2, the standard error of the mean value is

$$E_{\text{mean}} = \frac{0.6745s}{\sqrt{k}} = \frac{(0.6745)(0.31 \text{ ft})}{\sqrt{12}} = 0.06 \text{ ft}$$

The probability is 50% that the true distance is within the limits of 423.7 ± 0.06 ft.

Example 78.3

The true length of a tape is 100 ft. The most probable error of a measurement with this tape is 0.01 ft. What is the expected error if the tape is used to measure out a distance of 1 mi?

Solution

1 mi consists of 5280 ft. The number of individual measurements will be 5280 ft/100 ft = 52.8, or 53 measurements. The most probable error is given by Eq. 78.2.

$$E_{\text{total},k \text{ measurements}} = E_{\text{mean}}\sqrt{k} = (0.01 \text{ ft})\sqrt{53} = 0.073 \text{ ft}$$

2. ERROR ANALYSIS: MEASUREMENTS OF UNEQUAL WEIGHT

Some measurements may be more reliable than others. It is reasonable to weight each measurement with its relative reliability. Such weights can be determined subjectively. More frequently, however, they are determined from relative frequencies of occurrence or from the relative inverse squares of the probable errors.

The probable error and 50% confidence interval for weighted observations can be found from Eq. 78.3. x_i represents the ith observation, and w_i represents its relative weight.

$$E_{p,\text{weighted}} = 0.6745\sqrt{\frac{\sum\left(w_i(\overline{x} - x_i)^2\right)}{(k-1)\sum w_i}} \qquad 78.3$$

For related weighted measurements whose sum should equal some known quantity, the most probable weighted values are corrected inversely to the relative frequency of observation. Weights can also be calculated when the probable errors are known. The weights are the relative squares of the probable errors.

Example 78.4

An angle was measured five times by five equally competent crews on similar days. Two of the crews obtained a value of 39.77°, and the remaining three crews obtained a value of 39.74°. What is the probable value of the angle?

Solution

Weight the values by the relative frequency of observation.

$$\theta = \frac{(2)(39.77^\circ) + (3)(39.74^\circ)}{5}$$
$$= 39.75^\circ$$

Example 78.5

A distance has been measured by three different crews. The measurements' probable errors are given. What is the most probable value?

crew 1: 1206.40 ± 0.03 ft

crew 2: 1206.42 ± 0.05 ft

crew 3: 1206.37 ± 0.07 ft

Solution

The sum of squared probable errors is

$$(0.03 \text{ ft})^2 + (0.05 \text{ ft})^2 + (0.07 \text{ ft})^2 = 0.0083 \text{ ft}^2$$

The weights to be applied to the three measurements are

$$\frac{0.0083 \text{ ft}^2}{(0.03 \text{ ft})^2} = 9.22 \text{ ft}$$
$$\frac{0.0083 \text{ ft}^2}{(0.05 \text{ ft})^2} = 3.32 \text{ ft}$$
$$\frac{0.0083 \text{ ft}^2}{(0.07 \text{ ft})^2} = 1.69 \text{ ft}$$

The most probable length is

$$\frac{\begin{array}{l}(1206.40 \text{ ft})(9.22 \text{ ft}) \\ \quad + (1206.42 \text{ ft})(3.32 \text{ ft}) \\ \quad\quad + (1206.37 \text{ ft})(1.689 \text{ ft})\end{array}}{9.22 \text{ ft} + 3.32 \text{ ft} + 1.69 \text{ ft}} = 1206.40 \text{ ft}$$

Example 78.6

What is the 50% confidence interval for the measured distance in Ex. 78.5?

Solution

Work with the decimal portion of the answer.

$$\overline{x} = \frac{0.40 + 0.42 + 0.37}{3}$$
$$\approx 0.40$$

i	x_i	$\overline{x} - x_i$	$(\overline{x} - x_i)^2$	w_i	$w_i(\overline{x} - x_i)^2$
1	0.40	0	0	9.22	0
2	0.42	−0.02	0.0004	3.32	0.0013
3	0.37	0.03	0.0009	1.69	0.0015
			total	14.23	0.0028

Use Eq. 78.3.

$$E_{p,\text{weighted}} = 0.6745\sqrt{\frac{\sum\left(w_i(\overline{x} - x_i)^2\right)}{(k-1)\sum w_i}}$$
$$= 0.6745\sqrt{\frac{0.0028}{(3-1)(14.23)}}$$
$$= 0.0067$$

The 50% confidence interval is 1206.40 ± 0.0067 ft.

Example 78.7

The interior angles of a triangular traverse were repeatedly measured. What is the probable value for angle 1?

angle	value	number of measurements
1	63°	2
2	77°	6
3	41°	5

Solution

The total of the angles is

$$63^\circ + 77^\circ + 41^\circ = 181^\circ$$

So, -1° must be divided among the three angles. These corrections are inversely proportional to the number of measurements. The sum of the measurement inverses is

$$\tfrac{1}{2} + \tfrac{1}{6} + \tfrac{1}{5} = 0.5 + 0.167 + 0.2$$
$$= 0.867$$

The most probable value of angle 1 is then

$$63^\circ + \frac{\left(\frac{1}{2}\right)(-1^\circ)}{0.867} = 62.42^\circ$$

Example 78.8

The interior angles of a triangular traverse were measured. What is the most probable value of angle 1?

angle	value
1	$63^\circ \pm 0.01^\circ$
2	$77^\circ \pm 0.03^\circ$
3	$41^\circ \pm 0.02^\circ$

Solution

The total of the angles is

$$63^\circ + 77^\circ + 41^\circ = 181^\circ$$

So, $-1°$ must be divided among the three angles. The corrections are proportional to the square of the probable errors.

$$(0.01)^2 + (0.03)^2 + (0.02)^2 = 0.0014$$

The most probable value of angle 1 is

$$63° + \frac{(0.01)^2(-1°)}{0.0014} = 62.93°$$

3. ERRORS IN COMPUTED QUANTITIES

When independent quantities with known errors are added or subtracted, the error of the result is given by Eq. 78.4. The squared terms under the radical are added regardless of whether the calculation is addition or subtraction.

$$E_{\text{sum}} = \sqrt{E_1^2 + E_2^2 + E_3^2 + \cdots} \qquad 78.4$$

The error in the product of two quantities, x_1 and x_2, which have known errors, E_1 and E_2, is given by Eq. 78.5.

$$E_{\text{product}} = \sqrt{x_1^2 E_2^2 + x_2^2 E_1^2} \qquad 78.5$$

Example 78.9

An EDM instrument manufacturer has indicated that the measurement error with a particular instrument is ± 0.04 ft with another error of ± 10 ppm. The instrument is used to measure a distance of 3000 ft. What is the expected error of measurement?

Solution

There are two independent errors here. Since both parts can be positive or negative, they may have opposite signs. The variable error is

$$E = (3000 \text{ ft})\left(\frac{10}{1{,}000{,}000}\right) = 0.03 \text{ ft}$$

Use Eq. 78.4.

$$E = \sqrt{E_1^2 + E_2^2}$$
$$= \sqrt{(0.04 \text{ ft})^2 + (0.03 \text{ ft})^2} = 0.05 \text{ ft}$$

Example 78.10

The sides of a rectangular section were determined to be 1204.77 ± 0.09 ft and 765.31 ± 0.04 ft, respectively. What is the probable error in area?

Solution

Use Eq. 78.5.

$$E_{\text{area}} = \sqrt{x_1^2 E_2^2 + x_2^2 E_1^2}$$
$$= \sqrt{\begin{array}{l}(1204.77 \text{ ft})^2(0.04 \text{ ft})^2 \\ \quad + (765.31 \text{ ft})^2(0.09 \text{ ft})^2\end{array}}$$
$$= 84.06 \text{ ft}^2$$

4. ORDERS OF ACCURACY

The significance of a known measurement error can be quantified by a ratio of parts (e.g., 1 ft in 10,000 ft, or 1:10,000). A distance measurement error is divided by the distance measured. A traverse closure error is divided by the sum of all traverse leg lengths to determine the fractional error.

Survey precision is designated by its *order*, with *first order* being the most precise. In the United States, standard accuracies have been established for horizontal and vertical control, as well as for closure and triangulation errors. Theoretically, any organization or agency could establish its own standards, but the phrase "order of accuracy" generally refers to standards specified by the Federal Geodetic Control Committee. The American Land Title Association (ALTA) and the American Congress on Surveying and Mapping (ASCM) have also issued standards for land title surveys of small parcels.

There are three different national *orders* (i.e., *levels*) *of accuracy*: first, second, and third order. Some states include a fourth order of accuracy (less than 1:5000). There are two different classes of accuracy in second- and third-order surveys: Classes I and II. These are described in Table 78.1.

Increased use of very precise GPS techniques has created a demand for greater control. The National Geodetic Survey (NGS) has established both order A (accuracy of 1:10,000,000) and order B (accuracy of 1:1,000,000) points.

For land title surveys of parcels using ALTA/ACSM specifications, the *degree of precision* should be based on the intended use of the land parcel, without regard to its present use, provided the intended use is known. Four general survey classes are defined using various state regulations and accepted practices.

Class A, Urban Surveys: Surveys of land lying within or adjoining a city or town. This also includes the surveys of commercial and industrial properties, condominiums, townhouses, apartments, and other multiunit developments, regardless of geographic location.

Class B, Suburban Surveys: Surveys of land lying outside urban areas. This land is used almost exclusively for single-family residences or residential subdivisions.

Class C, Rural Surveys: Surveys of land such as farms and other undeveloped land outside the suburban areas that may have a potential for future development.

Class D, Mountain and Marshland Surveys: Surveys of land that normally lie in remote areas with difficult terrain and that usually have limited potential for development.

Table 78.1 *Federal Standards of Traverse Closure Errors*

order of accuracy	maximum error	application
first	1:100,000	primary control nets; precise scientific studies
second		support for primary control;
class I	1:50,000	control for large engineering
class II	1:20,000	projects
third		small-scale engineering
class I	1:10,000	projects; large-scale mapping
class II	1:5000	projects

5. TYPES OF SURVEYS

Plane surveys disregard the curvature of the earth. A plane survey is appropriate if the area is small. This is true when the area is not more than 12 mi (19 km) or so in any one direction. *Geodetic surveys* consider the curvature of the earth. *Zoned surveys*, as used in various *State Plane Coordinate Systems* and in the *Universal Transverse Mercator* (UTM) system, allow computations to be performed as if on a plane while accomodating larger areas.

6. SURVEYING METHODS

A *stadia survey* requires the use of a transit, theodolite, or engineer's level as well as a rod for reading elevation differences and a tape for measuring horizontal distances. Stadia surveys are limited by the sighting capabilities of the instrument as well as by the terrain ruggedness.

In a *plane table survey*, a plane table is used in conjunction with a *telescopic instrument*. The plane table is a drawing board mounted on a tripod in such a way that the board can be leveled and rotated without disturbing the azimuth. The primary use of the combination of the plane table and telescope is in field compilation of maps, for which the plane table is much more versatile than the transit.

Total station surveys integrate theodolites, electronic distance measurement (EDM), and data recorders, collecting vertical and horizontal data in a single operation. *Manual total stations* use conventional optical-reading theodolites. *Automatic total stations* use electronic theodolites. *Data collectors* work in conjunction with total stations to store data electronically. Previously determined data can be downloaded to the data recorders for use in the field to stake out or field-locate construction control points and boundaries.

Triangulation is a method of surveying in which the positions of survey points are determined by measuring the angles of triangles defined by the points. Each survey point or monument is at a corner of one or more triangles. The survey lines form a network of triangles. The three angles of each triangle are measured. Lengths of triangle sides are calculated from trigonometry. The positions of the points are established from the measured angles and the computed sides.

Triangulation is used primarily for geodetic surveys, such as those performed by the National Geodetic Survey. Most first- and second-order control points in the national control network have been established by triangulation procedures. The use of triangulation for transportation surveys is minimal. Generally, triangulation is limited to strengthening traverses for control surveys.

Trilateration is similar to triangulation in that the survey lines form triangles. In trilateration, however, the lengths of the triangles' sides are measured. The angles are calculated from the side lengths. Orientation of the survey is established by selected sides whose directions are known or measured. The positions of trilaterated points are determined from the measured distances and the computed angles.

Photogrammetric surveys are conducted using aerial photographs. The advantages of using photogrammetry are speed of compilation, reduction in the amount of surveying required to control the mapping, high accuracy, faithful reproduction of the configuration of the ground by continuously traced contour lines, and freedom from interference by adverse weather and inaccessible terrain. Disadvantages include difficulty in areas containing heavy ground cover, high cost of mapping small areas, difficulty of locating contour lines in flat terrain, and the necessity for field editing and field completion. Photogrammetry works with ground control panels that are 3 to 4 times farther apart than with conventional surveys. But a conventional survey is still required in order to establish control initially.

Airborne LIDAR (*Light Detection and Ranging*) units are aircraft-mounted laser systems designed to measure the 3D coordinates of a passive target. This is achieved by combining a laser with positioning and orientation measurements. The laser measures the distance to the ground surface or target, and when combined with the position and orientation of the sensors, yields the 3D position of the target. Unlike EDM, which uses phase shifts of a continuous laser beam, LIDAR measures the time of flight for a single laser pulse to make the round trip from the source to receiver. LIDAR systems typically use a single wavelength, either 1064 nm or 532 nm,

corresponding to the infrared and green areas of the electronic spectrum, respectively. Time can be measured to approximately 1/3 ns, corresponding to a distance resolution of approximately 5 cm.

7. GLOBAL POSITIONING SYSTEM

The NAVSTAR (Navigation Satellite Timing and Ranging) *Global Positioning System* (GPS) is a one-way (satellite to receiver) ranging system. The advantages of GPS are speed and access. The main disadvantages are cost of equipment and dependence on satellite availability/visibility. Four satellites must be visible for 3D work, and a clear view of the sky is needed.

GPS determines positions without reference to any other point. It has the advantage of allowing work to proceed day or night, rain or shine, in fair weather or foul. It is not necessary to have clear lines of sight between stations, or to provide mountaintop stations for *inversability*.

GPS uses precisely synchronized clocks on each end—atomic clocks in the satellites and quartz clocks in the receivers. Frequency shift (as predicted by the Doppler effect) data is used to determine positions. Accurate positions anywhere on the earth's surface can easily be determined.

GPS can be used in two modes. *Standalone navigational mode* yields positional accuracies of ±2 to 10 m; *differential* or *relative positioning* yields centimeter accuracies.

In relative positioning, one GPS receiver is placed on a point whose coordinates have been established in the National Geodetic Reference System, and one or more other receivers are placed at other points whose coordinates are to be determined. All receivers observe the same satellites at the same time for about an hour, more or less, depending on the accuracy required and the conditions of observation. A computer analysis (using proprietary software from the GPS equipment manufacturer) of the observed and recorded data determines the coordinates of the unknown points, the distance and elevation between the known point and each unknown point, and the direction (azimuth) from the known point to each unknown point. With relative positioning, the distance between points can be measured to 1 to 2 cm, and better than 1 part in 100,000.

Terms used when discussing GPS accuracy are *GDOP*, *HDOP*, and *VDOP*, standing for *geodetic*, *horizontal*, and *vertical dilution of position*. These numbers are inversely proportional to the volume of a pyramid that is formed by the position of the receiver and the four satellites being observed. In effect, GDOP is a measure of the geometry of the solution. A low GDOP number provides the best geometry and the most accurate solution.

GPS receivers are generally used in a fixed (stationary) position, hence the term *static GPS surveying*. With *rapid static mode* using a more sophisticated receiver, occupation times can be reduced from 45 to 60 min to 10 to 15 min for short baselines.

Using a modified observation procedure known as *kinematic GPS surveying*, the coordinates of any point can be determined in 45 to 60 sec. Kinematic GPS uses one stationary receiver and one or more roving receivers. However, this method is procedurally demanding and very unforgiving. For example, if the "lock" on a satellite is lost, a previously observed point must be reoccupied to continue the survey.

Pseudokinematic GPS surveying is similar to kinematic GPS in field procedure but similar to static GPS in processing. Rover units occupy each point for approximately 10 min, then reoccupy the positions later during a reverse run of the route.

GPS is less suited to elevation measurements. It is used in conjunction with traditional surveying methods to determine accurate elevations. Inaccuracies in elevation derive from the difference between the *spheroid* (the mathematical model selected by the software to best fit the surface of the entire earth) and the *geoid* (the actual shape of the earth at sea level). Depending on location, this difference in surface elevation can be 2 to 35 m.

8. INERTIAL SURVEY SYSTEMS

Inertial survey systems (ISSs) determine a position on the earth by analyzing the movement of a transport vehicle, usually a light-duty truck or helicopter in which the equipment is installed. An ISS system consists of a precise clock, a computer, a recording device, sensitive accelerometers, and gyroscopes. The equipment measures the acceleration of the vehicle in all three axes and converts the acceleration into distance. The production rate is 8 to 10 mph when mounted in tired vehicles. Helicopter ISSs can proceed at 50 to 70 mph.

To reduce errors and achieve horizontal accuracies of 1 part in 10,000 or even 20,000, the circuit is "double run" in opposite directions. This cancels some instrumentation errors caused by the earth's rotation and magnetic field. Vertical accuracies are less.

9. GEOGRAPHIC INFORMATION SYSTEMS

A *Geographic Information System* (GIS) is a computerized database management system used to capture, store, retrieve, analyze, and display spatial data in map and overlay form. GIS replaces rolls and piles of time-bleached paper prints stored in drawers.

The integrated database contains spatial information, literal information (e.g., descriptions), and characteristics (e.g., land cover and soil type). Users can pose questions involving both position and characteristics.

GIS can produce "intelligent supermaps" at the touch of a button. Details (e.g., lines, features, text) on maps that are *vector images* can be individually addressed,

edited, colored, moved, and so on. Maps that consist of *raster images*, on the other hand, can be edited on a pixel-by-pixel basis, but the individual details cannot be modified.

10. UNITS

In most of the United States, survey work is conducted using the foot and decimal parts for distance. The SI system, using meters to measure distance, is widely used throughout the world. In the United States, the SI system has been adopted by only some state highway departments.

In the United States, angles are measured in the *sexagesimal system* with degrees, minutes, and seconds. However, some countries have divided the circle into 400 units called *gons* (or *grads*). Thus, a right angle would have a measure of 100.0000 gon.

11. POSITIONS

Modern equipment permits surveyors to obtain positioning information directly from the theodolite.

It is not necessary to make a series of distance and angle measurements in the field and then return to the office to perform calculations to determine an unknown position.

Two methods are used to specify positions: (a) by latitude and longitude, and (b) by rectangular (Cartesian) coordinates measured from a reference point. The *state plane coordinate systems* are rectangular systems using a partial latitude/longitude system as baseline references.

12. BENCHMARKS

"Benchmark" is the common name given to permanent monuments of known vertical positions. Monuments with known horizontal positions are referred to as *control stations* or *triangulation stations*. A nail or hub in the pavement, the flange bolts of a fire hydrant, or the top of a concrete feature (e.g, curb) can be used as a *temporary benchmark*. The elevations of temporary benchmarks are generally found in field notes and local official filings.

Official benchmarks (monuments) installed by surveyors and engineers generally consist of a bronze (or other inert material) disk set in the top of a concrete post/pillar. (Bronze caps in iron pipes were once used, but these have limited lives due to corrosion.) Stainless steel pins and invar rods are also used. Bronze disks and identification plates are stamped, at the minimum, with the name of the agency or the state registration number of the individual setting the benchmark. Official USGS benchmarks are stamped with a unique identification code. Official benchmarks may or may not have the elevations indicated. If not, an official directory can be consulted for the information.

First-order monuments are widely spaced, but they are more accurately located for use in large-area control. Within the first-order network are a number of more closely spaced second-order monuments, followed by third-order and fourth-order networks of ever smaller scopes. Each lower-order monument is referenced to a higher-order monument.

Vertical positions (i.e.; elevations) are measured above a reference surface or *datum*, often taken as *mean sea level*. For small projects, a local datum on a temporary permanent benchmark can be used.

13. DISTANCE MEASUREMENT: TAPING

Gunter's chain (developed around 1620) consisted of 100 links totaling 66 ft. It was superseded by steel tape in the 1900s. However, steel tapes are still sometimes referred to as "chains," and measuring distance with a steel tape is still called "chaining." The earliest tapes were marked at each whole foot, with only the last foot being subdivided into hundredths, similar to a Gunter's chain. Tapes exactly 100 ft long were called *cut chains*. Other tapes were 101 ft long and were called *add chains*. Tapes are now almost universally subdivided into hundreds along their entire lengths. In practice, this enables the rear chainman to hold the zero mark on the point being measured from, while the head chainman reads the distance directly off the face of the tape.

Tapes are relatively inexpensive and easy to use, but they are mainly used only when measuring or staking short distances. Low-coefficient tapes made from nickel-steel alloy known as *invar* are fairly insensitive to temperature. The coefficient of thermal expansion, α, of invar is 2 to 5.5×10^{-7} ft/ft-°F (3.6 to 9.9×10^{-7} m/m·°C), and its modulus of elasticity, E, is 2.1×10^7 lbf/in^2 (145 GPa). For steel tapes, α is 6.45×10^{-6} ft/ft-°F (1.16×10^{-5} m/m·C) and the modulus of elasticity, E, is 2.9×10^7 lbf/in^2 (200 GPa). Some woven tapes (e.g., linen, dacron) may have embedded copper fibers to provide strength. Other tapes are manufactured from fiberglass, which neither stretch excessively nor conduct electricity.

Tapes can be marked with customary U.S. units, SI units, or both (on either side). They come in a variety of lengths, up to 100 m, though 100 ft and 30 m tapes are the most common.

Tape readings are affected by temperature, tension, and sag. Correction equations are given in Eqs. 78.6, 78.7, and 78.8 and are applied according to Table 78.2. L is the length of tape, α is the coefficient of thermal expansion, T and P are the temperature and tension at which the measurement was made, T_s and P_s are the temperature and tension at which the tape was standardized, A is the cross-sectional area of the tape, and E is the modulus of elasticity of the tape.

$$C_T = L\alpha(T - T_s) \quad \text{[temperature]} \qquad 78.6$$

$$C_P = \frac{(P - P_s)L}{AE} \quad \text{[tension]} \qquad 78.7$$

$$C_s = \pm\left(\frac{W^2L^3}{24P^2}\right) \quad \text{[sag]} \qquad 78.8$$

Table 78.2 *Correction for Surveyor's Tapes*

	measured flat	measured suspended
standardized flat	none	subtract C_s
standardized suspended	add C_s	none

14. DISTANCE MEASUREMENT: TACHYOMETRY

Tachyometric distance measurement involves sighting through a small angle at a distant scale. The angle may be fixed and the length measured (*stadia method*), or the length may be fixed and the angle measured (*European method*). Stadia measurement consists of observing the apparent locations of the horizontal crosshairs on a distant stadia rod. The interval between the two rod readings is called the *stadia interval* or the *stadia reading*.

The distance is directly related to the distance between the telescope and the rod. For rod readings, R_1 and R_2 (both in ft), the distance from the instrument to the rod is found from Eq. 78.9. The *instrument factor*, C, is the sum of the focal length and the distance from the plumb bob (or center of the instrument) to the forward lens. It varies from 0.6 to 1.4 ft but is typically set by the manufacturer at 1 ft. C is zero for internal focusing telescopes. The *interval factor*, K, often has a value of 100.

$$x = K(R_2 - R_1) + C \qquad 78.9$$

If the sighting is inclined, as it is in Fig. 78.2, it is necessary to find both horizontal and vertical distances. These can be determined from Eqs. 78.10 and 78.11, in which y is measured from the telescope to the sighting rod center. The height of the instrument above the ground must be known to calculate the elevation of the object above the ground.

$$x = K(R_2 - R_1)\cos^2\theta + C\cos\theta \qquad 78.10$$

$$y = \tfrac{1}{2}K(R_2 - R_1)\sin 2\theta + C\sin\theta \qquad 78.11$$

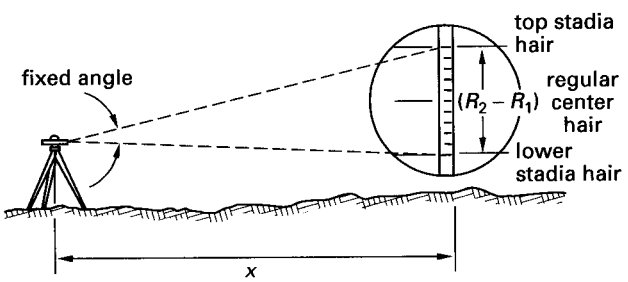

Figure 78.1 *Horizontal Stadia Measurement*

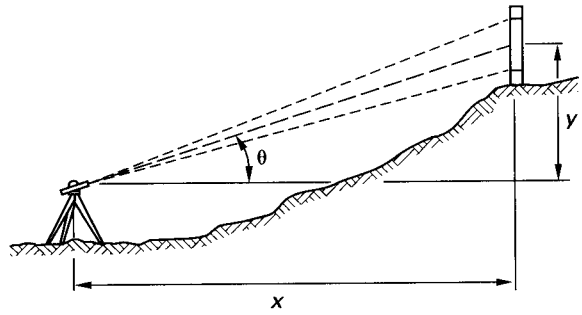

Figure 78.2 *Inclined Stadia Measurement*

15. DISTANCE MEASUREMENT: EDM

Long-range infrared and laser *electronic distance measurement* (EDM) equipment is capable of measuring lines up to 10 mi long in less than 1 sec with an accuracy of better than $\frac{1}{3}$ ft (100 mm). Shorter ranges are even more precise. EDM can measure lines 1 mi long in less than 5 sec with an accuracy of about 0.01 ft. Light beams are reflected back by glass *retroreflectors* (precisely ground trihedral prisms). Common EDM accuracy ranges up to 2 mi (3.2 km) are ± 3 to 7 mm and ± 2 to 7 ppm. Shorter distances enjoy even better accuracies.

An *optical plummet* allows the instrument or retroprism to be placed precisely over a point on the ground, in spite of winds that would make a string *plumb bob* swing.

16. STATIONING

In route surveying, lengths are divided into 100 ft or 100 m sections called *stations*. The word "station" can mean both a location and a distance. A station is a length of 100 ft or 100 m, and the unit of measure is frequently abbreviated "sta." (30 m and 1000 m stationing are also used.) When a length is the intended meaning, the unit of measure will come after the numerical value; for example, "the length of curve is 4 sta." When a location is the intended meaning, the unit of measure will come before the number. For example, "the point of intersection is at sta 4." The location is actually a distance from the starting point. Therefore, the two meanings are similar and related.

Interval *stakes* along an established route are ordinarily laid down at *full station* intervals. If a marker stake is placed anywhere else along the line, it is called a *plus station* and labeled accordingly. A stake placed 825 ft (251 m) from station 0+00 is labeled "8+25" (2+51). Similarly, a stake placed 2896 ft (883 m) from a reference point at station 10+00 (10+00) is labeled "38+96" (18+83).

17. LEVELS

Automatic and self-leveling laser *levels* have all but replaced the optical level for leveling and horizontal alignment. A tripod-mounted laser can rotate and project

a laser plane 300 to 2000 ft in diameter. A receiver mounted on a rod with visual and audible signals will alert the rodman to below-, at-, and above-grade conditions.

18. ELEVATION MEASUREMENT

Leveling is the act of using an engineer's level (or other leveling instrument) and rod to measure a vertical distance (*elevation*) from an arbitrary level surface.

If a level sighting is taken on an object with actual height h_a, the *curvature of the earth* will cause the object to appear taller by an amount h_c. In Eq. 78.12, x is measured in feet along the curved surface of the earth.

$$h_c = \left(2.4 \times 10^{-8} \frac{1}{\text{ft}}\right) x_{\text{ft}}^2 \quad \text{[U.S.]} \qquad 78.12$$

Atmospheric refraction will make the object appear shorter by an amount h_r.

$$h_r = \left(3.0 \times 10^{-9} \frac{1}{\text{ft}}\right) x_{\text{ft}}^2 \quad \text{[U.S.]} \qquad 78.13$$

The corrected rod reading (actual height) is

$$\begin{aligned} h_a &= R_{\text{observed}} + h_r - h_c \\ &= R_{\text{observed}} - \left(2.1 \times 10^{-8} \frac{1}{\text{ft}}\right) x_{\text{ft}}^2 \quad \text{[U.S.]} \end{aligned} \qquad 78.14$$

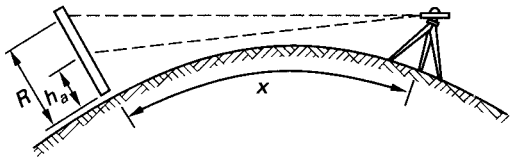

Figure 78.3 *Curvature and Refraction Effects*

19. ELEVATION MEASUREMENT: DIRECT LEVELING

A *telescope* is part of the sighting instrument. A *transit* or *theodolite* is often referred to as a "telescope" even though the telescope is only a part of the instrument. (Early telescoping theodolites were so long that it was not possible to invert, or "transit," them. Hence the name "transit" is used for inverting telescopes.) An *engineer's level* (*dumpy level*) is a sighting device with a telescope rigidly attached to the level bar. A sensitive level vial is used to ensure level operation. The engineer's level can be rotated, but in its basic form it cannot be elevated. (An *alidade* consists of the base and telescopic part of the transit but not the tripod or leveling equipment.)

In a *semi-precise level*, also known as a *prism level*, the level vial is visible from the eyepiece end. In other respects, it is similar to the engineer's level. The *precise* or *geodetic level* has even better control of horizontal angles. The bubble vial is magnified for greater accuracy.

Transits and levels are used with rods. *Leveling rods* are used to measure the vertical distance between the line of sight and the point being observed. The *standard rod* is typically made of fiberglass and is extendable. It is sometimes referred to as a *Philadelphia rod*. *Precise rods*, made of wood-mounted invar, are typically constructed in one piece and are spring-loaded in tension to avoid sagging.

With *direct leveling*, a level is set up at a point approximately midway between the two points whose difference in elevation is desired. The vertical *backsight* (*plus sight*) and *foresight* (*minus sight*) are read directly from the rod. HI is the height of the instrument above the ground, and h_{rc} is the correction for refraction and curvature.

Referring to Fig. 78.4,

$$y_{\text{A-L}} = R_{\text{A}} - h_{\text{rc,A-L}} - \text{HI} \qquad 78.15$$

$$y_{\text{L-B}} = \text{HI} + h_{\text{rc,L-B}} - R_{\text{B}} \qquad 78.16$$

The difference in elevations between points A and B is

$$\begin{aligned} y_{\text{A-B}} &= y_{\text{A-L}} + y_{\text{L-B}} \\ &= R_A - R_B + h_{\text{rc,L-B}} - h_{\text{rc,A-L}} \end{aligned} \qquad 78.17$$

If the backsight and foresight distances are equal (or approximately so), then the effects of refraction and curvature cancel.

$$y_{\text{A-B}} = R_A - R_B \qquad 78.18$$

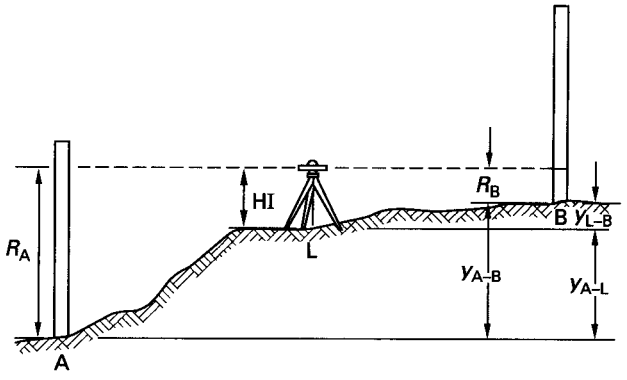

Figure 78.4 *Direct Leveling*

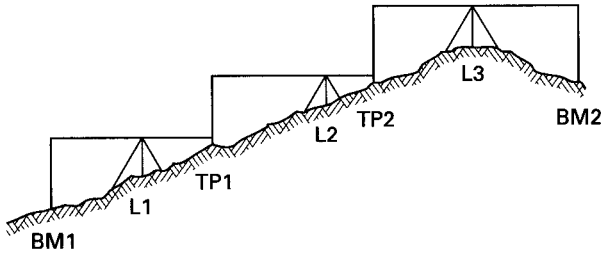
20. ELEVATION MEASUREMENT: DIFFERENTIAL LEVELING

Differential leveling is the consecutive application of direct leveling to the measurement of large differences in elevation. There is usually no attempt to exactly balance the foresights and backsights. Therefore, there is

Transportation

no record made of the exact locations of the level positions. Furthermore, the path taken between points need not be along a straight line connecting them, as only the elevation differences are relevant. If greater accuracy is desired without having to accurately balance the foresight and backsight distances, it is possible to eliminate most of the curvature and refraction error by balancing the sum of the foresights against the sum of the backsights.

The following abbreviations are used with differential leveling.

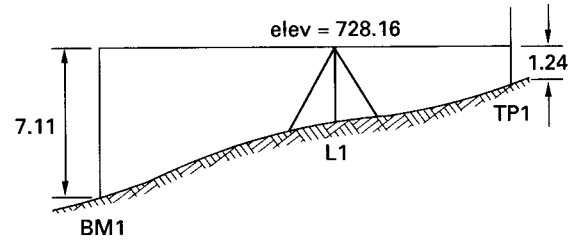


BM	benchmark or monument
TP	turning point
FS	foresight (also known as a minus sight)
BS	backsight (also known as a plus sight)
HI	height of the instrument
L	level position

HI (or H.I.) is the distance between the instrument axis and the datum. For differential leveling, the datum established for all elevations is used to define the HI. However, in stadia measurements, HI may be used (and recorded in the notes) to represent the height of the instrument axis above the ground.

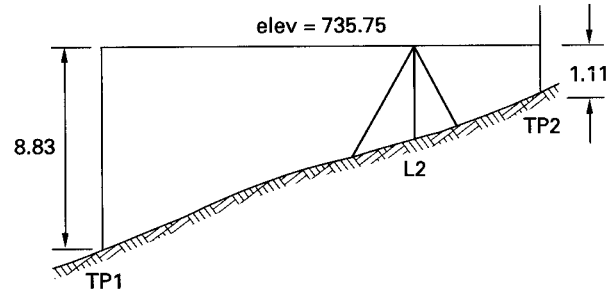
Example 78.11

The following readings were taken during a differential leveling survey between benchmarks 1 and 2. All values given are in feet. What is the difference in elevations between these two benchmarks?



station	BS	FS	elevation
BM1	7.11		721.05
TP1	8.83	1.24	
TP2	11.72	1.11	
sta 1+00		2.92	
sta 2+00		6.43	
BM2			10.21

Solution



The first measurement is shown in larger scale. The height of the instrument is

$$\begin{aligned} \text{HI1} &= \text{elev}_{\text{BM}} + \text{BS} \\ &= 721.05 \text{ ft} + 7.11 \text{ ft} = 728.16 \text{ ft} \end{aligned}$$

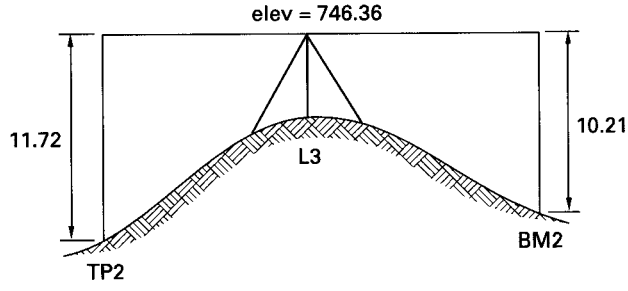
The height of the instrument at the second level position is

$$\begin{aligned} \text{HI2} &= \text{HI1} + \text{BS} - \text{FS} \\ &= 728.16 \text{ ft} + 8.83 \text{ ft} - 1.24 \text{ ft} \\ &= 735.75 \text{ ft} \end{aligned}$$

The height of the instrument at the third level position is

$$\begin{aligned} \text{HI3} &= \text{HI2} + \text{BS} - \text{FS} \\ &= 735.75 \text{ ft} + 11.72 \text{ ft} - 1.11 \text{ ft} \\ &= 746.36 \text{ ft} \end{aligned}$$

The elevation of sta 1+00 is



$$\begin{aligned} \text{elev}_{\text{sta 1+00}} &= \text{HI3} - \text{FS} \\ &= 746.36 \text{ ft} - 2.92 \text{ ft} = 743.44 \text{ ft} \end{aligned}$$

The elevation of sta 2+00 is

$$\begin{aligned} \text{elev}_{\text{sta 2+00}} &= \text{HI3} - \text{FS} \\ &= 746.36 \text{ ft} - 6.43 \text{ ft} \\ &= 739.93 \text{ ft} \end{aligned}$$

The elevation of BM2 is

$$\begin{aligned} \text{elev}_{\text{BM2}} &= \text{HI3} - \text{FS} \\ &= 746.36 \text{ ft} - 10.21 \text{ ft} \\ &= 736.15 \text{ ft} \end{aligned}$$

The difference in elevation is

$$\text{elev}_{BM2} - \text{elev}_{BM1} = 736.15 \text{ ft} - 721.05 \text{ ft} = 15.1 \text{ ft}$$

Check using the backsight and foresight sums.

The backsight sum is

$$7.11 \text{ ft} + 8.83 \text{ ft} + 11.72 \text{ ft} = 27.66 \text{ ft}$$

The foresight sum is

$$1.24 \text{ ft} + 1.11 \text{ ft} + 10.21 \text{ ft} = 12.56 \text{ ft}$$

The difference in elevation is

$$27.66 \text{ ft} - 12.56 \text{ ft} = 15.1 \text{ ft} \quad \text{[OK]}$$

21. ELEVATION MEASUREMENT: INDIRECT LEVELING

Indirect leveling, illustrated in Fig. 78.5, does not require a backsight. (A backsight reading can still be taken to eliminate the effects of curvature and refraction.) In Fig. 78.5, distance AC has been determined. Within the limits of ordinary practice, angle ACB is 90°. Including the effects of curvature and refraction, the elevation difference between points A and B is

$$y_{A\text{-}B} = AC \tan\alpha + 2.1 \times 10^{-8}(AC)^2 \quad \text{[U.S.]} \qquad 78.19$$

If a backsight is taken from B to A and angle β is measured, then

$$y_{A\text{-}B} = AC \tan\beta - 2.1 \times 10^{-8}(AC)^2 \quad \text{[U.S.]} \qquad 78.20$$

Adding Eqs. 78.19 and 78.20 and dividing by 2,

$$y_{A\text{-}B} = \tfrac{1}{2}AC(\tan\alpha + \tan\beta) \qquad 78.21$$

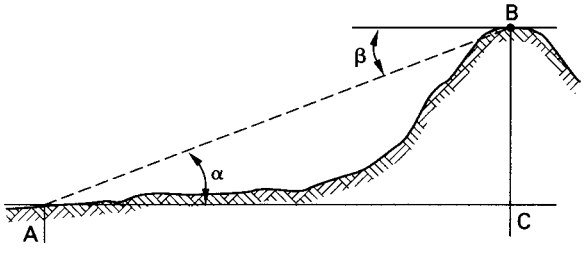


Figure 78.5 *Indirect Leveling*

22. EQUIPMENT AND METHODS USED TO MEASURE ANGLES

A *transit* is a telescope that measures vertical angles as well as horizontal angles. The conventional *engineer's transit* (*surveyor's transit*) used in the past had a 6¼ in diameter metal circle and vernier. It could be clamped vertically and used as a level. Few instruments of this nature are still available.

With a *theodolite*, horizontal and vertical angles are measured by looking into viewpieces. There may be up to four viewpieces, one each for the sighting-in telescope, the compass, the horizontal and vertical angles, and the optical plummet. Theodolites may be scale-reading optical, micrometer-reading optical, or electronic. Angles read electronically interface with EDM equipment and data recorders.

23. DIRECTION SPECIFICATION

The direction of any line can be specified by an angle between it and some other reference line, known as a *meridian*. If the meridian is arbitrarily chosen, it is called an *assumed meridian*. If the meridian is a true north-to-south line passing through the true north pole, it is called a *true meridian*. If the meridian is parallel to the earth's magnetic field, it is known as a *magnetic meridian*. A rectangular grid may be drawn over a map with any arbitrary orientation. If so, the vertical lines are referred to as *grid meridians*.

A true meridian differs from a magnetic meridian by the *declination* (*magnetic declination* or *variation*). If the north end of a compass points to the west of true meridian, the declination is referred to as a *west declination* or *minus declination*. Otherwise, it is referred to as an *east declination* or *plus declination*. Plus declinations are added to the magnetic compass azimuth to obtain the true azimuth. Minus declinations are subtracted from the magnetic compass azimuth.

A direction (i.e., the variation of a line from its meridian) may be specified in several ways. Directions are normally specified as either bearings or azimuths referenced to either north or south. In the United States, most control work is performed using directions stated as azimuths. Most construction projects and property surveys specify directions as bearings.

Azimuth: An azimuth is given as a clockwise angle from the reference direction, either "from the north" or "from the south" (e.g., "NAz 320"). Azimuths may not exceed 360°.

Deflection angle: The angle between a line and the prolongation of a preceding line is a deflection angle. Such measurements must be labeled as "right" for clockwise angles and "left" for counterclockwise angles.

Angle to the right: An angle to the right is a clockwise deflection angle measured from the preceding to the following line.

Azimuths from the back line: Same as angle to the right.

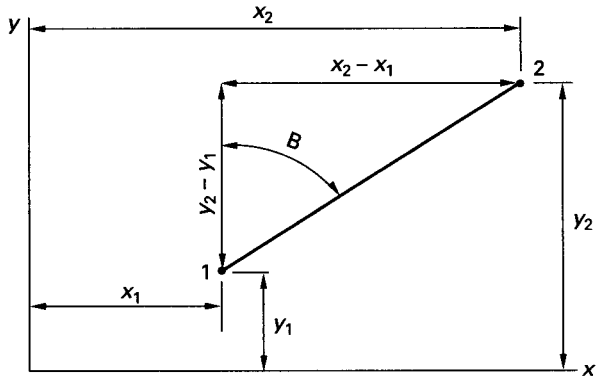

Figure 78.6 *Calculation of Bearing Angle*

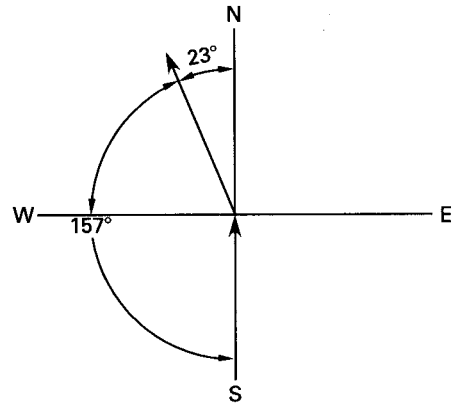
Bearing: The bearing of a line is referenced to the quadrant in which the line falls and the angle that the line makes with the meridian in that quadrant. It is necessary to specify the two cardinal directions that define the quadrant in which the line is found. The north and south directions are always specified first. A bearing contains an angle and a direction from a reference line, either north or south (e.g., "N45°E"). A bearing may not have an angular component exceeding 90°.

Bearings and azimuths are calculated from trigonometric and geometric relationships. From Fig. 78.6, the tangent of the bearing angle B of the line between the two points is given by Eq. 78.22.

$$\tan \mathrm{B} = \frac{x_2 - x_1}{y_2 - y_1} \qquad 78.22$$

The distance D between the two points is given by Eq. 78.23.

$$D = \sqrt{(y_2 - y_1)^2 + (x_2 - x_1)^2} \qquad 78.23$$



If the numerator in Eq. 78.22 is positive, the line from point 1 to 2 bears east. If the denominator is positive, the line bears north. Determining the bearing and length of a line from the coordinates of the two points is called *inversing the line.*

The *azimuth* A_{N} of a line from point 1 to 2 measured from the north meridian is given by Eq. 78.24.

$$\tan A_{\mathrm{N}} = \frac{x_2 - x_1}{y_2 - y_1} \qquad 78.24$$

The azimuth A_{S} of the same line from point 1 to 2 measured from the south meridian is given by Eq. 78.25.

$$\tan A_{\mathrm{S}} = \frac{x_1 - x_2}{y_1 - y_2} \qquad 78.25$$

azimuth from the south: 157°
azimuth from the north: 337°
deflection angle: 23°L
angle to the right: 157°
bearing: N23°W

Figure 78.7 *Equivalent Angle Measurements*

Example 78.12

A group of hikers on the Pacific Crest Trail (magnetic declination of +17°) uses a magnetic compass to sight in on a distant feature. What is the true azimuth if the observed angle is 42°?

Solution

A plus declination is added to the observed azimuth. Therefore, the true azimuth is 42° + 17° = 59°.

24. LATITUDES AND DEPARTURES

The *latitude* of a line is the distance that the line extends in a north or south direction. A line that runs toward the north has a positive latitude; a line that runs toward the south has a negative latitude. The *departure* of a line is the distance that the line extends in an east or west direction. A line that runs toward the east has a positive departure; a line that runs toward the west has a negative departure.

If the x- and y-coordinates of two points are known, the latitude and departure of the line between the two points are determined by Eqs. 78.26 and 78.27.

latitude of line from point 1 to 2: $y_2 - y_1$ 78.26
departure of line from point 1 to 2: $x_2 - x_1$ 78.27

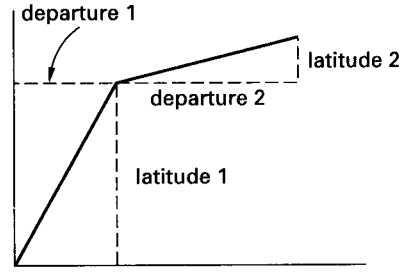


Figure 78.8 *Latitudes and Departures*

25. TRAVERSES

A *traverse* is a series of straight lines whose lengths and directions are known. A traverse that does not come back to its starting point is an *open traverse*. A traverse that comes back to its starting point is a *closed traverse*. The polygon that results from closing a traverse is governed by the following two geometric requirements.

(1) The sum of the deflection angles is 360°.

(2) The sum of the interior angles of a polygon with n sides is $(n-2)(180°)$.

There are three ways to specify angles in traverses: *deflection angles, interior angles* (also known as *explement angles*), and *station angles*. These are illustrated in Fig. 78.9.

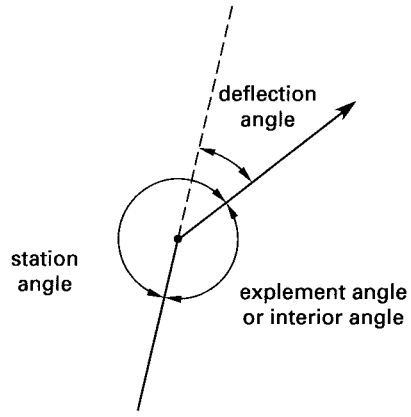

Figure 78.9 *Angles Used in Defining Traverses*

26. BALANCING

Refined field measurements are not the goal of measurement *balancing* (also known as *adjusting*). Balancing is used simply to accommodate the mathematical necessity of having a balanced column of figures. Balancing is considered inappropriate by some surveyors, since errors are not eliminated, only distributed to all of the measurements. Balancing does not make inaccurate measurements more accurate—it only makes inaccurate measurements more inaccurate. It is particularly inappropriate when a "blunder" (a measurement grossly in error that should be remeasured) is fixed by balancing.

27. BALANCING CLOSED TRAVERSE ANGLES

Due to measurement errors, variations in magnetic declination, and local magnetic attractions, it is likely that the sum of angles making up the interior angles will not exactly equal $(n-2)(180°)$. The following adjusting procedure can be used to distribute the angle error of closure among the angles.

step 1: Calculate the interior angle at each vertex from the observed bearings.

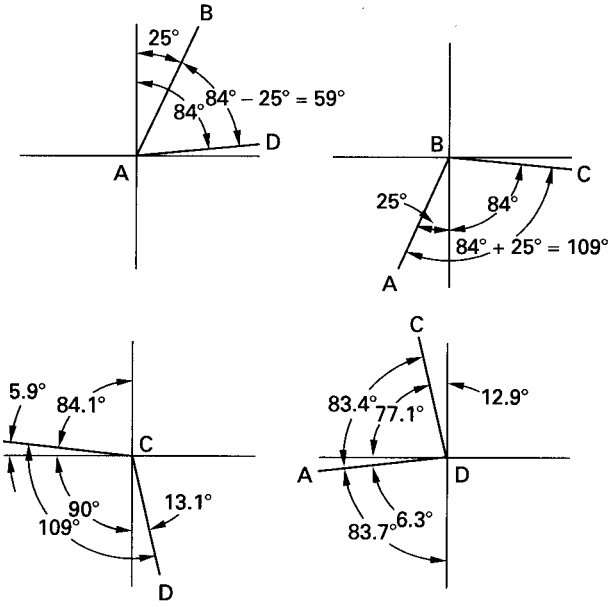
step 2: Subtract $(n-2)(180°)$ from the sum of the interior angles.

step 3: Unless additional information in the form of numbers of observations or probable errors is available, assume the angle error of closure can be divided equally among all angles. Divide the error by the number of angles.

step 4: Find a line whose bearing is assumed correct; that is, find a line whose bearing appears unaffected by errors, variations in magnetic declination, and local attractions. Such a line may be chosen as one for which the forward and back bearings are the same. If there is no such line, take the line whose difference in forward and back bearings is the smallest.

step 5: Start with the assumed correct line and add (or subtract) the prorated error to each interior angle.

step 6: Correct all bearings except the one for the assumed correct line.



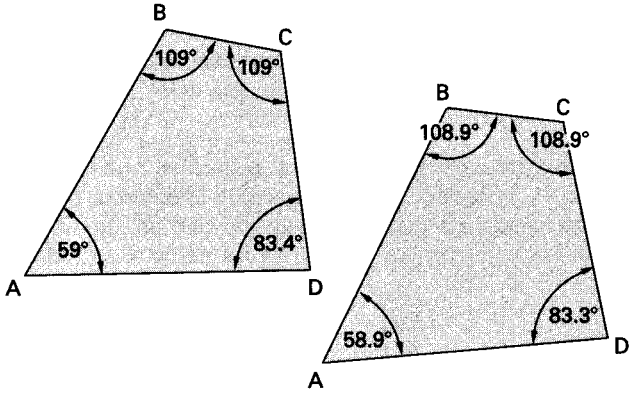
Example 78.13

Adjust the angles on the four-sided closed traverse whose magnetic foresights and backsights are as follows.

line	bearing
AB	N 25°E
BA	S 25°W
BC	S 84°E
CB	N 84.1°W
CD	S 13.1°E
DC	N 12.9°W
DA	S 83.8°W
AD	N 84°E

Solution

step 1: The interior angles are calculated from the bearings.



step 2: The sum of the angles is

$$59° + 109° + 109° + 83.4° = 360.4°$$

For a four-sided traverse, the sum of interior angles should be $(4 - 2)(180°) = 360°$, so a correction of $-0.4°$ must be divided evenly among the four angles. Since the backsight and foresight bearings of line AB are the same, it is assumed that the 25° bearings are the most accurate. The remaining bearings are then adjusted to use the corrected angles.

line	bearing
AB	N 25°E
BA	S 25°W
BC	S 83.9°E
CB	N 83.9°W
CD	S 12.8°E
DC	N 12.8°W
DA	S 83.9°W
AD	N 83.9°E

28. BALANCING CLOSED TRAVERSE DISTANCES

In a closed traverse, the algebraic sum of the latitudes should be zero. The algebraic sum of the departures should also be zero. The actual non-zero sums are called *closure in latitude* and *closure in departure*, respectively.

The *traverse closure* is the line that will exactly close the traverse. Since latitudes and departures are orthogonal, the closure in latitude and closure in departure can be considered as the rectangular coordinates and the traverse closure length calculated from the Pythagorean theorem. The coordinates will have signs opposite the closures in departure and latitude. That is, if the closure in departure is positive, point A will lie to the left of point A′, as shown in Fig. 78.10.

The length of a traverse closure is calculated from the Pythagorean theorem.

$$L = \sqrt{\begin{matrix}(\text{closure in departure})^2 \\ + (\text{closure in latitude})^2\end{matrix}} \qquad 78.28$$

To balance a closed traverse, the traverse closure must be divided among the various legs of the traverse. (Of course, if it is known that one leg was poorly measured due to difficult terrain, all of the error may be given to that leg.) This correction requires that the latitudes and departures be known for each leg of the traverse.

Computer-assisted traverse balancing systems offer at least two balancing methods: compass rule, transit rule, *Crandall method*, and *least squares*. The use of one rule or the other is often arbitrary or a matter of convention.

The most common balancing method is the *compass rule*, also known as the *Bowditch method*: the ratio of a leg's correction to the total traverse correction is equal to the ratio of leg length to the total traverse length, with the signs reversed. The compass rule is used when the angles and distances in the traverse are considered equally precise.

$$\frac{\text{leg departure correction}}{\text{closure in departure}} = \frac{-\text{leg length}}{\text{total traverse length}} \qquad 78.29$$

$$\frac{\text{leg latitude correction}}{\text{closure in latitude}} = \frac{-\text{leg length}}{\text{total traverse length}} \qquad 78.30$$

If the angles are precise but the distances are less precise (such as when the distances have been determined by taping through rugged terrain), the *transit rule* is a preferred method of distributing the correction to the traverse legs. This rule distributes the closure error in proportion to the absolute values of the latitudes and departures.

$$\frac{\text{leg departure correction}}{\text{closure in departure}} = -\left(\frac{\text{leg departure}}{\text{sum of departure absolute values}}\right) \qquad 78.31$$

$$\frac{\text{leg latitude correction}}{\text{closure in latitude}} = -\left(\frac{\text{leg latitude}}{\text{sum of departure absolute values}}\right) \qquad 78.32$$

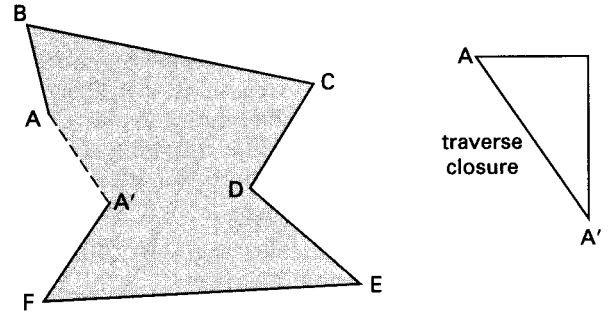


Figure 78.10 *Traverse Closure*

Example 78.14

A closed traverse consists of seven legs, the total of whose lengths is 2705.13 ft. Leg CD has a departure of 443.56 ft and a latitude of 219.87 ft. The total closure in departure for the traverse was +0.41 ft; the total closure in latitude was −0.29 ft. Use the compass rule to determine the corrected latitude and departure for leg CD.

Solution

The length of leg CD is

$$L_{CD} = \sqrt{(443.56 \text{ ft})^2 + (219.87 \text{ ft})^2}$$
$$= 495.06 \text{ ft}$$

Use the compass rule, Eq. 78.30.

$$\frac{\text{latitude correction}}{-0.29 \text{ ft}} = -\frac{495.06 \text{ ft}}{2705.13 \text{ ft}}$$

$$\text{latitude correction} = 0.05 \text{ ft}$$

The corrected latitude is

$$219.87 \text{ ft} + 0.05 \text{ ft} = 219.92 \text{ ft}$$

$$\frac{\text{departure correction}}{+0.41 \text{ ft}} = -\frac{495.06 \text{ ft}}{2705.13 \text{ ft}}$$

$$\text{departure correction} = -0.08 \text{ ft}$$

The corrected departure is

$$443.56 \text{ ft} - 0.08 \text{ ft} = 443.48 \text{ ft}$$

29. RECONSTRUCTING MISSING SIDES AND ANGLES

If one or more sides or angles of a traverse are missing or cannot be determined by measurement, they can sometimes be reconstructed from geometric and trigonometric principles.

The traverse shown in Fig. 78.11(a) has one leg missing. However, line EA can be reconstructed from its components EE′ and E′A. These components are equal to the sum of the departures and the sum of the latitudes, respectively, with the signs changed. The angle can be determined from the ratio of the sides. The length EA can be found from Eq. 78.28.

Figure 78.11(b) shows a traverse that has two adjacent legs missing. The traverse can be closed as long as some length/angle information is available. The technique is to close the traverse by using the same method for when one leg is missing. This will give the line DA. Then, the triangle EAD can be completed from other information.

Figure 78.11(c) shows a traverse with two nonadjacent legs missing. Since the latitudes and departures of two parallel lines are equal, this can be solved by closing the traverse and shifting one missing leg as a parallel leg, to be adjacent to the other missing leg. This reduces the problem to the case of two adjacent legs missing.

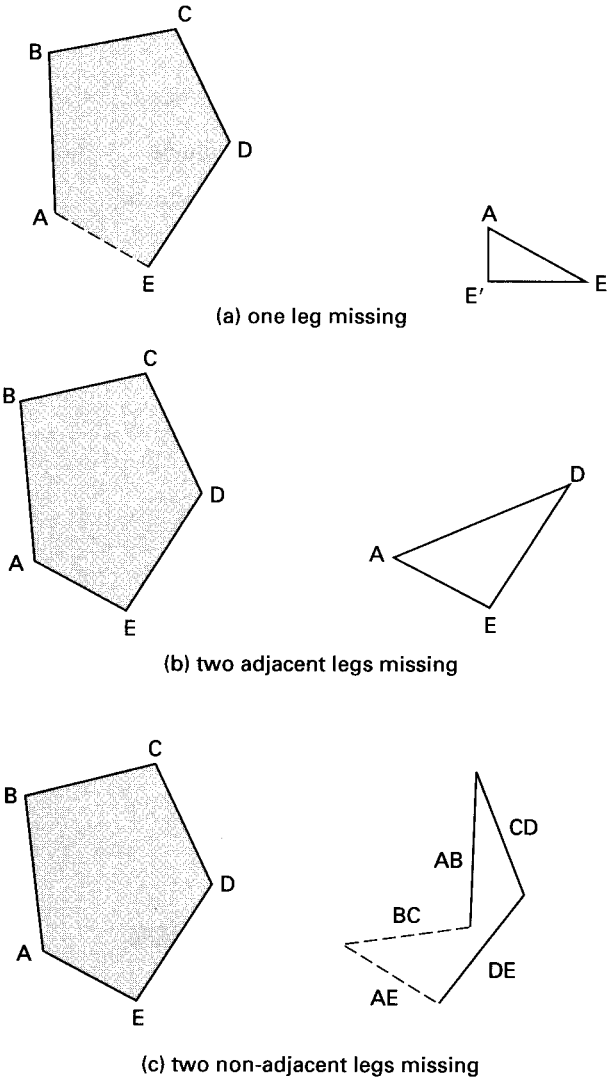

Figure 78.11 *Completing Partial Traverses*

30. TRAVERSE AREA: METHOD OF COORDINATES

The area of a simple traverse can be found by dividing the traverse into a number of geometric shapes and summing their areas.

If the coordinates of the traverse leg end points are known, the *method of coordinates* can be used. The coordinates can be x-y coordinates referenced to some arbitrary set of axes, or they can be sets of departure and latitude. In Eq. 78.33, x_n is substituted for x_0. Similarly, x_1 is substituted for x_{n+1}.

$$A = \tfrac{1}{2}\left|\left(\sum_{i=1}^{n} y_i(x_{i-1} - x_{i+1})\right)\right| \qquad 78.33$$

Transportation

The area calculation is simplified if the coordinates are written in the following form.

$$\frac{x_1}{y_1} \times \frac{x_2}{y_2} \times \frac{x_3}{y_3} \times \frac{x_4}{y_4} \times \frac{x_1}{y_1} \quad \text{etc.}$$

The area is

$$A = \tfrac{1}{2} \left| \sum \text{ of full line products} - \sum \text{ of broken line products} \right| \qquad 78.34$$

Example 78.15

Calculate the area of a triangle with x-y coordinates of its corners given as (3,1), (5,1), and (5,7).

$$\frac{3}{1} \times \frac{5}{1} \times \frac{5}{7} \times \frac{3}{1}$$

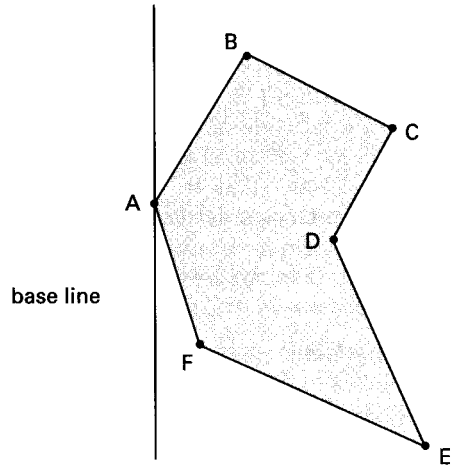
Solution

Use Eq. 78.33.

$$\begin{aligned} A &= \left(\tfrac{1}{2}\right)\left((3)(1) + (5)(7) + (5)(1) - (1)(5) \right. \\ &\quad \left. - (1)(5) - (7)(3)\right) \\ &= \left(\tfrac{1}{2}\right)(43 - 31) \\ &= 6 \end{aligned}$$

31. TRAVERSE AREA: DOUBLE MERIDIAN DISTANCE

If the latitudes and departures are known, the *double meridian distance* (DMD) method can be used to calculate the area of a traverse. Equation 78.35 defines a double meridian distance for a leg.



$$\text{DMD}_{\text{leg } i} = \text{DMD}_{\text{leg } i-1} + \text{departure}_{\text{leg } i-1} + \text{departure}_{\text{leg } i} \qquad 78.35$$

Special rules are required to handle the first and last legs. The DMD of the first course is defined as the departure of that course. The DMD of the last course is the negative of its own departure. The traverse area is calculated from Eq. 78.36. A tabular approach is the preferred manual method of using the DMD method.

$$A = \tfrac{1}{2} \left| \sum (\text{latitude}_{\text{leg } i} \times \text{DMD}_{\text{leg } i}) \right| \qquad 78.36$$

Example 78.16

The latitudes and departures (in ft) of a six-leg traverse have been determined as given. Use the DMD method to calculate the traverse area.

leg	latitude (ft)	departure (ft)
AB	200	200
BC	−100	200
CD	−200	−100
DE	−300	200
EF	200	−400
FA	200	−100

Solution

By the special starting rule, the DMD of the first leg, AB, is the departure of leg AB. The DMD of leg BC is given by Eq. 78.35.

$$\begin{aligned} \text{DMD}_{\text{BC}} &= \text{DMD}_{\text{AB}} + \text{departure}_{\text{AB}} + \text{departure}_{\text{BC}} \\ &= 200 \text{ ft} + 200 \text{ ft} + 200 \text{ ft} \\ &= 600 \text{ ft} \end{aligned}$$

The other DMDs are calculated similarly.

leg	latitude (ft)	departure (ft)	DMD (ft)	lat × DMD (ft^2)
AB	200	200	200	40,000
BC	−100	200	600	−60,000
CD	−200	−100	700	−140,000
DE	−300	200	800	−240,000
EF	200	−400	600	120,000
FA	200	−100	100	20,000
			total	−260,000

The area is given by Eq. 78.36.

$$\begin{aligned} A &= \tfrac{1}{2} \left| \sum (\text{latitude}_{\text{leg } i} \times \text{DMD}_{\text{leg } i}) \right| \\ &= \left(\tfrac{1}{2}\right)(260{,}000 \text{ ft}^2) = 130{,}000 \text{ ft}^2 \end{aligned}$$

32. AREAS BOUNDED BY IRREGULAR BOUNDARIES

Areas of sections with irregular boundaries, such as creek banks, cannot be determined precisely, and approximation methods must be used. If the irregular side can be divided into a series of cells of width d, either the trapezoidal rule or Simpson's rule can be used. (If the coordinates of all legs in the irregular boundary are known, the DMD method can be used.)

If the irregular side of each cell is fairly straight, the *trapezoidal rule* as given in Eq. 78.37 can be used.

$$A = d\left(\frac{h_1 + h_n}{2} + \sum_{i=2}^{n-1} h_i\right) \qquad 78.37$$

If the irregular side of each cell is curved or parabolic, then *Simpson's rule* (sometimes referred to as *Simpson's 1/3 rule*) as given in Eq. 78.38 can be used.

$$A = \left(\frac{d}{3}\right)\left(h_1 - h_n + 2\sum_{\substack{\text{for all odd numbers} \\ \text{starting at } i=3}}^{n-1} h_i + 4\sum_{\substack{\text{for all even numbers} \\ \text{starting at } i=2}}^{n-1} h_i\right) \qquad 78.38$$

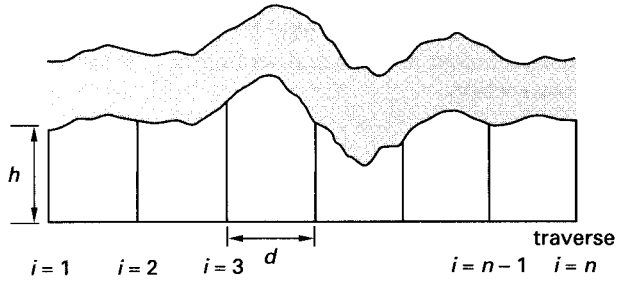


Figure 78.12 *Area Bounded by Irregular Areas*

33. PHOTOGRAMMETRY

Photogrammetry (*aerial mapping*) uses photography to obtain distance measurements. Either vertical or oblique (inclined) photographs can be used, as shown in Fig. 78.13. The controlling dimensions are taken between large paint marks or flags set out on the ground that are visible in the aerial photographs. Adjacent photographs overlap by 60% or more, forming a "stereo pair." Stereo pair photographs enable the operator to see the ground in three dimensions so that elevations of the features can also be determined.

The *scale* of a photograph is the ratio of the dimension on the photo and the dimension on the ground. It is also the ratio of the focal length and the flight altitude. Precise mappings use scales of 1 in = 50 to 500 ft, whereas more general mappings might use 1 in = 600 to 1300 ft. Scale is constantly changing, since the elevation above the ground level depends on the surface terrain. Also, the distance from the camera to the ground directly below the camera will be less than the distance from the camera to points on the outer fringes of the photograph. Therefore, an average distance from camera to ground level is used as the flight altitude. The number of photographs and the number of flight paths required depend on the film size and lap percentages.

$$\text{scale} = \frac{\text{focal length}}{\text{flight altitude}} = \frac{\text{length in photograph}}{\text{true length}} \qquad 78.39$$

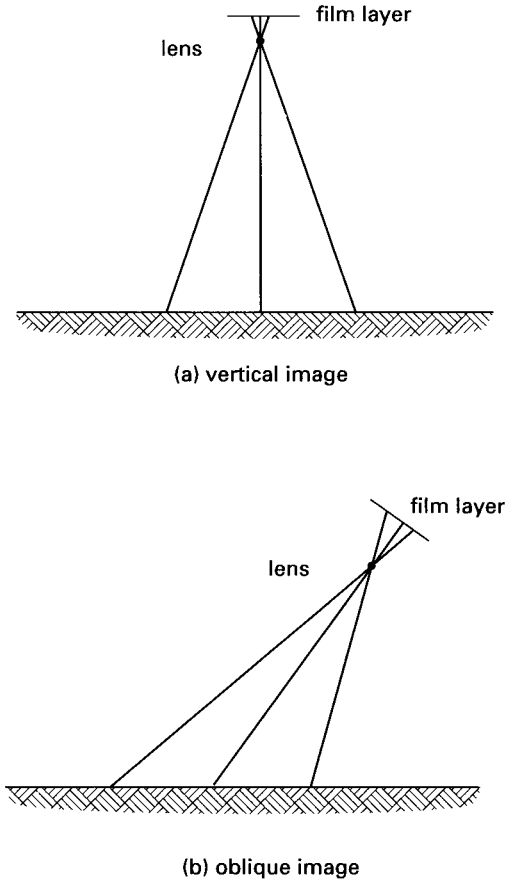

Figure 78.13 *Photogrammetric Images*

Example 78.17

Aerial mapping is being used with a scale of 1 in:1000 ft. The film holder uses 8 in by 8 in film. The focal length of the camera is 6 in. The area to be mapped is square, 6 mi on each side. A side-lap from photo to photo of 30% is desired, as well as an end-lap from photo to photo of 60%. The plane travels at 150 mph.

(a) What is the area covered by each photograph? (b) At what altitude should the plane fly while taking photographs? (c) How far apart will the flight paths be? (d) How many flight paths are required? (e) How

many photographs are required per flight path? (f) How many photographs will be taken altogether? (g) How frequently should the photographs be taken?

Solution

(a) The photograph area is

$$(8 \text{ in})(8 \text{ in}) = 64 \text{ in}^2$$

The area covered by each photograph is

$$(64 \text{ in}^2)\left(1000 \frac{\text{ft}}{\text{in}}\right)^2 = 64{,}000{,}000 \text{ ft}^2$$

(b) The flight altitude is calculated using Eq. 78.39.

$$\text{altitude} = \frac{\text{focal length}}{\text{scale}} = \frac{6 \text{ in}}{\frac{1 \text{ in}}{1000 \text{ ft}}} = 6000 \text{ ft}$$

(c) Each photograph covers 64,000,000 ft^2, or an area 8000 ft on each side. With a 30% overlap, the distance between flight paths is calculated as

$$(1 - 0.30)(8000 \text{ ft}) = 5600 \text{ ft}$$

(d) The number of flight paths is

$$\frac{(6 \text{ mi})\left(5280 \frac{\text{ft}}{\text{mi}}\right)}{5600 \text{ ft}} = 5.7 \quad \text{[use 6]}$$

(e) With an end lap of 60%, the distance between photos along the flight path is

$$(8000 \text{ ft})(1 - 0.60) = 3200 \text{ ft}$$

The number of photographs per flight path is

$$\frac{(6 \text{ mi})\left(5280 \frac{\text{ft}}{\text{mi}}\right)}{3200 \text{ ft}} = 9.9 \quad \text{[use 10]}$$

(f) The total number of photos will be $(6)(10) = 60$.

(g) At 150 mph, the frequency of camera shots will be

$$\frac{3200 \text{ ft}}{\frac{\left(150 \frac{\text{mi}}{\text{hr}}\right)\left(5280 \frac{\text{ft}}{\text{mi}}\right)}{3600 \frac{\text{sec}}{\text{hr}}}} = 14.5 \text{ sec/photo}$$

34. PUBLIC LAND SYSTEM

The *U.S. Rectangular Surveying System* was devised with the objective of locating, marking, and fixing subdivisions "for all time." The land was divided into *tracts* approximately 24 mi by 24 mi by means of meridians and parallels of latitude. These tracts were then divided into 16 *townships*, which were approximately 6 mi on a side. The last step was to divide the township into 36 *sections*, each approximately 1 mi by 1 mi. Each township has an area of approximately 36 mi^2, containing 36 sections, each 1 mi^2 in area. Sections were further divided into quarter sections.

Townships were labeled using a range and township number. The *township number* assigned to the parcel of land was determined according to its location relative to the standard parallel of latitude defining the northern and southern boundaries. The *range number* assigned to that parcel was determined according to its location relative to the principal meridian defining the eastern and western boundaries. For example, the parcel of land that is 2 rows south of the standard parallel and 3 rows east of the principal meridian bordering the township would be numbered "T2S, R3E." Figure 78.14 illustrates the numbering of townships and ranges for a 24 mi^2 tract of land. The township's 36 sections are numbered as shown in Fig. 78.15, beginning in the northeasternmost section and ending in the southeasternmost section.

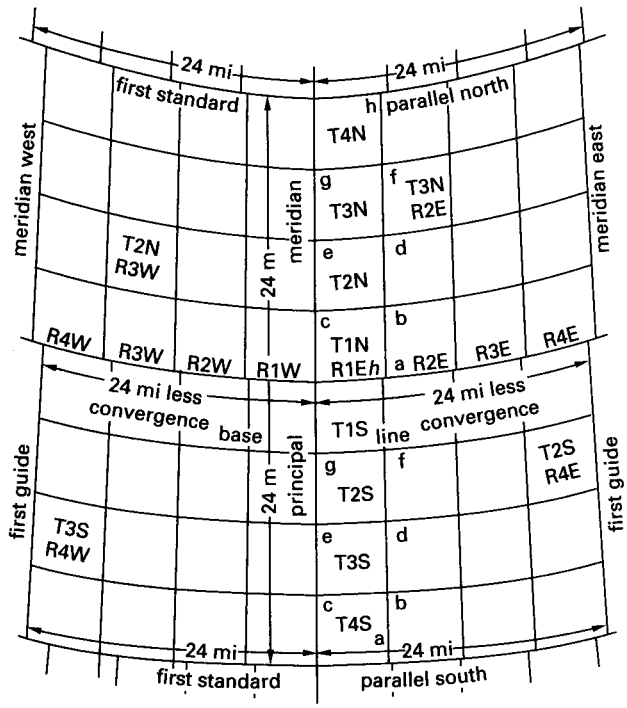

Figure 78.14 *Standard Parallels and Guide Meridians*

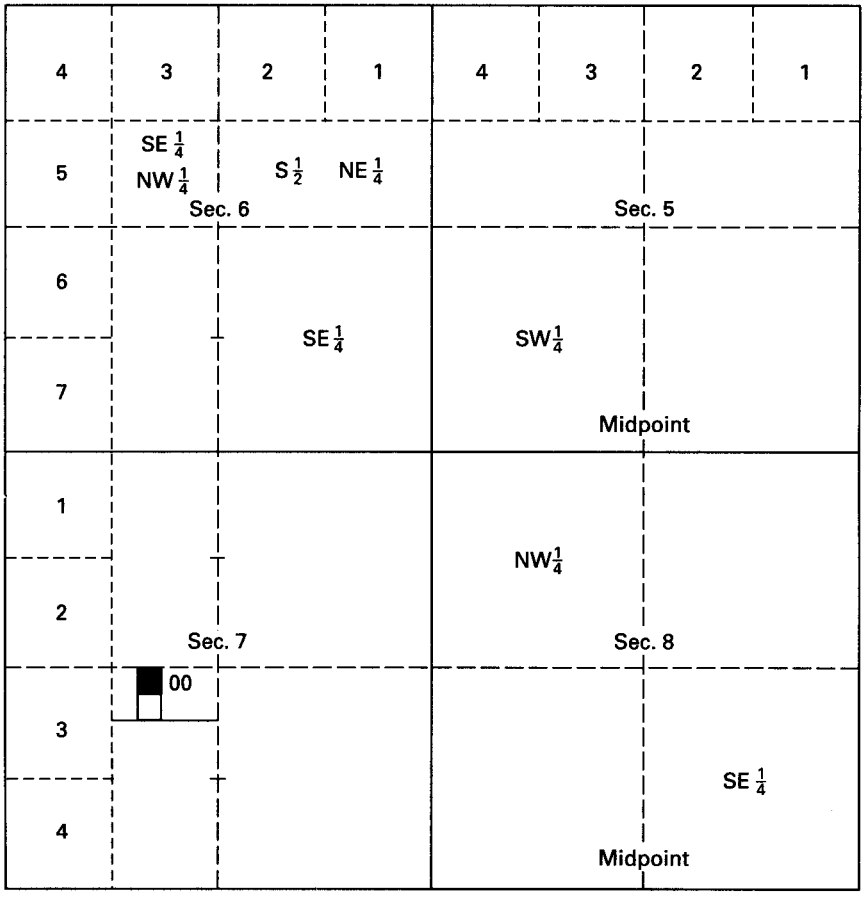
Example 78.18

Give a legal description of the parcel of land shown, located in Section 7 of T12S, R9W, of the 10 Principal Meridian, located in Williams County, Pennsylvania.

Solution

Beginning with the smallest identifiable quarter section of land, the legal identification would be as follows.



The NE¼ of the NW¼ of the NE¼ of the SW¼ of Section 7, T12S, R9W, of the 10 Principal Meridian, located in Williams County, Pennsylvania.

35. TOPOGRAPHIC MAPS

Topographic maps are graphic representations of the surface of the earth. They contain a plan view of the land, scales to measure distance, bearings to indicate direction, coordinate systems to locate features, symbols of natural and artificial features, and contour lines to show elevation, slope, and relief of the landscape. The standard USGS mapping symbols are shown in Fig. 78.16.

The *map scale* can be specified in several ways: a fractional scale (e.g., "1:50,000") indicating that one unit of distance on the map corresponds to a number of the same units on the ground, an explicit verbal scale (e.g., "1 cm to 1 km"), and a graphic scale consisting of a calibrated bar or line.

The *vertical exaggeration* is the distortion of the vertical scale of a topographic profile used to emphasize relief

and slope. The vertical exaggeration is calculated as the vertical scale divided by the horizontal scale.

Official USGS topographic maps can be selected by scale or coverage angle. Available scales include 1:24,000 or 1:25,000, 1:62,500, 1:100,000, and 1:250,000. Some 1:500,000 maps are also available. The two most common coverage angles are (a) 7.5′ (1/8°) quadrangle maps, which extend 7.5′ of latitude from north to south and 7.5′ of longitude from east to west; and (b) 15′ (1/4°) quadrangle maps, which extend 15′ of latitude from north to south and 15′ of longitude from east to west. North is always at the top of the map.

Contour lines are imaginary lines connecting points of equal elevation. They can be used to show elevation, *relief* (the difference in elevations between two points), and slope. The *contour interval* (e.g., 10 ft or 20 ft) is constant on any given map. Every fifth line is an *index contour*, printed thicker and marked with the elevation for reference. When ground is level, no contours are shown. Closely spaced contours indicate a steep slope. Merged contours indicate a cliff.

Two types of coordinate systems are given on most topographic maps: (a) latitude-longitude and (b) township-range. The township-range system is only used in the western and southern United States, whereas the latitude-longitude system is used throughout the world.

The *Universal Transverse Mercator* (UTM) grid generally appears on topographic maps. A UTM coordinate is essentially the x-y coordinates on the map. The first half of the UTM digits are the x-coordinates; the second half are the y-coordinates. 4-, 6-, 8-, and 10-digit coordinates can be specified, with some interpolation on the map being required. For complete identification, the map number, zone, or other regional information must also be specified.

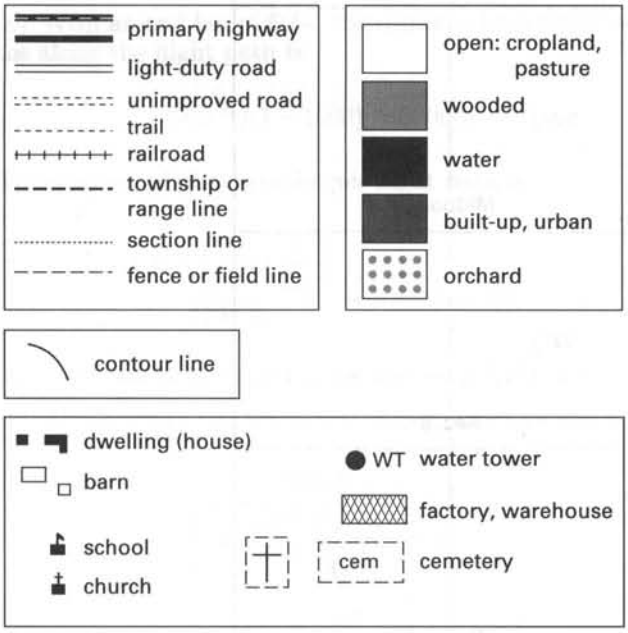


Figure 78.16 *Standard USGS Topographic Map Symbols*

PRACTICE PROBLEMS

Errors

1. Four level circuits were run over four different routes to determine the elevation of a benchmark. The observed elevations and probable errors for each circuit are as given. What is the most probable value of the benchmark's elevation?

route 1: 745.08 ± 0.03

route 2: 745.22 ± 0.01

route 3: 745.45 ± 0.09

route 4: 745.17 ± 0.05

Answer: 745.21

Leveling

2. A level is placed where the height of the instrument above the datum is 294.43 ft. The rod is held on a point 5000 ft away, and a rod reading of 4.63 ft is recorded. (a) What is the effect of the earth's curvature on the rod reading? (b) What is the effect of atmospheric refraction on the rod reading?

Answers: (a) 0.6 ft; (b) 0.075 ft

3. Complete the survey notes from a leveling session.

station	+ BS	HI	−FS	elevation
BMA	5.54			100.60
1+00			2.88	
2+00			5.56	
3+00			4.37	
4+00			2.22	
TP1			7.89	
	6.34			
5+00			10.89	
6+00			11.12	
7+00			10.45	
8+00			12.61	
TP2			9.32	
	1.45			
9+00			5.82	
10+00			6.99	
11+00			5.34	
12+00			4.98	
TP3			5.67	
	2.38			
13+00			6.24	
14+00			6.76	
BMB			4.90	

4. A transit with an interval factor of 100 and an instrument factor of 1.0 is used to take the stadia sights recorded. The height of the instrument above the

ground was 4.8 ft. The ground elevation where the instrument was set up was 297.8 ft. (a) What is the horizontal distance between points A and B? (b) What is the elevation of point B?

point	azimuth	rod interval ($R_2 - R_1$)	middle hair reading	vertical angle
A	42.17°	3.22	5.7	−6.3°
B	222.17°	2.60	10.9	+4.17°

Answers: (a) 578.7 ft; (b) 310.6 ft

5. Recorded data from a leveling circuit is shown. (a) What is the elevation of BM11? (b) What is the elevation of BM12?

station	backsight	foresight	elevation
BM10	4.64		179.65
TP1	5.80	5.06	
TP2	2.25	5.02	
BM11	6.02	5.85	
TP3	8.96	4.34	
TP4	8.06	3.22	
TP5	9.45	3.71	
TP6	12.32	2.02	
BM12		1.98	

Answers: (a) 176.41; (b) 205.95

Traverses

6. The balanced latitudes and departure of the legs of a closed traverse were determined as shown. What is the traverse area?

leg	latitude	departure
AB	N 350	E 0
BC	N 550	E 600
CD	S 250	E 1200
DE	S 750	E 200
EF	S 550	W 1100
FA	N 650	W 900

Answer: 2,065,000

7. Use the compass rule. Balance and adjust (to the nearest 0.1) the traverse.

leg	bearing	length
AB	N	500
BC	N 45.00°E	848.6
CD	S 69.45°E	854.4
DE	S 11.32°E	1019.8
EF	S 79.70°W	1118.0
FA	N 54.10°W	656.8

8. A five-leg closed traverse is taped and scoped in the field, but obstructions make it impossible to collect all readings. It is known that the general direction of EA is easterly. Complete the field notes.

leg	north azimuth	distance
AB	106.22°	1081.3
BC	195.23°	1589.5
CD	247.12°	1293.7
DE	332.37°	_____
EA	_____	1737.9

Answers: distance DE: 2503.5; azimuth EA: 86°

Photogrammetry

9. *(Time limit: one hour)* A camera with a focal length of 6.0 in and a picture size of 12 in by 12 in is used to photograph an area from an altitude of 4000 ft above sea level.

(a) If the average ground elevation is 650 ft, what is the average scale of the photo?

(A) 1 in = 558 ft
(B) 1 in = 600 ft
(C) 1:6000
(D) 1:6500

The answer is (A).

(b) What is the ground area covered by a single photograph?

(A) 1030 ac
(B) 1500 ac
(C) 2000 ac
(D) 2070 ac

The answer is (A).

(c) If overlap and sidelap are 60% and 20% respectively, what is the ground spacing between exposures?

(A) 2670 ft
(B) 2672 ft
(C) 2678 ft
(D) 2778 ft

The answer is (C).

(d) With the overlap as given in part (c), what is the ground spacing between flight lines?

(A) 5236 ft
(B) 5336 ft
(C) 5346 ft
(D) 5356 ft

The answer is (D).

(e) If the aircraft flies at a ground speed of 300 mph along the flight line outlined, what is the time interval, to the nearest 0.1 sec, between exposures along the flight line?

(A) 6.0 sec
(B) 6.1 sec
(C) 6.2 sec
(D) 8.1 sec

The answer is (B).

(f) Two points at an elevation of 665 ft appear on a photograph. The distance between these points is 89 mm on the photograph. What is the ground distance, in ft, between the two points?

(A) 1557 ft
(B) 1647 ft
(C) 1737 ft
(D) 1947 ft

The answer is (D).

(g) At what elevation should the plane be flown to obtain photography at an average scale of 1:10,000 if the terrain to be photographed lies in the range of 1000 to 1200 ft above sea level?

(A) 6000 ft
(B) 6050 ft
(C) 6100 ft
(D) 6150 ft

The answer is (C).

(h) A pair of images lie 5.68 in apart on a photo taken with a lens whose focal length is 12 in. A map with a scale of 1 in = 1680 ft shows the same points 0.54 in apart. What is the scale of the photo?

(A) 1 in = 160 ft
(B) 1 in = 200 ft
(C) 1:1500
(D) 1:2000

The answer is (A).

(i) For part (h), how high above ground was the plane flying if the elevation of the points is 889 ft?

(A) 2000 ft
(B) 2500 ft
(C) 2800 ft
(D) 3000 ft

The answer is (C).

(j) For part (h), how high above ground was the plane flying if the same two points are 0.98 in apart on the map?

(A) 4400 ft
(B) 4500 ft
(C) 4600 ft
(D) 4700 ft

The answer is (A).

1. HORIZONTAL CURVES

A *horizontal circular curve* is a circular arc between two straight lines known as *tangents*. When traveling in a particular direction, the first tangent encountered is the *back tangent (approach tangent)*, and the second tangent encountered is the *forward tangent (departure tangent)*.

The geometric elements of a horizontal circular curve are shown in Fig. 79.1. Table 79.1 lists the standard terms and abbreviations used to describe the elements. Equations 79.1 through 79.7 describe the basic relationships between the elements. The *interior angle*, I, has units of degrees unless indicated otherwise. (Equations that contain the *degree of curve* term, D, are only to be used with customary U.S. units.)

$$R = \frac{5729.578}{D} \quad \text{[U.S.—arc definition]} \qquad 79.1$$

$$R = \frac{50}{\sin\left(\frac{D}{2}\right)} \quad \text{[U.S.—chord definition]} \qquad 79.2$$

$$L = \frac{2\pi RI}{360^\circ} = RI_{\text{radians}} = 100\left(\frac{I}{D}\right) \quad \text{[U.S.]} \qquad 79.3$$

$$T = R\tan\left(\frac{I}{2}\right) \qquad 79.4$$

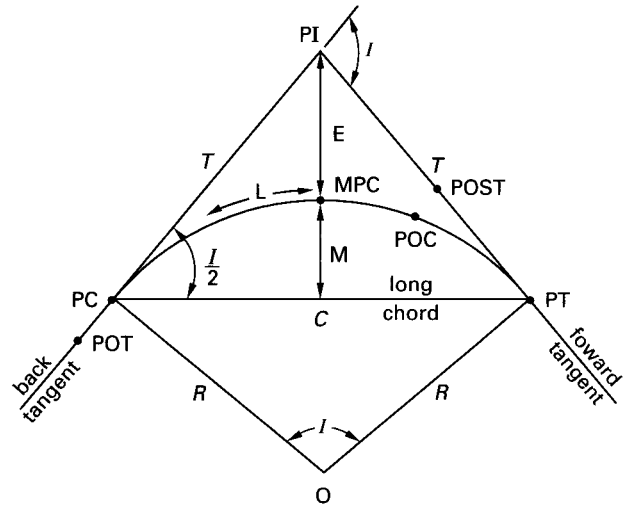
$$E = R\left(\sec\left(\frac{I}{2}\right) - 1\right) \qquad 79.5$$

$$M = R\left(1 - \cos\left(\frac{I}{2}\right)\right) = \left(\frac{C}{2}\right)\tan\left(\frac{I}{4}\right) \qquad 79.6$$

$$C = 2R\sin\left(\frac{I}{2}\right) = 2T\cos\left(\frac{I}{2}\right) \qquad 79.7$$

Table 79.1 *Horizontal Curves: Abbreviations and Terms*

preferred	
c	short chord (any straight distance from one point on the curve to another)
C	long chord (chord PC to PT); same as LC
D	degree of curve
E	external distance (the distance from the vertex to the midpoint of the curve)
I	interior angle; central angle of curve; deflection angle between back and forward tangents
L	length of the curve (the length of the curve from the PC to the PT)
LC	long chord (chord PC to PT); same as C
M	middle ordinate (the distance from the curve midpoint to the midpoint of the long chord)
MPC	midpoint of curve
PC	point of curvature (the point where the back tangent ends and the curve begins)
PI	point of intersection of back and forward tangents
POC	(any) point on the curve
POCT	point of curve tangent
POST	(any) point on the semitangent
POT	(any) point on the tangent
PT	point of tangency (the point where the curve ends and the forward tangent begins)
R	radius of the curve
RP	radius point (center of curve)
T	(semi-) tangent distance from V to PC or from V to PT
V	vertex of the tangent intersection point
alternate/archaic	
BC	beginning of curve (same as PC and TC)
CT	change from curve to tangent (same as PT and EC)
Δ	interior angle (same as I)
EC	end of curve (same as PT and CT)
PVI	point of vertical intersection (same as PI)
TC	a change from a tangent to a curve (same as BC and PC)



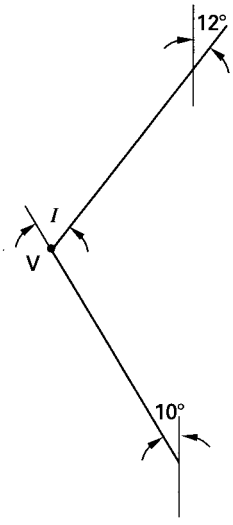


Figure 79.1 *Horizontal Curve Elements*

Example 79.1

Two tangents—the first entering a horizontal curve and the second leaving the horizontal curve—have bearings of N10°W and N12°E, respectively. The curve radius is 1300 ft. Determine the interior angle.

Solution

Since the two tangents do not originate from a single point, the interior angle is the deflection angle between the two tangents.

$$I = 10^\circ + 12^\circ = 22^\circ$$

2. DEGREE OF CURVE

In the United States, curvature of city streets, highways, and railway curves can be specified by either the radius, R, or the *degree of curve*, D. There is no parallel concept in metric highway design. Therefore, curves are only denoted by radius when using metric units.

$$D = \frac{(360^\circ)(100)}{2\pi R} = \frac{5729.578}{R} \quad \text{[arc basis]} \qquad 79.8$$

In most highway work, the *length of the curve* is understood to be the actual curved arc length, and the degree of the curve is the angle subtended by an arc of 100 ft. When the degree of curve is related to an arc of 100 ft, it is said to be calculated on an *arc basis*.

Railway curves have very large radii. The radii are so large that short portions of the curves are essentially straight. In railroad surveys, the *chord basis* is used, and the degree of curve has a different definition. The railroad degree of curve is the angle subtended by a chord of 100 ft. In that case, the degree of curve and radius are related by Eq. 79.9. Once the radius is calculated, other arc-basis equations (Eqs. 79.1 through 79.7) can be used.

$$\sin\left(\frac{D}{2}\right) = \frac{50}{R} \quad \text{[chord basis]} \qquad 79.9$$

Where the radius is large (4° curves or smaller), the difference between the arc length and the chord length is insignificant. Therefore, the length of the curve in railroad practice is equal to the number of 100 ft chords.

$$L \approx \left(\frac{I}{D}\right)(100 \text{ ft}) \qquad 79.10$$

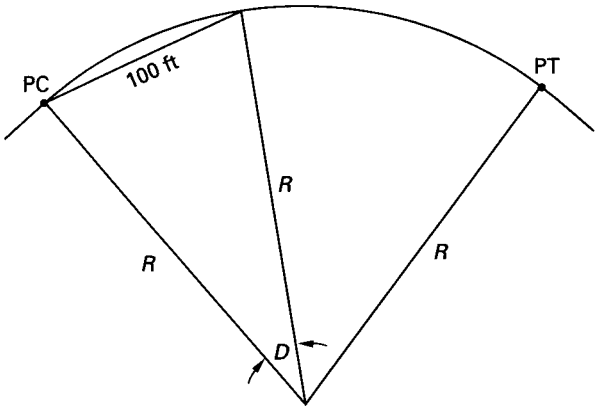

Figure 79.2 *Horizontal Railroad Curve (chord basis)*

3. STATIONING ON A HORIZONTAL CURVE

When the route is initially laid out between PIs, the curve is undefined. The "route" distance is measured from PI to PI. The route distance changes, though, when the curve is laid out. Stationing along the curve is continuous, as a vehicle's odometer would record the distance. The PT station is equal to the PC station plus the curve length.

$$\text{sta PT} = \text{sta PC} + L \qquad 79.11$$

$$\text{sta PC} = \text{sta PI} - T \qquad 79.12$$

When the curve is laid out, each PI will have two stations associated with it. The *forward station* is equal to the PC station plus the tangent length. The *back station* is equal to the PT station minus the tangent length.

Example 79.2

An interior angle of 8.4° is specified for a 2° horizontal curve. The forward PI station is 64+27.46. Locate the PC and PT stations.

Solution

Use Eq. 79.8.

$$R = \frac{(360°)(100 \text{ ft})}{2\pi D} = \frac{(360°)(100 \text{ ft})}{(2\pi)(2°)}$$
$$= 2864.79 \text{ ft}$$

Use Eqs. 79.4 and 79.3.

$$T = R\tan\left(\frac{I}{2}\right) = (2864.79 \text{ ft})\tan\left(\frac{8.4°}{2}\right)$$
$$= 210.38 \text{ ft}$$

$$L = RI\left(\frac{2\pi}{360°}\right) = (2864.79 \text{ ft})(8.4°)\left(\frac{2\pi}{360°}\right)$$
$$= 420.00 \text{ ft}$$

The PC and PT points are located at

$$\text{sta PC} = \text{sta PI} - T = (64{+}27.46) - 210.38 \text{ ft}$$
$$= 62{+}17.08$$

$$\text{sta PT} = \text{sta PC} + L = (62{+}17.08) + 420.00 \text{ ft}$$
$$= 66{+}37.08$$

4. CURVE LAYOUT BY DEFLECTION ANGLE

Construction survey stakes should be placed at the PC, at the PT, and at all full stations. (In the United States, 100 ft stations are the rule. Metric stationing may be 100 or 1000 m, depending on the organization.) Stakes may also be required at quarter or half stations and at all other critical locations.

The *deflection angle method* is a common method used for staking out the curve. A *deflection angle* is the angle between the tangent and a chord. Deflection angles are related to corresponding arcs by the following principles.

(1) The deflection angle between a tangent and a chord (Fig. 79.3(a)) is half of the subtended arc.

(2) The angle between two chords (Fig. 79.3(b)) is half of the subtended arc.

In Fig. 79.3(a), angle V-PC-A is a deflection angle between a tangent and a chord. Using Principle 1,

$$\alpha = \angle\text{V-PC-A} = \frac{\beta}{2} \qquad 79.13$$

Transportation

Angle β can be found from the following relationships.

$$\frac{\beta}{360^\circ} = \frac{\text{arc length PC-A}}{2\pi R} \qquad 79.14$$

$$\frac{\beta}{I} = \frac{\text{arc length PC-A}}{L} \qquad 79.15$$

The chord distance PC-A is given by Eq. 79.16. The entire curve can be laid out from the PC by sighting the deflection angle V-PC-A and taping the chord distance PC-A.

$$C_{\text{PC-A}} = 2R\sin\alpha = 2R\sin\left(\frac{\beta}{2}\right) \qquad 79.16$$

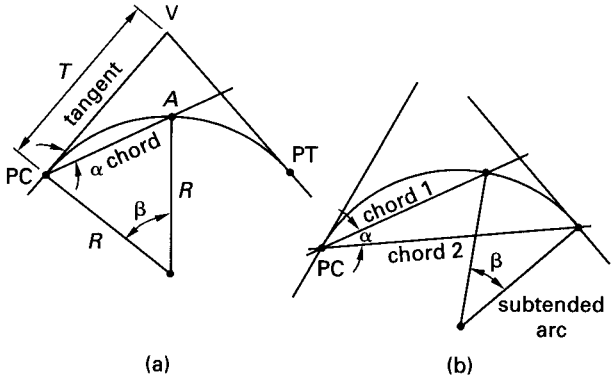

Figure 79.3 *Circular Curve Deflection Angle*

Example 79.3

A circular curve is to be constructed with a 225 ft radius and an interior angle of 55°. The separation between the stakes along the arc is 50 ft. (a) Determine the chord lengths between stakes. (b) Assuming the curve is laid out from point to point, specify the first and last deflection angles. (c) Determine the length of the final (partial) chord.

Customary U.S. Solution

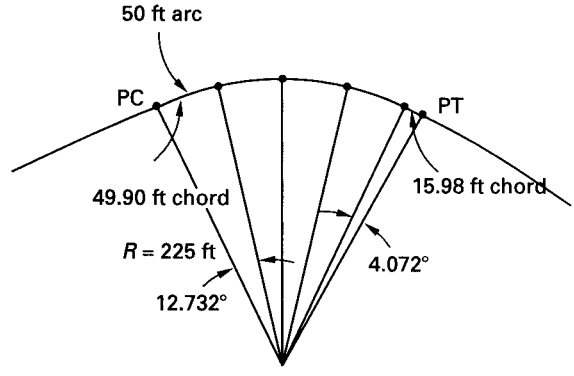
(a) The central angle for an arc of 50 ft is given by Eq. 79.14.

$$\beta = \frac{(360^\circ)(\text{arc length})}{2\pi R}$$

$$= \frac{(360^\circ)(50\text{ ft})}{2\pi(225\text{ ft})} = 12.732^\circ$$

From Eq. 79.16, the required chord length for full 50 ft arcs is

$$C = 2R\sin\left(\frac{\beta}{2}\right) = (2)(225\text{ ft})\sin\left(\frac{12.732^\circ}{2}\right)$$



$$= 49.90\text{ ft}$$

(b) The first central angle is 12.732°. From Principle 1, the first deflection angle is half of this or 6.366°.

12.732° goes into 55° four times with a remainder of 4.072°. The last deflection angle (sighting to the PT) is 2.036°. Use Eq. 79.16.

(c) $$C = (2)(225\text{ ft})\sin\left(\frac{4.072^\circ}{2}\right)$$

$$= 15.98\text{ ft}$$

5. TANGENT OFFSETS

A *tangent offset*, y, is the perpendicular distance from an extended tangent line to the curve. A *tangent distance*, x, is the distance along the tangent to a perpendicular point. Tangent offsets for circular curves can be calculated from Eq. 79.17.

$$y = R(1-\cos\beta) \qquad 79.17$$

$$= R - \sqrt{R^2 - x^2}$$

$$\beta = \arcsin\left(\frac{x}{R}\right) = \arccos\left(\frac{R-y}{R}\right) \qquad 79.18$$

$$x = R\sin\beta = \sqrt{2Ry - y^2} \qquad 79.19$$

Offsets from *parabolic curves* (*parabolic flares, parabolic tapers*, or *curb flares*) are calculated from Eq. 79.20. W is the maximum offset, L is the length of the *flare* (*taper*), x is the distance along the baseline, and y is the offset.

$$\frac{y}{W} = \frac{x^2}{L^2} \qquad 79.20$$

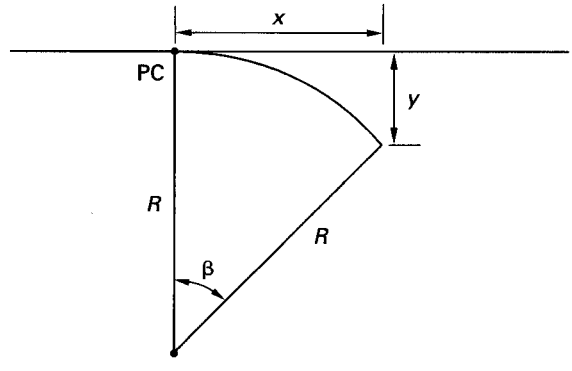


Figure 79.4 *Tangent Offset*

6. CURVE LAYOUT BY TANGENT OFFSETS

The *tangent offset method* can be used to lay out horizontal curves. This method is typically used on short curves. The method is named for the way in which the measurements are made, which is by measuring offsets from the tangent line.

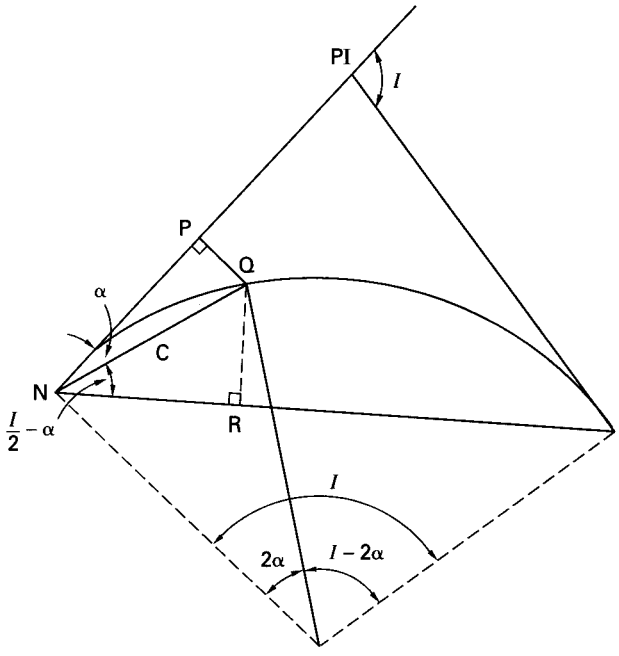

Figure 79.5 *Tangent and Chord Offset Geometry*

Consider the two right triangles NPQ and NRQ in Fig. 79.5. Point Q is at any point along the circular curve, and α is the deflection angle from the tangent to point α.

$$\text{NP} = \text{tangent distance} = \text{NQ}\cos\alpha \qquad 79.21$$

$$\text{PQ} = \text{tangent offset} = \text{NQ}\sin\alpha \qquad 79.22$$

The short chord distance is

$$\text{NQ} = C = 2R\sin\alpha \qquad 79.23$$

$$\begin{aligned}\text{NP} &= (2R\sin\alpha)\cos\alpha \\ &= c\cos\alpha\end{aligned} \qquad 79.24$$

$$\begin{aligned}\text{PQ} &= (2R\sin\alpha)\sin\alpha \\ &= 2R\sin^2\alpha\end{aligned} \qquad 79.25$$

7. CURVE LAYOUT BY CHORD OFFSET

The *chord offset method* is a third method for laying out horizontal curves. This method is also suitable for short curves. The method is named for the way in which the measurements are made, which is by measuring distances along the main chord from the instrument location at PC.

$$\begin{aligned}\text{NR} = \text{chord distance} &= \text{NQ}\cos\left(\frac{I}{2}-\alpha\right) \\ &= (2R\sin\alpha)\cos\left(\frac{I}{2}-\alpha\right) \\ &= C\cos\left(\frac{I}{2}-\alpha\right)\end{aligned} \qquad 79.26$$

$$\begin{aligned}\text{RQ} = \text{chord offset} &= \text{NQ}\sin\left(\frac{I}{2}-\alpha\right) \\ &= (2R\sin\alpha)\sin\left(\frac{I}{2}-\alpha\right) \\ &= C\sin\left(\frac{I}{2}-\alpha\right)\end{aligned} \qquad 79.27$$

8. HORIZONTAL CURVES THROUGH POINTS

Occasionally, it is necessary to design a horizontal curve to pass through a specific point. The following procedure can be used. (Refer to Fig. 79.6.)

step 1: Calculate α and m from x and y. (If α and m are known, skip this step.)

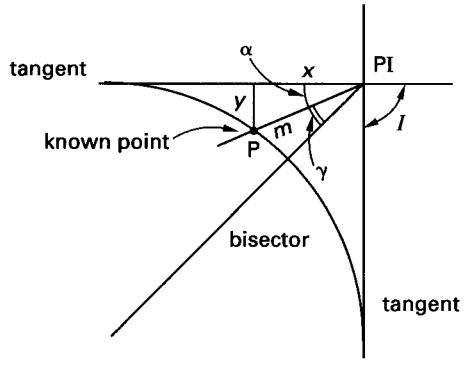
$$\alpha = \arctan\left(\frac{y}{x}\right) \qquad 79.28$$

$$m = \sqrt{x^2+y^2} \qquad 79.29$$

step 2: Calculate γ.

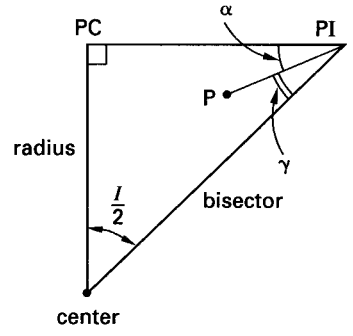
$$\gamma = 90^\circ - \frac{I}{2} - \alpha \qquad 79.30$$

step 3: Calculate ϕ.



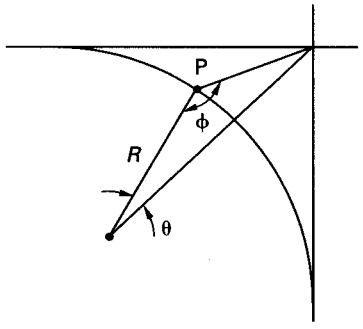
$$\phi = 180^\circ - \arcsin\left(\frac{\sin\gamma}{\cos\left(\frac{I}{2}\right)}\right) \qquad 79.31$$

step 4: Calculate θ.



$$\theta = 180^\circ - \gamma - \phi \qquad 79.32$$

step 5: Calculate the curve radius, R, from the law of sines.



$$\frac{\sin\theta}{m} = \frac{\sin\phi\cos\left(\frac{I}{2}\right)}{R} \qquad 79.33$$

(a) step 1

(b) step 2

(c) steps 3 & 4

Figure 79.6 *Horizontal Curve Through a Point (I known)*

9. COMPOUND HORIZONTAL CURVES

A *compound curve* comprises two or more curves of different radii that share a common tangent point, with their centers on the same side of the common tangent. The PT for the first curve and the PC for the second curve coincide. This point is the *point of common curvature* (PCC).

Compound curves should only be used on low-speed roadways, such as on entrance or exit ramps. Their use is reserved for applications where design constraints, such as topography or high land cost, preclude the use of a circular or spiral curve. For safety, the radius of the larger curve should be less than or equal to four thirds times the radius of the smaller curve (three halves on interchanges).

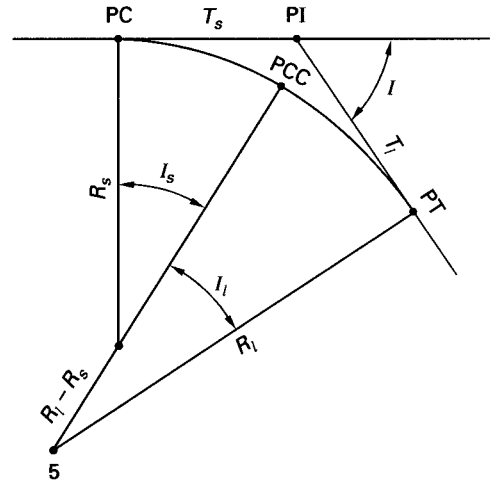


Figure 79.7 *Compound Circular Curve*

10. SUPERELEVATION

If a vehicle travels in a circular path with instantaneous radius R and tangential velocity (i.e., speed) v_t, it will experience an apparent centrifugal force, F_c.

$$F_c = \frac{mv_t^2}{R} \quad \text{[consistent units]} \qquad 79.34$$

The centrifugal force can be resisted by banking, friction, or a combination of the two. If it is intended that banking (no friction) alone will resist the centrifugal force, the banking angle, ϕ, is given by Eq. 79.35. The elevation difference between the inside and outside edges of the curve is the *superelevation*. The transverse slope of the roadway has units of ft/ft (m/m), hence the synonymous name of *superelevation rate*, e, for slope. (However, runoff and transition "rates" are not the same.)

$$e = \tan\phi = \frac{v^2}{gR} \quad \text{[consistent units]} \qquad 79.35$$

Some of the centrifugal force is usually resisted by *sideways friction*. (One-half of the theoretical superelevation rate is usually adequate.) Equation 79.36 is the basic formula used for determining the superelevation rate when friction is relied upon to counteract some of the centrifugal force. The sum, $e + f_s$, may be referred to as the *centrifugal factor*.

$$e = \tan\phi = \frac{v^2}{gR} - f_s \quad \text{[consistent units]} \qquad 79.36$$

If the velocity, v, is expressed in common units, Eq. 79.36 becomes

$$e = \tan\phi = \frac{v_{\text{km/h}}^2}{127R} - f_s \quad \text{[SI]} \qquad 79.37(a)$$

$$e = \tan\phi = \frac{v_{\text{mph}}^2}{15R} - f_s \quad \text{[U.S.]} \qquad 79.37(b)$$

In general, a lower *banking angle* is used in urban areas than in rural areas. For arterial streets in downtown areas, the maximum superelevation rate is approximately 0.04 to 0.06. For arterial streets in suburban areas and on freeways where there is no snow or ice, the maximum superelevation rate is approximately 0.10 to 0.12. For arterial streets and freeways that experience snow and ice, the maximum should be 0.06 to 0.08.

Since the maximum superelevation rate is approximately 0.08 or 0.10, Eq. 79.35 can be used to calculate the minimum curve radius if the speed is known.

Many studies have been performed to determine values of the *side friction factor*, f_s, and most departments of transportation have their own standards. One methodology is to assume the side friction factor to be 0.16 for speeds less than 30 mph (50 km/h). Equations 79.38 or 79.39 can be used for higher speeds.

$$f_s = \frac{0.16 - 0.01(v_{mph} - 30)}{10} \quad [< 50 \text{ mph}] \qquad 79.38$$

$$f_s = \frac{0.14 - 0.02(v_{mph} - 50)}{10} \quad [50 \text{ to } 70 \text{ mph}] \qquad 79.39$$

Although the sophistication may be unwarranted, the friction factor for sideways slipping, f_s, can be differentiated from the straight-ahead friction factor. For sideways slipping, the friction factor may be referred to as the *side friction factor, lateral ratio, cornering ratio,* or *unbalanced centrifugal ratio.*

11. TRANSITIONS TO SUPERELEVATION

Transitions from crowned sections to superelevated sections should be gradual. When a curve is to be superelevated, it is first necessary to establish a rotational axis (often referred to as a "point") on the cross section. This is the axis around which the pavement will be rotated (longitudinally) to gradually change to the specified superelevated cross slope. The rotational axis ("point") is a longitudinal axis parallel to the instantaneous direction of travel. The location of the rotational point varies with the basic characteristics of the typical section. The following guidelines can be used.

(1) For two-lane and undivided highways, the axis of rotation is generally at (along) the original crown of the roadway. However, it may also be the edge of the outside or inside lane.

(2) On divided highways with relatively wide depressed medians, the axis of rotation can be at the crown of each roadway or at the edge of the lane or shoulder nearest the median of each roadway. Placing the axis at the crown results in median edges at different elevations, but it reduces the elevation differential between extreme pavement edges. If it is likely that the highway will be widened in the future, it will be desirable to rotate the pavement cross-slope about the inside lane or shoulder.

(3) On divided highways with narrow raised medians and moderate superelevation rates, the axis of rotation should be at the center of the median. If the combination of pavement width and superelevation rate results in substantial differences between pavement edge elevations, the axis of rotation should be at the edge of the lane or shoulder nearest the median of each roadway. If an at-grade crossing is located on the superelevated curve, the impact of intersecting traffic should be considered in selecting the axis of rotation.

(4) On divided highways with concrete median barriers, criterion (C) will control, except that rotation should occur at the barrier gutter when that method of rotation is selected.

For maximum comfort and safety, superelevation should be introduced and removed uniformly over a length adequate for the likely travel speeds. The total length of the *superelevation transition distance* is the sum of the tangent (crown) runout and the superelevation runoff. The following design factors should be considered in designing the superelevation transition distance.

(1) *Tangent runout*, T_R, also known as *tangent runoff* and *crown runoff*, is a gradual change from a normal crowned section to a point where the *adverse cross slope* on the outside of the curve has been removed. When the adverse cross slope has been removed, the elevation of the outside pavement edge will be equal to the centerline elevation. The inside pavement edge will be unchanged. The rate of removal is usually the same as the superelevation runoff rate.

(2) *Superelevation runoff*, L, is a gradual change from the end of the tangent runout to a cross section that is fully superelevated. The *superelevation runoff rate* (also known as the *transition rate*), SRR, is the rate at which the normal cross-slope of the roadway is transitioned to the superelevated cross-slope. The superelevation runoff rate is expressed in units of cross-slope elevation per unit width per unit length of traveled roadway.

For single lanes, a common superelevation runoff rate is 1 ft per foot of width for every 400 ft (120 m) length, expressed as 1:400. For two-lane widths that are superelevated, a common transition rate for the outside of the second lane is 1:200. If conditions are restrictive and if sufficient room is not available for a 1:400 transition rate, more abrupt rates may be used.

(3) Tangent runout and superelevation runoff distances may be calculated using Eqs. 79.40 and 79.41. w is the lane width, and p is the rate of cross slope.

$$T_R = \frac{wp}{\text{SRR}} \qquad 79.40$$

$$L = \frac{we}{\text{SRR}} \qquad 79.41$$

(4) Superelevation runoff rate on a curve may be determined by a *time rule* (e.g., "runoff shall be completed within 4 sec at the design speed") or by a *speed rule* (e.g., "3 ft of runoff for every mph of design speed"), regardless of the initial superelevation. Time and speed rules depend on the specifying agency.

(5) On circular curves, the superelevation runoff should be developed two thirds on the tangent and one third on the curve. This results in two thirds of the full superelevation at the beginning and ending of the curve. This is a compromise between placing the entire transition on the tangent section, where superelevation is not needed, and placing the transition on the curve, where full superelevation is needed.

(6) On spiral curves, the superelevation is developed entirely within the length of the spiral.

(7) All shoulders should slope away from the traveled lanes. The angular breaks at the pavement edges of the superelevated roadways should be rounded by the insertion of vertical curves. The minimum curve length in feet should be approximately numerically equal to the design speed in mph.

Example 79.4

One end of a horizontal curve on a two-lane highway has 12 ft lanes and a crown cross-slope of 0.02 ft/ft. The PC is at sta 10+00. The transition rate is 1:400, and the required superelevation is 0.04. Calculate the stationing where (a) the superelevation runoff begins, (b) the tangent runout begins, and (c) the curve is fully superelevated.

Solution

(a) Use Eqs. 79.40 and 79.41.

$$T_R = \frac{wp}{\text{SRR}} = \frac{(12\text{ ft})\left(0.02\ \frac{\text{ft}}{\text{ft}}\right)}{\frac{1}{400}\ \frac{\text{ft}}{\text{ft}}}$$

$$= 96\text{ ft}$$

$$L = \frac{we}{\text{SRR}} = \frac{(12\text{ ft})\left(0.04\ \frac{\text{ft}}{\text{ft}}\right)}{\frac{1}{400}\ \frac{\text{ft}}{\text{ft}}}$$

$$= 192\text{ ft}$$

The superelevation should be developed two thirds before the curve and one third after. Therefore, the superelevation begins at $2L/3$ before the PC.

$$\text{sta } 10{+}00 - \frac{2L}{3} = \text{sta } 10{+}00 - \left(\tfrac{2}{3}\right)(192\text{ ft})$$

$$= \text{sta } 10{+}00 - 128\text{ ft} = \text{sta } 8{+}72$$

(b) The tangent runout begins at

$$\text{sta } 8{+}72 - 96\text{ ft} = \text{sta } 7{+}76$$

(c) The pavement should be fully superelevated at $L/3$ after the PC, at station

$$\text{sta } 10{+}00 + \frac{L}{3} = \text{sta } 10{+}00 + \frac{192\text{ ft}}{3}$$

$$= \text{sta } 10{+}00 + 64\text{ ft} = \text{sta } 10{+}64$$

12. SUPERELEVATION OF RAILROAD LINES

The method of specifying superelevation for railroad lines is somewhat different than for roadways. The *equilibrium elevation*, E, of the outer rail relative to the inner rail is calculated from Eq. 79.42. The effective gauge, G_{eff}, is the center-to-center rail spacing.

$$E = \frac{G_{\text{eff}}\text{v}^2}{gR} \quad \text{[railroads]} \qquad 79.42$$

13. STOPPING SIGHT DISTANCE

The *stopping sight distance* is the distance required by a vehicle traveling at the design speed to stop before reaching a stationary object that has suddenly appeared in its path. Calculated stopping sight distances are the minimums that should be provided at any point on any roadway. Greater distances should be provided wherever possible.

Stopping sight distance is the sum of two distances: the distance traveled during driver perception and reaction time, and the distance traveled during brake application. The equations used to calculate sight distance assume that the driver's eyes are 3.50 ft (1079 mm) above the surface of the roadway. For stopping sight distances, it is assumed that the object being observed has a height of 0.5 ft (150 mm).

Equation 79.43 can be used to calculate the stopping sight distance, S, for straight-line travel on a constant grade. In Eq. 79.43, the grade, G, is in decimal form and is negative if the roadway is downhill. The coefficient of friction, f, is evaluated for a wet pavement.

$$S = \left(0.278\ \frac{\frac{\text{m}}{\text{s}}}{\frac{\text{km}}{\text{h}}}\right) t_p \text{v}_{\text{km/h}} + \frac{\text{v}_{\text{km/h}}^2}{(254)(f+G)}$$

[SI] 79.43(a)

$$S = \left(1.47\ \frac{\frac{\text{ft}}{\text{sec}}}{\frac{\text{mi}}{\text{hr}}}\right) t_p \text{v}_{\text{mph}} + \frac{\text{v}_{\text{mph}}^2}{(30)(f+G)}$$

[U.S.] 79.43(b)

"Desirable values" of stopping sight distance, S, are listed in Table 79.2 for various design speeds. If the actual distance is less than the design value, the distance

Table 79.2 *AASHTO Minimum Stopping and Passing Sight Distances*

design speed, mph (km/h)	assumed initial speed, mph (km/h)	minimum desirable stopping sight distance[a], ft (m)	assumed passing speed, mph (km/h)	passing sight distance two-lane highway[b], ft (m)

[a] wet pavement
[b] Values should be increased by 18% for downgrades steeper than 3% and longer than 1 mi (1.609 km) in length.

Compiled from *A Policy on Geometric Design of Highways and Streets*, Tables III-1 and III-5, copyright © 1994 by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

is known as a "minimum value." The minimum speed to be used is defined by Eq. 79.44.

$$v_{min} = v_{design} - 0.2(v_{design} - 30 \text{ km/h}) \quad \text{[SI]} \qquad 79.44(a)$$

$$v_{min} = v_{design} - 0.2(v_{design} - 20 \text{ mph}) \quad \text{[U.S.]} \qquad 79.44(b)$$

14. PASSING SIGHT DISTANCE

The *passing sight distance* is the length of open roadway ahead necessary to pass without meeting an oncoming vehicle. Passing sight distance is applicable only to two-lane, two-way highways. Passing sight distance is not relevant on multilane highways.

Passing sight distances assume that the driver's eyes are 3.50 ft (1.07 m) above the surface of the roadway. The object being viewed is assumed to be at a height of 4.25 ft (1.30 m). Minimum passing sight distances are given in Table 79.2.

15. MINIMUM HORIZONTAL CURVE LENGTH FOR STOPPING DISTANCE

A horizontal circular curve is shown in Fig. 79.8. Obstructions along the inside of curves, such as retaining walls, cut slopes, trees, buildings, and bridge piers, can limit the available sight distance. Often, a curve must be designed that will simultaneously provide the required stopping sight distance while maintaining a clearance from a roadside obstruction.

The equations for calculating the geometry of a horizontal curve to see around an obstruction assume that the stopping sight distance is greater than the curve length (i.e., $S \geq L$). The stopping sight distance and length along the curve are the same. The angles are given in degrees, not radians.

$$S = \left(\frac{R}{28.65}\right)\left(\arccos\left(\frac{R-M}{R}\right)\right) \qquad 79.45$$

$$M = R(1-\cos\theta) = R\left(1-\cos\left(\frac{DS}{200}\right)\right) = R\left(1-\cos\left(\frac{28.65S}{R}\right)\right) \qquad 79.46$$

Decision sight distance should be added on a horizontal curve whenever a driver is confronted with additional information that may unduly complicate the highway information the driver must process. 10 sec of decision time is considered to be the minimum.

The curve length methods presented in this section are based on horizontal tangent grades only. If a vertical grade occurs in conjunction with a circular curve, these methods cannot be used.

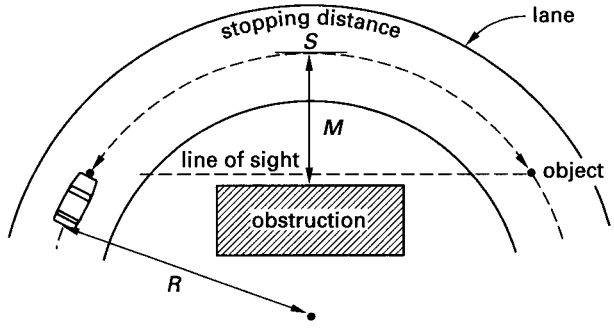

Figure 79.8 *Horizontal Curve with Obstructions*

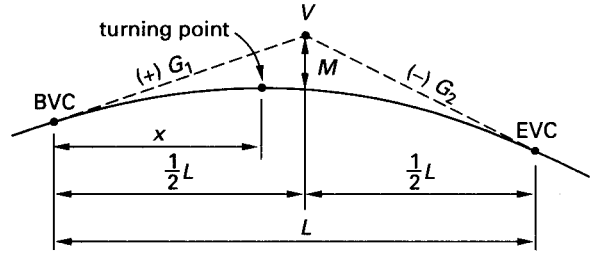
16. VERTICAL CURVES

Vertical curves are used to change the grade of a highway. Most vertical curves take the shape of an *equal-tangent parabola*. Such curves are symmetrical about the vertex. Since the grades are very small, the actual arc length of the curve is approximately equal to the chord length BVC-EVC. Table 79.3 lists the standard abbreviations used to describe geometric elements of vertical curves.

A vertical parabolic curve is completely specified by the two grades and the curve length. Alternatively, the *rate of grade change per station*, R, can be used in place of curve length. The rate of grade change per station is given by Eq. 79.47. Units of %/sta are the same as ft/(sta)^2.

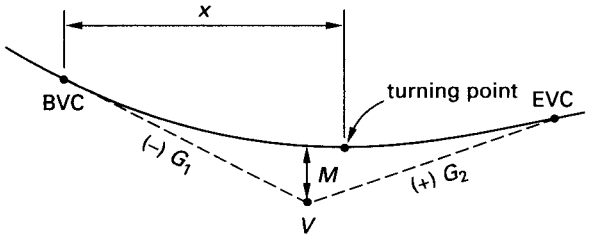
$$R = \frac{G_2 - G_1}{L} \qquad 79.47$$

Equation 79.48 defines an equal-tangent parabolic curve. x is the distance to any point on the curve, measured in stations beyond the BVC, and y is measured in ft. The same reference point is used to measure all elevations.



$$\text{elev}_x = \left(\frac{R}{2}\right)x^2 + G_1 x + \text{elev}_{\text{BVC}} \qquad 79.48$$

The maximum or minimum elevation will occur when the slope is equal to zero, which is located as determined by Eq. 79.49. This point is known as the *turning point*. In sag vertical curves, the turning point is the location at which catch basins should be installed.



$$x_{\text{turning point}} = \frac{-G_1}{R} \quad \text{[in stations]} \qquad 79.49$$

The *middle ordinate distance* is found from Eq. 79.50.

$$M_{\text{ft}} = \frac{|G_1 - G_2| L_{\text{sta}}}{8} \qquad 79.50$$

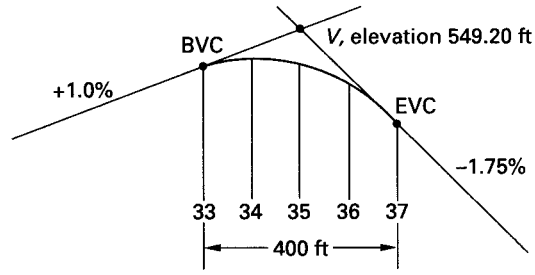
(a) crest curve

(b) sag curve

Figure 79.9 *Symmetrical Parabolic Vertical Curve*

Table 79.3 *Vertical Curves: Abbreviations and Terms*

preferred



A	change in gradient, $G_2 - G_1$
BVC	beginning of the vertical curve
EVC	end of the vertical curve
G_1	grade from which the stationing starts, in percent
G_2	grade toward which the stationing heads, in percent
L	length of curve
M	middle ordinate
R	rate of change in grade per station
V	vertex (the intersection of the two tangents)

alternate/archaic

E	tangent offset at V (same as M)
EVT	end of vertical tangency (same as EVC and PVT)
PVC	same as BVC
PVI	same as V
PVT	same as EVC
VPI	vertical point of intersection (same as V)

Example 79.5

A crest vertical curve with a length of 400 ft connects grades of +1.0% and −1.75%. The vertex is located at station 35+00 and elevation 549.20 ft. What are the elevations of the (a) BVC, (b) EVC, and (c) all full stations on the curve?

Solution

(a)
$$\begin{aligned}\text{elev}_{\text{BVC}} &= \text{elev}_{\text{V}} - G_1\left(\frac{L}{2}\right)\\ &= 549.20\text{ ft} - \left(1\ \frac{\text{ft}}{\text{sta}}\right)\left(\frac{4\text{ sta}}{2}\right)\\ &= 547.20\text{ ft}\end{aligned}$$

(b)
$$\begin{aligned}\text{elev}_{\text{EVC}} &= \text{elev}_{\text{V}} - G_2\left(\frac{L}{2}\right)\\ &= 549.20\text{ ft} - \left(1.75\ \frac{\text{ft}}{\text{sta}}\right)\left(\frac{4\text{ sta}}{2}\right)\\ &= 545.70\text{ ft}\end{aligned}$$

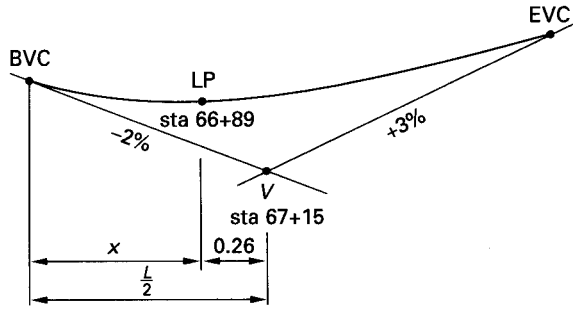
(c) Use Eq. 79.47.

$$R = \frac{G_2 - G_1}{L}$$
$$= \frac{-1.75\% - 1\%}{4 \text{ sta}}$$
$$= -0.6875 \text{ \%/sta}$$
$$\frac{R}{2} = \frac{-0.6875 \frac{\%}{\text{sta}}}{2}$$
$$= -0.3438\%/\text{sta} \quad [\text{same as } -0.3438 \text{ ft/sta}^2]$$

The equation of the curve is

$$y = \left(\frac{R}{2}\right) x^2 + x + \text{elev}_{\text{BVC}}$$
$$= -0.3438x^2 + x + 547.20 \text{ ft}$$

At sta 34+00, $x = 34 - 33 = 1$ sta.



$$y_{34+00} = \left(-0.3438 \frac{\text{ft}}{\text{sta}^2}\right)(1 \text{ ft})^2 + 1 \text{ ft} + 547.20 \text{ ft}$$
$$= 547.86 \text{ ft}$$

Similarly,

$$y_{35+00} = \left(-0.3438 \frac{\text{ft}}{\text{sta}^2}\right)(2 \text{ ft})^2 + 2 \text{ ft} + 547.20 \text{ ft}$$
$$= 547.82 \text{ ft}$$
$$y_{34+00} = \left(-0.3438 \frac{\text{ft}}{\text{sta}^2}\right)(3 \text{ ft})^2 + 3 \text{ ft} + 547.20 \text{ ft}$$
$$= 547.11 \text{ ft}$$

Example 79.6

A vertical sag curve with vertex located at sta 67+15 has a low point at sta 66+89. The grade into the curve is −2%, and the grade out of the curve is +3%. What is the length of curve?

Solution

The location of the low point is defined by Eqs. 79.47 and 79.49.

$$R = \frac{G_2 - G_1}{L} = \frac{3\frac{\%}{\text{sta}} - \left(-2\frac{\%}{\text{sta}}\right)}{L} = \frac{5\frac{\%}{\text{sta}}}{L}$$
$$x = \frac{-G_1}{R} = \frac{-\left(-2\frac{\%}{\text{sta}}\right)}{\frac{5\frac{\%}{\text{sta}}}{L}}$$
$$= 0.4L$$

The distance between the low point and the vertex is 0.26 sta. The distance between BVC and the vertex is

$$\frac{L}{2} = x + 0.26 \text{ sta}$$

Substituting $x = 0.4L$,

$$\frac{L}{2} = 0.4L + 0.26 \text{ sta}$$
$$L = 2.6 \text{ sta} \quad (260 \text{ ft})$$

17. VERTICAL CURVES THROUGH POINTS

If a curve is to have some minimum clearance from an obstruction as shown in Fig. 79.10, the curve length generally will not be known in advance. If the station and elevation of the point, P, the station and elevation of the BVC or the vertex, and the gradient values G_1 and G_2 are known, the curve length can be determined explicitly.

step 1: Find the elevation of points E, F, and G.

step 2: Calculate the constant (no physical significance) s.

$$s = \sqrt{\frac{\text{elev}_{\text{E}} - \text{elev}_{\text{G}}}{\text{elev}_{\text{E}} - \text{elev}_{\text{F}}}} \qquad 79.51$$

step 3: Solve for L directly.

$$L = \frac{2d(s+1)}{s-1} \qquad 79.52$$

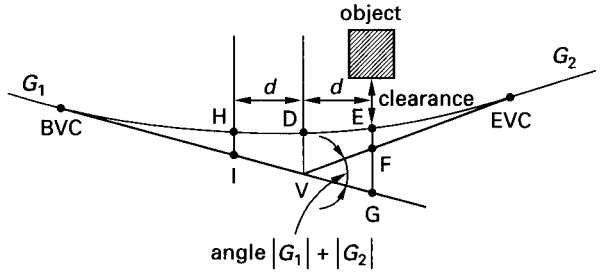


Figure 79.10 *Vertical Curve with an Obstruction*

Example 79.7

Determine the length of a sag vertical curve that passes through a point at elevation 614.00 ft and sta 17+00. The grades are $G_1 = -4.2\%$ and $G_2 = +1.6\%$. The BVC is at sta 13+00, elevation = 624.53 ft.

Solution

At the given point for this curve,

$$y = 614.00 \text{ ft}$$

$$R = \frac{G_2 - G_1}{L} = \frac{1.6\frac{\%}{\text{sta}} - \left(-4.2\frac{\%}{\text{sta}}\right)}{L} = \frac{5.8\frac{\%}{\text{sta}}}{L}$$

The equation of the curve is

$$y = \frac{Rx^2}{2} + G_1 x + \text{elev}_{\text{BVC}}$$

$$614.00 \text{ ft} = \frac{\left(\frac{5.8\frac{\%}{\text{sta}}}{L}\right)(4 \text{ sta})^2}{2} + \left(-4.2\frac{\text{ft}}{\text{sta}}\right)(4 \text{ sta}) + 624.53 \text{ ft}$$

$$-10.53 \text{ ft} = \frac{46.4}{L} - 16.8 \text{ ft}$$

$$L = 7.4 \text{ sta} \quad (740 \text{ ft})$$

18. VERTICAL CURVE TO PASS THROUGH TURNING POINT

Another common situation involving equal-tangent vertical curves is calculating the length of a sag or crest curve needed to pass through a turning point, TP, at a particular elevation. Equation 79.24 can be used to determine the curve length directly. Grades G_1 and G_2 and the elevations of the PVI and the turning point must be known.

$$L = \frac{2(\text{elev}_{\text{V}} - \text{elev}_{\text{TP}})}{G_1\left(\frac{G_1}{G_2 - G_1} + 1\right)} \qquad 79.53$$

19. MINIMUM VERTICAL CURVE LENGTH FOR SIGHT DISTANCES (CREST CURVES)

Crest curve lengths are generally determined based on stopping sight distances. (Headlight sight distance and rider comfort control the design of sag vertical curves.) The passing sight distance could also be used, except that the required length of the curve would be much greater than that based only on the stopping sight distance. Since the curve length determines the extent of the earthwork required, and it is easier (i.e., less expensive) to prohibit passing on crest curves than to perform the earthwork required to achieve the required passing sight distance, only the stopping sight distance is usually considered in designing the curve length.

Two factors affect the sight distance: the algebraic difference, A, between gradients of the intersecting tangents, and the length of the vertical curve, L. With a small algebraic difference in grades, the length of the vertical curve may be short. However, to obtain the same sight distance with a large algebraic difference in grades, a much longer vertical curve is needed.

Table 79.4 implies that the choice of a curve length is a simple selection of sight distance based on design speed. This is actually the case in simple curve length design problems where the design speed, v, and grades, G_1 and G_2, are known. The required stopping distance is determined from Table 79.2 or calculated from Eq. 79.43 or 79.45. The required curve length, L, is calculated from the formulas in Table 79.4. Since it is initially unknown, curve length is calculated for both the $S < L$ and $S > L$ cases. The calculated curve length that is inconsistent with its assumption is discarded.

The constants in Table 79.4 are based on specific heights of objects and driver's eyes above the road surface. In general, the sight distance over the crest of a vertical curve is given by Eqs. 75.54 and 79.55, where h_1 is the height of the eyes of the driver and h_2 is the height of the object sighted, both in feet.

$$L = \frac{AS^2}{200\left(\sqrt{h_1} + \sqrt{h_2}\right)^2} \qquad 79.54$$

$$L = 2S - \frac{200\left(\sqrt{h_1} + \sqrt{h_2}\right)^2}{A} \qquad 79.55$$

The sight distance under an overhead structure to see an object beyond a sag vertical curve is given by Eqs. 79.56 and 79.57. Various assumptions, including headlight height and beam divergence, were made by AASHTO in developing the following equations.

$$L = \frac{AS^2}{120 + 3.5S} \quad [S < L] \quad \text{[SI]} \qquad 79.56(a)$$

$$L = \frac{AS^2}{400 + 3.5S} \quad [S < L] \quad \text{[U.S.]} \qquad 79.56(b)$$

$$L = 2S - \frac{120 + 3.5S}{A} \quad [S > L] \quad \text{[SI]} \qquad 79.57(a)$$

$$L = 2S - \frac{400 + 3.5S}{A} \quad [S > L] \quad \text{[U.S.]} \qquad 79.57(b)$$

Table 79.4 *AASHTO Required Lengths of Curves on Grades*[a]

	stopping sight distance[b] (crest curves)	passing sight distance (crest curves)	stopping sight distance (sag curves)
SI units			
$S < L$	$\frac{AS^2}{404}$	$\frac{AS^2}{946}$	$\frac{AS^2}{120+3.5S}$
$S > L$	$2S - \frac{404}{A}$	$2S - \frac{946}{A}$	$2S - \frac{120+3.5S}{A}$
U.S. units			
$S < L$	$\frac{AS^2}{1329}$	$\frac{AS^2}{3093}$	$\frac{AS^2}{400+3.5S}$
$S > L$	$2S - \frac{1329}{A}$	$2S - \frac{3093}{A}$	$2S - \frac{400+3.5S}{A}$

[a] $A = G_1 - G_2$, the algebraic difference in grades.
[b] The driver's eye is 3.50 ft (1070 mm) above road surface, viewing an object 0.5 ft (150 mm) high.

Example 79.8

A car is traveling up a 1.25% grade with a design speed of 40 mph. The descending grade is −2.75%. What is the required length of curve for minimum proper stopping sight distance?

Solution

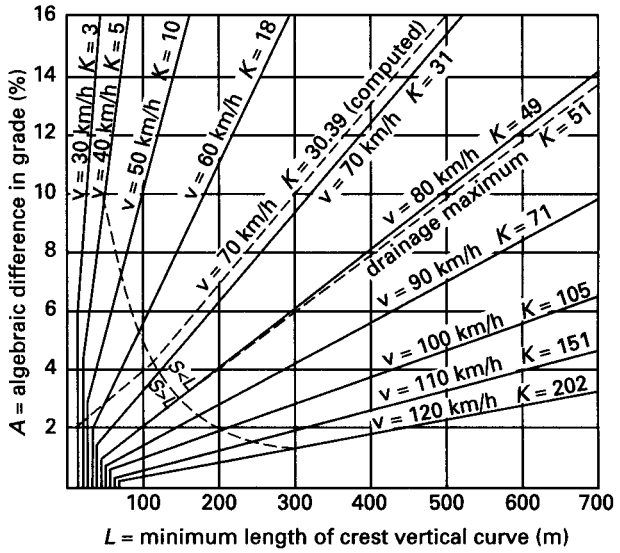
Table 79.2 gives the minimum stopping sight distance at 40 mph as 243.8 ft. Refer to Table 79.4. Assume $S > L$.

$$L = 2S - \frac{1329}{G_1 - G_2}$$
$$= (2)(243.8 \text{ ft}) - \frac{1329}{1.25 - (-2.75)} = 155.4 \text{ ft}$$

Using Table 79.4 and assuming $S < L$,

$$L = \frac{(G_1 - G_2)S^2}{1329}$$
$$= \frac{\left(1.25 - (-2.75)\right)(243.8 \text{ ft})^2}{1329} = 178.9 \text{ ft}$$

Since 243.8 ft is greater than 178.9 ft ($S > L$), the second assumption is not valid. The required curve length is 155.4 ft.

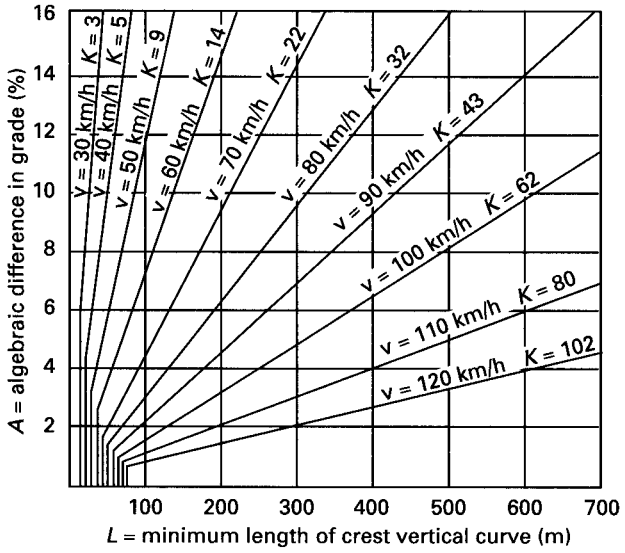


20. DESIGN OF CREST CURVES USING *K*-VALUE

AASHTO extends the sight-distance procedure by considering the design speed to be a nominal value. The actual speed of a vehicle might be higher or lower. If the actual speed is equal to the design speed, travel is considered to be in the "upper range of speeds." Alternatively, the vehicle may be assumed to be driven somewhat more slowly than the design speed to compensate for weather, wet pavement, lighting, or other adverse conditions. This case is referred to as the "lower range of speeds." (AASHTO reports that studies have concluded that vehicles are not always actually driven more slowly under these conditions, but the assumption may yet be made.) The normally used upper- and lower-range speed values are listed as the "initial speed" values in Table 79.2.

The *K-value method* of analysis used in AASHTO's Green Book is a simplified method of choosing a stopping sight distance for a crest vertical curve. The length of vertical curve per percent grade difference, K, is the ratio of the curve length, L, to grade difference, A.

$$K = \frac{L}{A} = \frac{L}{G_1 - G_2} \qquad 79.58$$



The $L = KA$ relationship is conveniently linear. In order to facilitate rapid calculation of curve lengths, AASHTO has prepared several graphs. Figure 79.11 gives minimum lengths of crest vertical curves for the upper speed range, and Fig. 79.12 gives minimum curve lengths for the lower speed range. Since for a fixed grade difference the speed determines the stopping distance, every value of speed has a corresponding value of K. Thus, the curves in the figures are identified concurrently with the speed and the K-value. It is not necessary to specify both A and L in a design problem, as knowing K is sufficient.

Figure 79.12 *Design Controls for Crest Vertical Curves (lower range)*

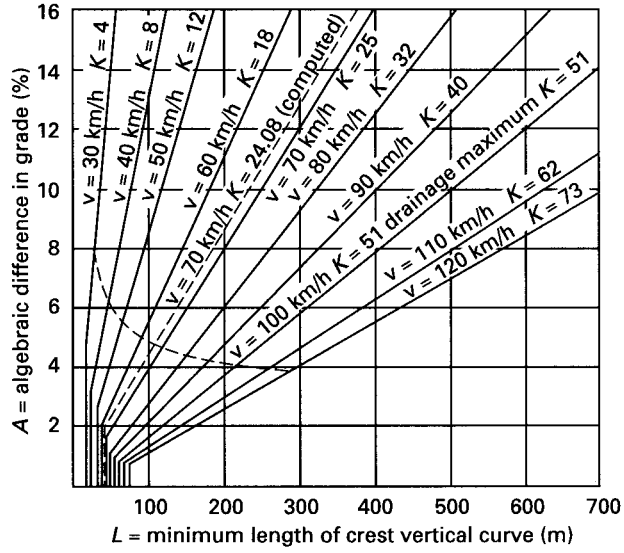
The simplified procedure is to select one figure or another based on upper or lower speed range, then select one of the curves based on the speed or the K-value, and finally read the curve length that corresponds to the grade difference, A. K-values shown on the graphs have been rounded for design.

The shorter curve lengths in the AASHTO figure have been determined by other overriding factors, the most important of which are experience and state requirements. Curve lengths calculated from Table 79.4 for $S > L$ often do not represent desirable design practice and are replaced by estimated values of three times the design speed. This is consistent with the minimum curve lengths of 100 to 300 ft (30 to 90 m) prescribed by most states. The estimated solutions in the AASHTO figures are also justified on the basis that the longer curve lengths are obtained inexpensively when the difference in grades is small.

21. MINIMUM VERTICAL CURVE LENGTH FOR HEADLIGHT SIGHT DISTANCE: SAG CURVES

A *sag curve* should be designed so that a vehicle's headlights will illuminate a minimum distance of road ahead equal to the stopping sight distance. When full roadway lighting is available and anticipated to be available for the foreseeable future, designing for the *headlight sight distance* (also known as *light distance*) may not be necessary.

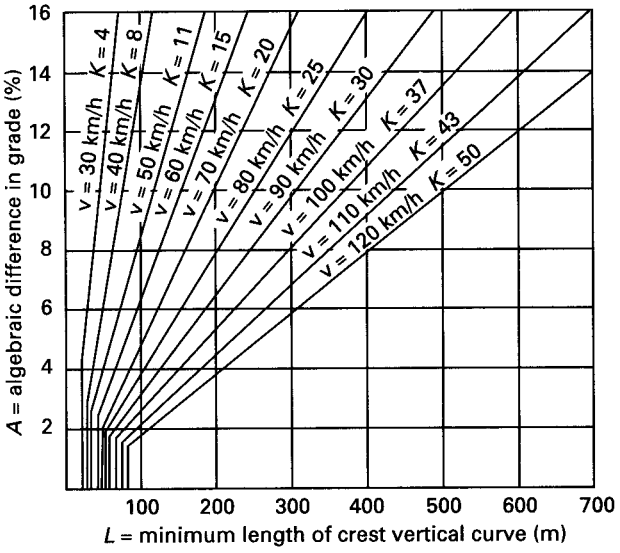
22. MINIMUM VERTICAL CURVE LENGTH FOR COMFORT: SAG CURVES



In a sag curve, gravitational and centrifugal forces combine to simultaneously act on the driver and passengers and comfort becomes the design control. A formula for calculating the minimum length of curve for comfort is given in Eq. 79.59. The curve length for comfort may be shorter or longer than the safe passing or stopping sight distances.

$$L = \frac{Av_{km/h}^2}{395} \qquad \text{[SI]} \quad 79.59(a)$$

$$L = \frac{Av_{mph}^2}{46.5} \qquad \text{[U.S.]} \quad 79.59(b)$$



23. DESIGN OF SAG CURVES USING *K*-VALUE

The AASHTO Green Book contains a graphical method for determining the minimum lengths of sag vertical curves also. Factors taken into consideration are the headlight sight distance, rider comfort, drainage control, and rules of thumb. Figures 79.13 and 79.14 provide graphical methods of determining the lengths using the K-value concept. As with crest curves, the procedure is to select one figure or another based on upper or lower speed range, then select one of the curves based on the speed or the K-value, and finally read the curve length that corresponds to the grade difference, A.

24. UNEQUAL TANGENT (UNSYMMETRICAL) VERTICAL CURVES

Not all vertical curves are symmetrical about their vertices. Figure 79.15 illustrates a curve in which the distance from the BVC to the vertex, l_1, is not the same as the distance from the vertex to the EVC, l_2. To evaluate the curve, a line v_1v_2 is drawn parallel with AB such that $Av_1 = v_1V$ and $Vv_2 = v_2B$. This line divides the curve into two halves of equal-tangent parabolic vertical curves: the first from A to K, and the second from K to B. The elevation of v_1 is the average of that of A and V; the elevation of v_2 is the average of that of V and B. Therefore, CK = KV. The vertical distance, CV, is defined by Eq. 79.27.

$$\mathrm{CV} = \left(\frac{l_1 l_2}{L}\right)(G_2 - G_1) \qquad 79.60$$

In Eq. 79.60, l_1, l_2, and L are expressed in stations, and G_2 and G_1 are expressed in percent. Eq. 79.61 can be used to solve for the distance CK.

$$\mathrm{CK} = \mathrm{KV} = \left(\frac{l_1 l_2}{2L}\right)(G_2 - G_1) \qquad 79.61$$

The grade, G', of the line v_1v_2 is the same as that of AB, found by Eq. 79.62.

$$G' = \frac{\mathrm{elev_B} - \mathrm{elev_A}}{L} \qquad 79.62$$

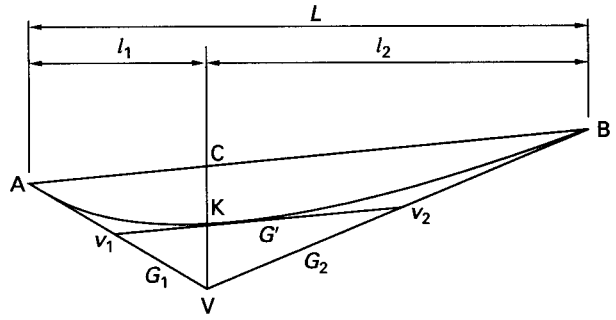

Figure 79.15 *Unequal Tangent Vertical Curve*

25. SPIRAL CURVES

Spiral curves (also known as *transition curves* and *easement curves*) are used to produce a gradual transition from tangents to circular curves. A spiral curve is a curve of gradually changing radius and gradually changing degree of curvature. Figure 79.16 illustrates the geometry of spiral curves connecting tangents with a circular curve of radius R and degree of curvature D. The *entrance spiral* begins at the left at the TS (tangent to spiral) and ends at the SC (spiral to curve). The circular curve begins at the SC and ends at the CS (curve to spiral). The *exit spiral* begins at the CS and ends at the ST (spiral to tangent).

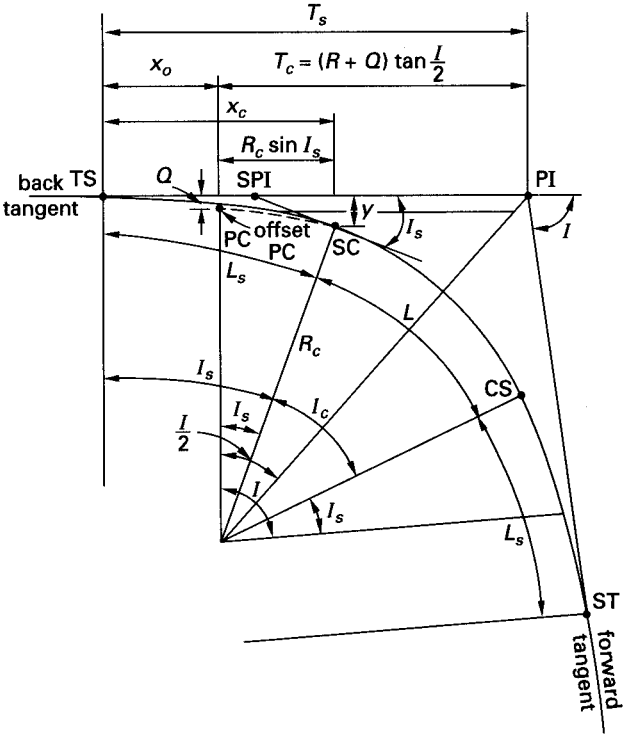

Figure 79.16 *Spiral Curve Geometry*

Entrance and exit spirals are geometrically identical. Their length, L_s, is the arc distance from the TS to the SC (or CS to ST). This length is selected to provide sufficient distance for introducing the curve's superelevation. The length of a spiral curve can be adjusted to

between 75% and 200% of the theoretical value to meet other design criteria.

There are various ways of selecting the spiral length, L_s, including rules of thumb, tables, formulas, and codes. Equation 79.63 is a modification of the 1909 Shortt equation.

$$L_{s,\mathrm{m}} \approx \frac{0.035 v_{\mathrm{kph}}^3}{R_{\mathrm{m}}} \quad \text{[SI]} \qquad 79.63(a)$$

$$L_{s,\mathrm{ft}} \approx \frac{1.6 v_{\mathrm{mph}}^3}{R_{\mathrm{ft}}} \quad \text{[U.S.]} \qquad 79.63(b)$$

A tangent to the entrance spiral at the SC projected to the back tangent locates the SPI (spiral point of intersection). The angle at the SPI between the two tangents is the *spiral angle*, I_s. (As with spiral curves, the symbol I and Δ are both used for spiral angle.) The spiral's degree of curvature changes uniformly from 0° at TS to D (the circular curve's degree) at SC. Since the change is uniform, the average degree of curve over the spiral's length is $D/2$. The spiral angle is given by Eq. 79.64. L_s is the length of spiral curve in ft, and I_s, I_c, and D are in degrees.

$$I_s = \left(\frac{L_s}{100}\right)\left(\frac{D}{2}\right) = \frac{L_s D}{200} \qquad 79.64$$

The *total deflection angle* is equal to the interior angle, I, of the two intersecting tangents.

$$I = I_c + 2I_s \qquad 79.65$$

The *total length of the curve system* is

$$L = L_c + 2L_s \qquad 79.66$$

As with circular curves, spiral curves can be laid out using deflection angles or tangent offsets. The total deflection angle, α_s, from the TS to the SC is

$$\alpha_s = \frac{y}{x} \approx \frac{I_s}{3} \qquad 79.67$$

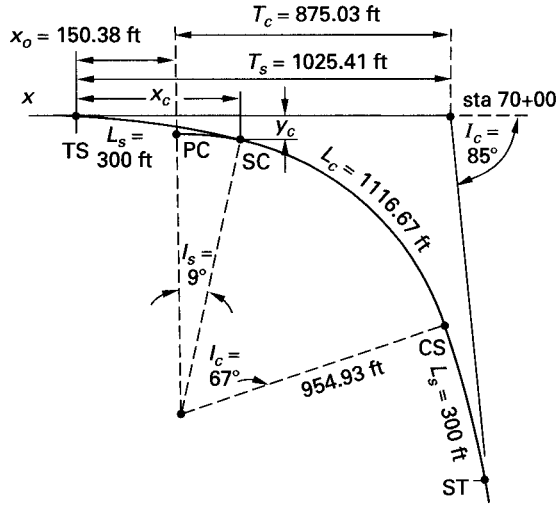
At any other point, P, along the spiral curve, spiral angles, α_{P}, are proportional to the square of the distance from the TS to the point. I_{P} is the central spiral angle at any point P whose distance from TS is L_{P}.

$$\frac{\alpha_{\mathrm{P}}}{\alpha_s} = \frac{I_{\mathrm{P}}}{I_s} = \left(\frac{L_{\mathrm{P}}}{L_s}\right)^2 \qquad 79.68$$

For any spiral curve length L up to L_s, the tangent offset is

$$\begin{aligned} y &= x \tan \alpha_{\mathrm{p}} \approx x\alpha_{\mathrm{p,radians}} \\ &= \frac{xI_{s,\mathrm{radians}}}{3} \\ &= \frac{xL_s D}{(200)(3)} \\ &= \frac{xL_s}{6R} \quad [I < 20°] \end{aligned} \qquad 79.69$$

$$T_c = (R+Q)\tan\frac{I}{2} \qquad 79.70$$



$$\begin{aligned} Q &= y - R(1-\cos I_s) \\ &= \frac{L_s^2}{6R} - R(1-\cos I_s) \end{aligned} \qquad 79.71$$

Table 79.5 Spiral Curve Abbreviations

CS	curve to spiral point
I_s	spiral angle
L	chord length
L_{P}	distance to any point, P
L_s	length of spiral
Q	offset of ghost PC to new tangent (tangent shift)
R	radius of circular curve
SC	spiral to curve point
SPI	spiral to point of intersection
ST	spiral to tangent
TS	tangent to spiral point

Example 79.9

A 300 ft long spiral curve is used as a transition to a 6° circular curve. The interior angle of the tangents is 85°. The station of the PI is 70+00. Determine the stations of the (a) TS, (b) SC, (c) CS, and (d) ST.

Solution

Use Eq. 79.64.

$$I_s = \frac{L_s D}{200} = \frac{(300\ \mathrm{ft})(6°)}{200} = 9°$$

The circular curve's subtended angle between the SC and CS is

$$I_c = I - 2I_s = 85° - (2)(9°) = 67°$$

Use Eq. 79.1 to calculate the circular curve's radius.

$$R_c = \frac{5729.578}{D_c} = \frac{5729.578}{6°} = 954.93\ \mathrm{ft}$$

Use Eq. 79.10 to calculate the length of the circular curve.

$$\begin{aligned} L_c &= 100\left(\frac{I_c}{D_c}\right) = (100)\left(\frac{67°}{6°}\right) \\ &= 1116.67\ \mathrm{ft} \end{aligned}$$

Use Eq. 79.69 to calculate the offset from the tangent at the SC. At that point, $x = L_s$.

$$y = \frac{L_s^2}{6R_c} = \frac{(300 \text{ ft})^2}{(6)(954.93 \text{ ft})} = 15.71 \text{ ft}$$

Since $9° < 20°$, the tangent distance can be approximated as

$$x_c = \frac{y_c}{\tan\left(\frac{I_s}{3}\right)} = \frac{15.71 \text{ ft}}{\tan\left(\frac{9°}{3}\right)} = 299.76 \text{ ft}$$

$$x_o = x_c - R_c \sin I_s = 299.76 \text{ ft} - (954.93 \text{ ft})(\sin 9°) = 150.38 \text{ ft}$$

Use Eq. 79.70.

$$Q = \frac{L_s^2}{6R} - R(1 - \cos I_s) = \frac{(300 \text{ ft})^2}{(6)(954.93 \text{ ft})} - (954.93 \text{ ft})(1 - \cos 9°) = 3.95 \text{ ft}$$

Use Eq. 79.70.

$$T_c = (R_c + Q)\tan\left(\frac{I}{2}\right) = (954.93 \text{ ft} + 3.95 \text{ ft})\tan\left(\frac{85°}{2}\right) = 878.65 \text{ ft}$$

$$T_s = x_o + T_c = 150.38 \text{ ft} + 878.65 \text{ ft} = 1029.03 \text{ ft}$$

(a) sta TS = sta PI $- T_s$
= (70+00) − 1029.03 ft = 59+70.97

(b) sta SC = sta TS $+ L_s$
= (59+70.97) + 300 ft = 62+70.97

(c) sta CS = sta SC $+ L_c$
= (62+70.97) + 1116.67 ft = 73+87.64

(d) sta ST = sta CS $+ L_s$ = (73+87.64) + 300 ft
= 76+87.64

26. AIRPORT PAVEMENT GRADES

Longitudinal grades of airport runways should be limited to 1.5% for transport airports and 2.0% for utility airports. Similarly, the maximum grade change from one runway grade to another grade should be limited to 1.5% for transport airports and 2.0% for utility airports. The maximum grade on the first and last quarter of the runway distance should be 0.8% for transport airports. The minimum lengths of vertical curves (PC to PT) should be 1000 ft/% grade change for transport airports and 300 ft/% grade change for utility airports. The minimum separation between points of intersection (PIs) of runway vertical curves should be (1000 ft)$(|G_1| + |G_2|)$ for transport airports and (250 ft)$(|G_1| + |G_2|)$ for utility airports.

27. RAILROAD GRADES

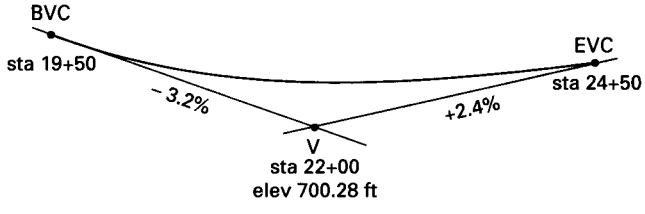
Table 79.6 gives general recommendations for maximum rates of change of gradients for railroad curves.

Table 79.6 *Maximum Rate of Change of Gradient on Railroad Lines (percent per 100 ft station)*

	curve type	
track line rating	sag	crest
high-speed main line	0.05	0.10
secondary or branch line	0.10	0.20

PRACTICE PROBLEMS

Vertical Sag Curves



1. A falling grade of 4% meets a rising grade of 5% in a sag curve. At the start of the curve, the elevation is 123.06 ft at sta 4034+20. At sta 4040+20, there is an overpass with an underside elevation of 134.06 ft. If the curve is designed to afford a clearance of 15 ft under the overpass, calculate the required length.

Answer: 8.1 sta

2. An existing length of road consists of a rising gradient of 1 in 20 followed by a vertical parabolic crest curve 300 ft long, and then a falling gradient of 1 in 40. The curve joins both gradients tangentially, and the elevation of the highest point on the curve is 173.07 ft. Visibility is to be improved over this stretch of road by replacing the curve with another parabolic curve 600 ft long. (a) Find the depth of excavation required at the midpoint of the curve. (b) Tabulate the elevations of points at 100 ft intervals along the new curve.

Answers: (a) 2.81 ft; (b) 160.57 ft, 164.95 ft, 168.07 ft, 169.95 ft, 170.57 ft, 169.95 ft, 168.07 ft

3. *(Time limit: one hour)* A sag vertical curve is shown.

Transportation

(a) At what station is the low point located?
(A) sta 22+15
(B) sta 22+36
(C) sta 22+68
(D) sta 22+79

The answer is (B).

(b) What is the elevation of the low point?
(A) 701 ft
(B) 702 ft
(C) 703 ft
(D) 704 ft

The answer is (D).

(c) What is the elevation of sta 21+25.04?
(A) 701 ft
(B) 704 ft
(C) 706 ft
(D) 708 ft

The answer is (B).

(d) What is the highest design speed for this curve?
(A) 60 mph
(B) 64 mph
(C) 68 mph
(D) 72 mph

The answer is (B).

(e) What is the rate of grade change per station?
(A) 1.0%/sta
(B) 1.1%/sta
(C) 1.4%/sta
(D) 1.6%/sta

The answer is (B).

(f) If 20 ft of clearance are required, what is the lowest elevation that the bottom of an overhead bridge deck may have at sta 23+16?
(A) 724 ft
(B) 726 ft
(C) 728 ft
(D) 730 ft

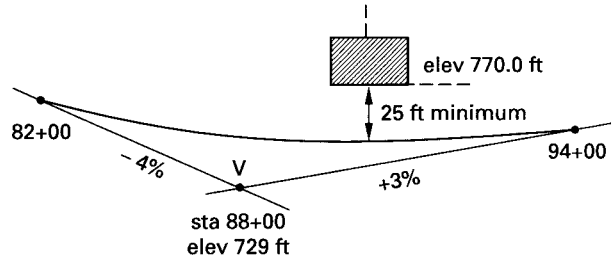
The answer is (A).

(g) What would the curve length have to be if the bridge deck in part (f) were kept at the same elevation, but 22 ft (6.7 m) of clearance were required? Assume that the stationing and elevation of the PVC are kept the same.
(A) 660 ft
(B) 680 ft
(C) 700 ft
(D) 710 ft

The answer is (B).

(h) For the curve solved in part (g), how much additional excavation is required at sta 22+00?
(A) 1.0 ft
(B) 1.9 ft
(C) 2.5 ft
(D) 2.9 ft

The answer is (A).

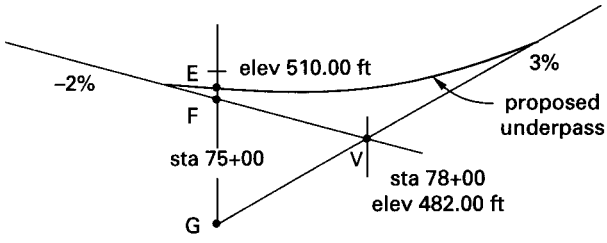


(i) What is the AASHTO K-value for the longer curve?
(A) 120.8 ft/%
(B) 121.8 ft/%
(C) 122.8 ft/%
(D) 123.8 ft/%

The answer is (B).

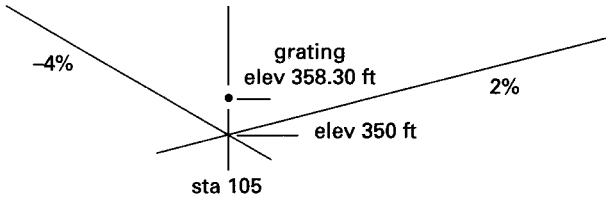
(j) At 65 mph, stopping sight distance for the longer curve is approximately equal to
(A) 200 ft
(B) 400 ft
(C) 600 ft
(D) 800 ft

The answer is (C).



4. *(Time limit: one hour)* Two highways are planned, each running perpendicular to the other. The geometric details of the underpass have been determined. The design process is continuing for the perpendicular overpass, which must maintain a 25 ft clearance (measured between highway surface centerlines). (a) What is the minimum station where the new highway can be constructed? (b) Locate the maximum station where the new highway can be constructed. (c) What is the station of the lowest point on the existing curve? (d) What is the elevation of the lowest point on the existing curve?

Answers: (a) sta 84+43; (b) sta 93+29; (c) sta 88+86; (d) 739.29 ft



5. *(Time limit: one hour)* A new highway can go either over or under (perpendicular to) an existing highway at sta 75+00. The elevation of the existing highway at sta 75+00 is 510.00 ft. 22 ft of clearance (between the centerlines of the two road surfaces) are required if the new highway goes over the existing highway. 20 ft of clearance are required if the new highway goes under the old highway. (a) What is the longest vertical curve

that will pass under the existing highway? (b) What is the shortest vertical curve that will pass over the existing highway?

Answers: (a) 12.2 sta; (b) 82.0 sta

6. *(Time limit: one hour)* The grades on a vertical curve intersect at sta 105+00 and elevation 350 ft. A drain grating exists at sta 105+00 and elevation 358.30 ft. (a) If a curve length of 1900 ft is used, what is the elevation of the BVC? (b) If a length of 1900 ft is used, what is the elevation at sta 106+40? (c) If a curve length of 1900 ft is used, what is the elevation of the lowest point on the curve? (d) If a curve length of 1900 ft is used, what is the sta of the BVC? (e) If a curve length of 1900 ft is used, what is the station of the EVC? (f) What is the minimum continuous curve length such that no point on the curve will be lower than the drain grating?

Answers: (a) 388 ft; (b) 363.17 ft; (c) 362.68 ft; (d) sta 95+50; (e) sta 114+50; (f) 12.45 sta

Vertical Crest Curves

7. *(Time limit: one hour)* An equal-tangent vertical curve has the following geometric properties.

BVC sta	110+00
PVI sta	116+00
PVI elev	1262
EVC	122+00
ascending grade	+3%
descending grade	−2%

(a) Find the centerline roadway elevation of sta 110.5. (b) Find the centerline roadway elevation of sta 115.5. (c) The road continues on to a horizontal curve to the right. Superelevation is 8%. The road is 60 ft wide at all points. The horizontal curve is supported by three pile bents symmetrical about the curve's PVI. The pile bents are located at stations 115+50, 116+00, and 116+50. Each pile bent consists of seven piles symmetrical about the road centerline, placed 10 ft apart. The tops of the piles are 3.5 ft below the roadway. What are the elevations of the pile heads at stations 115+50, 116+00, and 116+50?

Answers: (a) 1245.5 ft; (b) 1254.2 ft

Horizontal Curves

8. Three points (A, B, and C) were selected on the centerline of an existing horizontal circular curve. The instrument was set horizontally at point B. Readings were taken on a vertical staff at points A and C. The instrument had constants of 100 and 0. The instrument axis was 4.7 ft above the road at point B. (a) What is the radius of the curve? (b) What is the line-of-sight gradient AB? (c) What is the line-of-sight gradient BC?

staff at	horizontal bearing	stadia readings (ft)		
A	0.00°	10.038	6.221	2.403
C	211.14°	7.236	5.778	4.320

Answers: (a) 989.9 ft; (b) +0.00199 ft/ft; (c) −0.00370 ft/ft

9. *(Time limit: one hour)* Two straight tangents of a two-line highway intersect at point B. The tangents have azimuths of 270°and 110°, respectively. They are to be joined by a circular curve that must pass through a point D, 350 ft from point B. The azimuth of line BD is 260°.

(a) The required radius is most nearly
(A) 7280 ft
(B) 7330 ft
(C) 7650 ft
(D) 7900 ft

The answer is (A).

(b) The tangent lengths are most nearly
(A) 1280 ft
(B) 1300 ft
(C) 1340 ft
(D) 1380 ft

The answer is (A).

(c) The length of curve is most nearly
(A) 2000 ft
(B) 2500 ft
(C) 3000 ft
(D) 3500 ft

The answer is (B).

Transportation

(d) The angle required to set out a 500 ft arc is most nearly

(A) 1°
(B) 2°
(C) 3°
(D) 4°

The answer is (D).

(e) If the curve is laid out by the tangent-offset method, the tangent-offset distance required to place the stake located an arc distance of 100 ft from the PC is most nearly

(A) 80 ft
(B) 90 ft
(C) 100 ft
(D) 200 ft

The answer is (C).

(f) Assuming that snow and ice are not normally encountered on the highway, the maximum design speed for this curve is most nearly

(A) 55 mph
(B) 60 mph
(C) 65 mph
(D) 70 mph

The answer is (D).

(g) Assuming a design speed of 70 mph, the passing sight distance for this curve is most nearly

(A) 2000 ft
(B) 2500 ft
(C) 3000 ft
(D) 3500 ft

The answer is (B).

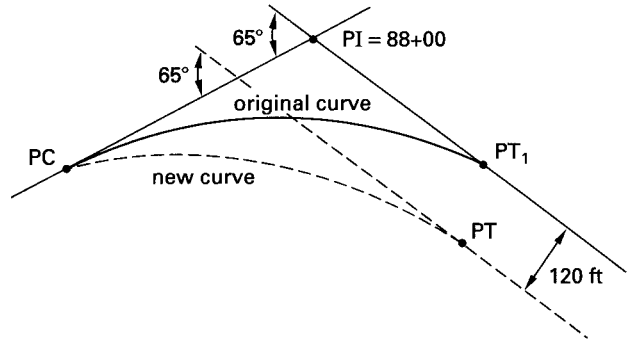
(h) What would the maximum superelevation rate be if snow and ice were commonly encountered on the freeway?

(A) 0.02
(B) 0.04
(C) 0.06
(D) 0.08

The answer is (C).

(i) Assume lane widths are 12 ft and the crown cross-slope is most nearly 0.02 ft/ft. A vehicle is traveling out of the curve. Over what distance (from the PC) should all superelevation be removed from the alignment and the crown be fully developed?

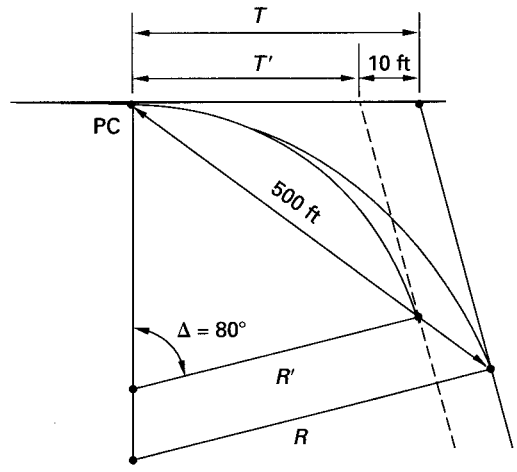
(A) 130 ft
(B) 140 ft
(C) 170 ft
(D) 190 ft



The answer is (B).

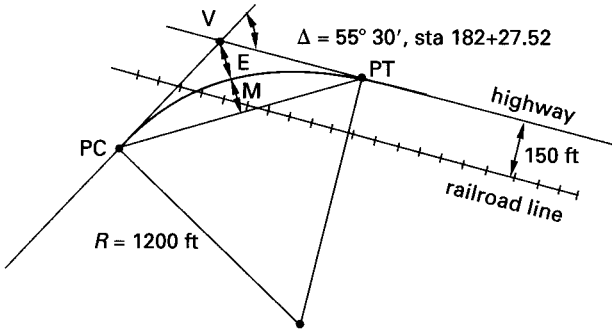
(j) What is the approximate maximum stopping sight distance for this curve for a vehicle traveling at 70 mph?

(A) 700 ft
(B) 800 ft
(C) 850 ft
(D) 900 ft



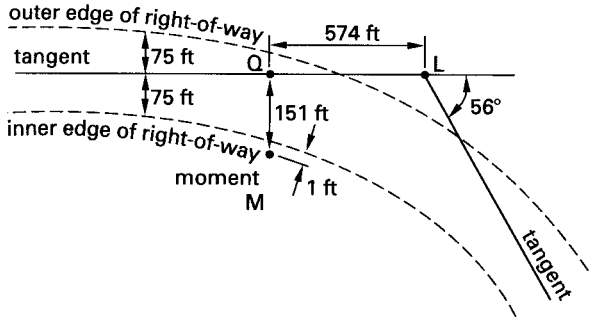
The answer is (B).

10. *(Time limit: one hour)* An existing 6° horizontal circular curve connects a PC and PT_1 as shown. It is desired to avoid having vehicles pass too close to a historical monument, so a proposal has been made to relocate the curve 120 ft forward. The PC will remain the same. (a) What is the PC station? (b) What is the radius of curvature of the new curve? (c) What is the stationing of the new curve's PT?



Answers: (a) sta 81+91.64; (b) 747.09 ft; (c) sta 90+39.19

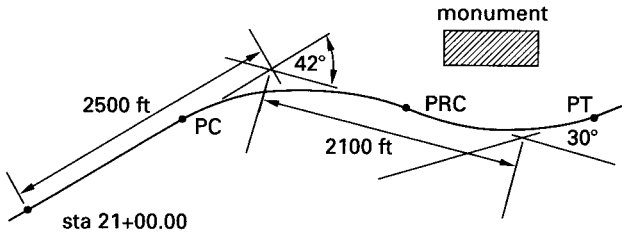
11. The tangent of the horizontal curve shown is relocated 10 ft west of its original position. The PC remains the same. (a) What is the original curve radius? (b) What is the new curve radius?



Answers: (a) 388.9 ft; (b) 377.0 ft

12. *(Time limit: one hour)* The tangent of a horizontal curve is parallel to a railroad line 150 ft away. The two curve tangents intersect at sta 182+27.52. Other information is provided in the illustration. Determine the (a) station of the PC, (b) the station of the PT, (c) the middle ordinate, (d) the external ordinate, and (e) the station of the railroad line's intersection with the highway.

Answers: (a) sta 175+96.17; (b) sta 187+58.56; (c) 138.0 ft; (d) 155.95 ft; (e) sta 181+52.02

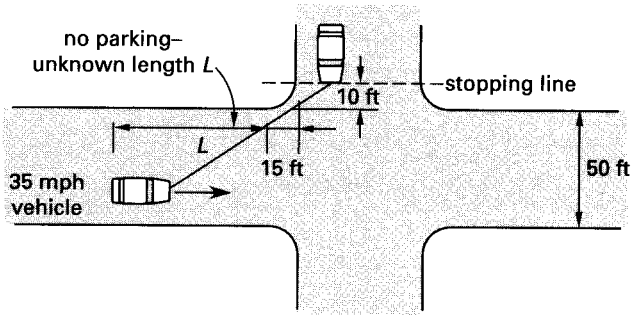


13. *(Time limit: one hour)* A freeway is being constructed to pass close to an existing first-order USGS survey monument. The freeway can be on either side of the monument. The freeway has a 75 ft right-of-way on either side of the curve centerline. A 1 ft clearance from the monument (which is considered to be a dimensionless point) to the edge of the right-of-way is required. The clearance is radial, measured along a line from the curve center to the monument. Find the range of radii of circular arcs that will provide the required clearance.

Answers: 2108.35 ft; 3405.01 ft

Compound Curves

14. *(Time limit: one hour)* A historical monument must be avoided near a proposed highway. A reverse compound curve is being considered. Both curves will have the same curvature. What is the station of the (a) PC, (b) PRC, and (c) PT? (d) What is the deflection angle from the PC to the center of the first curve? (e) What are the disadvantages associated with reverse curves?



Answers: (a) sta 33+63.20; (b) sta 57+24.24; (c) 74+10.70; (d) 10.5°

Sight Distance

15. *(Time limit: one hour)* An unsignalized blind intersection is shown. It is desired to prohibit parking near the intersection in order to provide adequate sight distance into the intersection. Vehicles travel on the major street at 35 mph or slower 85% of the time. PIEV time is 1.0 sec for the average driver. Assume wet pavement and worn tires. Vehicles accelerate according to the data given. (a) Determine the length, L, needed to allow adequate sight distance. (b) How many parallel parking places will be lost?

distance, ft	time, sec
10	2.3
30	3.7
50	6.2
80	8.5
100	11.8

Answers: (a) approximately 319 ft; (b) approximately 14 spaces

1. VOLUMES OF PILES

The volumes of piles of soil, recycled pavement, and paving materials can be calculated if the pile shapes are assumed. The *angle of repose*, ϕ, depends on the material, but is approximately 30° for smooth gravel, 40° for sharp gravel, 25 to 35° for dry sand, 30 to 45° for moist sand, 20 to 40° for wet sand, and 37° for cement.

$$V = \left(\frac{h}{3}\right)\pi r^2 \quad \text{[cone]} \qquad 80.1$$

$$V = \left(\frac{h}{6}\right)b(2a + a_1) = \tfrac{1}{6}hb\left(3a - \frac{2h}{\tan\phi}\right) \quad \text{[wedge]} \qquad 80.2$$

$$V = \left(\frac{h}{6}\right)\left(ab + (a + a_1)(b + b_1) + a_1 b_1\right)$$
$$= \left(\frac{h}{6}\right)\left(ab + 4\left(a - \frac{h}{\tan\phi_1}\right)\left(b - \frac{h}{\tan\phi_2}\right) + \left(a - \frac{2h}{\tan\phi_1}\right)\left(b - \frac{2h}{\tan\phi_2}\right)\right)$$
$$\left[\text{frustrum of a rectangular pyramid}\right] \qquad 80.3$$

$$a_1 = a - \frac{2h}{\tan\phi_1} \qquad 80.4$$

$$b_1 = b - \frac{2h}{\tan\phi_2} \qquad 80.5$$

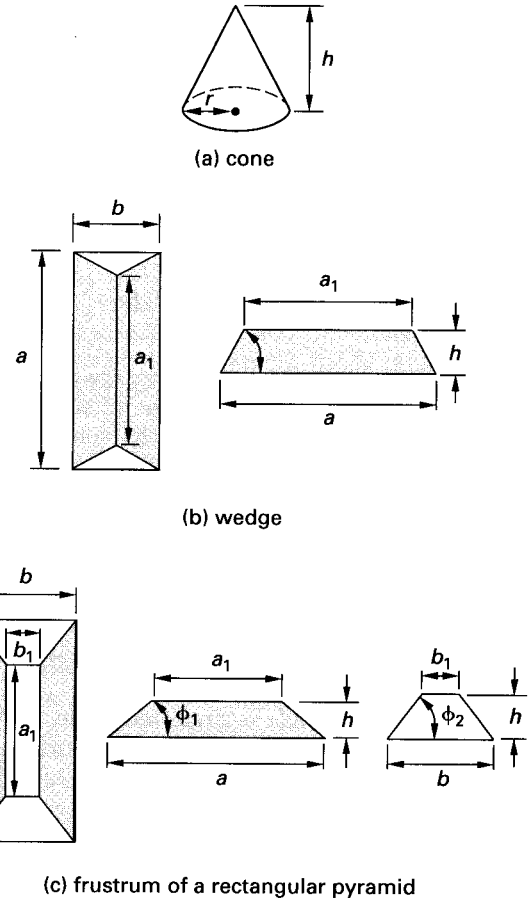

Figure 80.1 *Pipe Shapes*

Transportation

2. EARTHWORK VOLUMES

A three-dimensional soil volume between two points is known as a soil *prismoid* or *prism*. The prismoid (prismatic) volume must be calculated in order to estimate hauling requirements. Such volume is generally expressed in units of cubic yards ("yards") or cubic meters. There are two methods of calculating the prismoid volume: the average end area method and the prismoidal formula method.

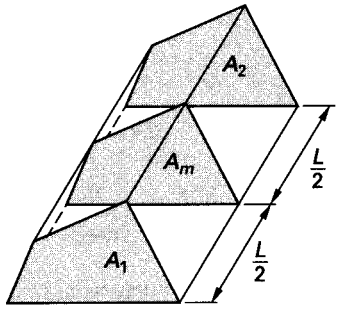

Figure 80.2 *Soil Prismoid*

3. AVERAGE END AREA METHOD

With the *average end area method*, the volume is calculated by averaging the two end areas and multiplying by the prism length. This disregards the slopes and orientations of the ends and sides, but is sufficiently accurate for most earthwork calculations. When the end area is complex, it may be necessary to use a planimeter or to plot the area on fine grid paper and simply count the squares. The average end area method usually overestimates the actual soils volume, favoring the contractor in earthwork cost estimates.

$$V = \frac{L(A_1 + A_2)}{2} \qquad 80.6$$

The precision obtained from the average end area method is generally sufficient unless one of the end areas is very small or zero. In that case, the volume should be computed as a pyramid or truncated pyramid.

$$V_{\text{pyramid}} = \frac{LA_{\text{base}}}{3} \qquad 80.7$$

4. PRISMOIDAL FORMULA METHOD

The *prismoidal formula* is preferred when the two end areas differ greatly or when the ground surface is irregular. It generally produces a smaller volume than the average end area method and thus favors the owner-developer in earthwork cost estimating.

The prismoidal formula uses the mean area, A_m, midway between the two end sections. In the absence of actual observed measurements, the dimensions of the middle area can be found by averaging the similar dimensions of the two end areas. The middle area is not found by averaging the two end areas.

$$V = \left(\frac{L}{6}\right)(A_1 + 4A_m + A_2) \qquad 80.8$$

When using the prismoidal formula, the volume is not found as LA_m, although that quantity is usually sufficiently accurate for estimating purposes.

5. MASS DIAGRAMS

A *profile diagram* is a cross section of the existing ground elevation along a route alignment. The elevation of the route is superimposed to identify the *grade points*, the points where the final grade coincides with the natural elevation.

A *mass diagram* is a record of the cumulative earthwork volume moved along an alignment, usually plotted below profile sections of the original ground and finished grade. The mass diagram can be used to establish a finished grade that balances cut-and-fill volumes and minimizes long hauls.

Distance in stations is plotted on the horizontal axis, and the cumulative sum of positive *excavation (cut) volumes* and negative *embankment (fill) volumes* is plotted on the vertical axis. The starting volume is arbitrarily chosen to keep the plotted volume positive.

A rising line on the mass diagram represents areas of excavation; a falling line represents areas of embankment. The local minima and maxima on the mass diagram identify the grade points. Vertical distances on a mass diagram represent volumes of material (areas on the profile diagram). Areas in a mass diagram represent the product of volume and distance.

A *balance line* is a horizontal line drawn between two adjacent *balance points* in a crest or sag area. The volumes of excavation and embankment between the balance points are equal. Thus, a contractor can plan on using the earth volume from the excavation on one side of the grade point for the embankment on the other side of the grade point. In Fig. 80.3, a balance line has been drawn that intersects the mass diagram at two points. These points represent the inclusive stations for which the cut-and-fill volumes are equal. That is, the cut soil (area B) can be used for the fill soil (area A).

When factors such as *shrinkage, swell, loss during transport*, and *subsidence* can be estimated, they are included in determining embankment volumes. A 5 to 15% excess is usually included in the figure. This is achieved by increasing all fill volumes by the necessary percentage.

The average *haul distance* is the separation of the centroids of the excavation and embankment areas on the profile diagram. This distance is usually determined for each section of earthwork rather than for the entire mass of earthwork in a project.

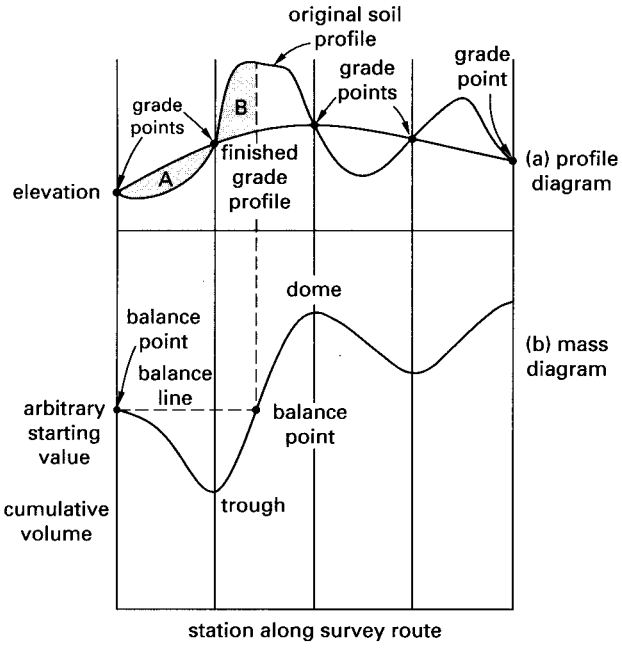

Figure 80.3 *Balance Line Between Two Points*

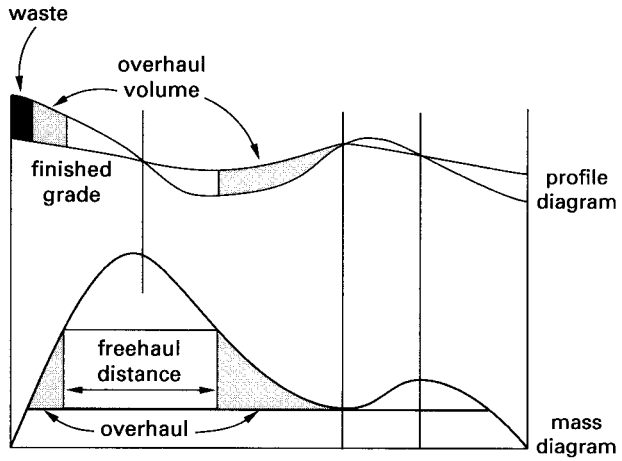

Figure 80.4 *Freehaul and Overhaul*

The average haul can also be calculated from the mass diagram. For customary U.S. usage, the curve area under a balance line represents the total haul in *yard-stations*, which is the number of cubic yards moved in 100 ft. This figure can be used by the contractor to determine hauling costs. The height of the curve, or the distance between the balance line and the minimum or maximum, represents the *solidity* or the volume of the total haul. The average haul distance is found by dividing the curve area by the curve height.

The *freehaul distance* is the maximum distance, as specified in the construction contract, that the contractor is expected to transport earth without receiving additional payment. Typically, the freehaul distance is between 500 and 1000 ft (150 to 300 m). Any soil transported more than the freehaul distance is known as *overhaul*.

Freehaul and overhaul can be determined from the mass diagram. The procedure begins by drawing a balance line equal in length to the freehaul distance. The enclosed area on the mass diagram represents material that will be hauled with no extra cost. The actual volume moved (the solidity) is the vertical distance between the balance line and the maximum or minimum.

The overhaul is found directly from the overhaul area on the mass diagram. It can also be calculated indirectly from the overhaul volume and overhaul distance. The overhaul volume is determined from the maximum height of the overhaul area on the mass diagram, or from the overhaul area on the profile diagram. The overhaul distance is found as the separation in overhaul centroids on the profile diagram.

6. STAKING

Surveying markers are referred to as *construction stakes, alignment stakes, offset stakes, grade stakes*, or *slope stakes*, depending on their purpose. Stakes come in different sizes, including $1 \times 2 \times 18$ markers, $^{5}/_{16} \times 1^{1}/_{2} \times 24$ *half-lath stakes*, and various lengths (usually 12 or 18 in) of 2×2 *hubs* and 1×1 *guineas*. (All measurements are in inches.) Fill stakes can be ripped diagonally lengthwise to give them a characteristic shape. Pin flags, full-length lagging, or colored paint may be used to provide further identification and visibility.

Distances are measured in feet or meters, with precisions depending on the nature of the feature being documented. A precision of 0.1 ft (30 mm) vertically and 0.5 ft (150 mm) horizontally is considered standard with earthwork (e.g., setting slope stakes). A precision of 0.01 ft (3 mm) is considered standard for locating curb and alignment stake positions and elevations so that the feature can be built to within 0.1 ft (30 mm). Bridges and buildings are located with higher precision.

7. STAKE MARKINGS

Stake markings vary greatly from agency to agency. The abbreviations shown in Table 80.1 and the procedures listed in this chapter are typical but not universal.

The front (the side facing the construction) and back are marked permanently using pencil, carpenter's crayon, or permanent ink markers. Stakes are read from top to bottom. The front of the stake is marked with *header information* (e.g., RPSS, offset distance) and *cluster information* (e.g., horizontal and vertical measurements, slope ratio). The header is separated from the first cluster by a double horizontal line. Multiple clusters are separated by single horizontal lines. All cluster information is measured in the same direction from the same point.

Table 80.1 *Common Stake Marking Abbreviations*

@	from the
1/4SR	quarter point of slope rounding
1/2SR	midpoint of slope rounding
ABUT	abutment
BC	begin curve
BCH	bench

JT	joint trench
L	length or left
L/2	midpoint
L/4	quarter point
LIP	lip
L/O	line only
LOL	lay-out line
LT	left
MC	middle of curve
MH	manhole
MP	midpoint
MSR	midpoint of slope rounding
OG	original ground
O/S	offset
PC	point of curvature
PCC	point of compound curve
PG	pavement grade or profile grade
PI	point of intersection
POC	point on curve
POL	point on line
POT	point on tangent
PP	power pole
PPP	pavement plane projected
PRC	point of reverse curvature
PT	point of tangency
PVC	point of vertical curvature
PVT	point of vertical tangency
QSR	quarterpoint of slope rounding
R	radius
RGS	rough grade stake
RT	right
RP	radius point or reference point
RPSS	reference point for slope stake
ROW	right of way
R/W	right of way
SD	storm drain
SE	superelevation
SHLD	shoulder
SHO	shoulder
SL	stationing line
SR	slope rounding
SS	sanitary sewer or slope stake
STA	station
STR	structure
SW	sidewalk
TBC	top back of curb
TBM	temporary benchmark
TC	toe of curb or top of curve
TOE	toe
TOP	top
TP	turning point
TW	traveled way
VP	vent pipe
WALL	wall
WL	water line
WM	water meter
WV	water valve
WW	wingwall

Compiled from various sources. Not intended to be exhaustive. Differences may exist from agency to agency.

Words like "from" and "to" are understood and are seldom written on a stake. For example, "2.0 FC" and "4.3 FG" mean "2.0 feet from the face of the curb" and "4.3 feet above the finished grade," respectively.

The back of a stake is used to record the station and other information, including literal descriptions (e.g., "at ramp"). Other information identifying the survey may also be included on the back. Actual elevations, when included, are marked on the thin edge of the stake. Figure 80.5 illustrates how a construction stake would be marked to identify a trench for a storm drain.

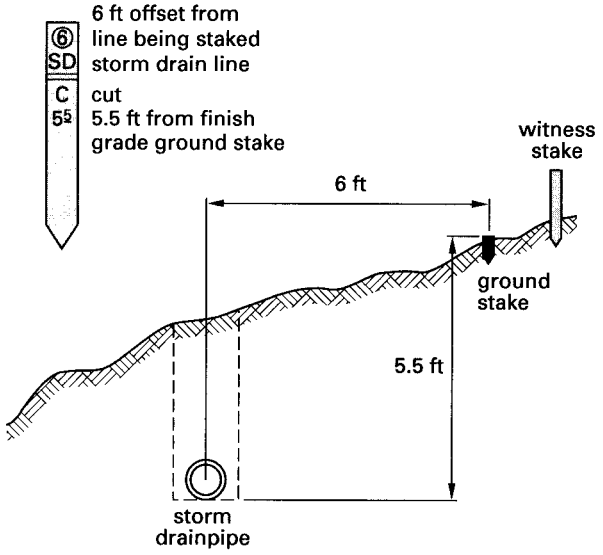

Figure 80.5 *Construction Stake for Storm Drain*

A stake both locates and identifies a specific point. A distance referenced on a stake is measured from the natural ground surface at the point where the stake is driven. Another system involves measuring from a tack or a reference mark on the stake itself. A *crow's foot*, which consists of a horizontal line drawn on the stake with a vertical arrow pointing to it, may be used. A crow's foot should be drawn on the edge of the stake.

Many times, measurements are taken from a *hub stake*, also referred to as a *ground stake* or *reference point stake*, which is driven flush with the ground. No markings are made on hub stakes, since such stakes are entirely below grade.

Hub stakes are located, identified, and protected by witness stakes or guard stakes. A *witness stake* calls attention to a hub stake but does not itself locate a specific point. A *guard stake* may be driven at an angle with its top over the flush-driven hub stake.

Alignment stakes marked with the station indicate centerline alignment along a proposed roadway. They are placed every half, whole, or even-numbered station along tangents with uniform grade, and at every quarter or half station along horizontal and vertical curve alignments.

Offset stakes are used to mark excavations. Offset stakes are offset from the actual edge to protect the stakes from earthmoving and other construction equipment. The offset distance is circled on the stake and is separated from the subsequent data by a double line. For close-in work, the offset distance may be standardized (e.g., 2 ft). For highway work, offset stakes can be set at 25, 50, or 100 ft from the alignment centerline. Unless a separate ground stake or hub is used, distances (e.g. cuts, fills, and distances to centerline) marked on an offset stake refer to the point of insertion, not to the imaginary point located the offset distance away.

Slope stakes indicate *grade points*—points where the cuts and fills begin and the planned side slopes intersect the natural ground surface. Slope stakes are marked "SS" to indicate their purpose. Typically, they are placed with a 10 ft (3 m) offset. Figure 80.6 illustrates the use of slope stakes along three adjacent sections of a proposed highway.

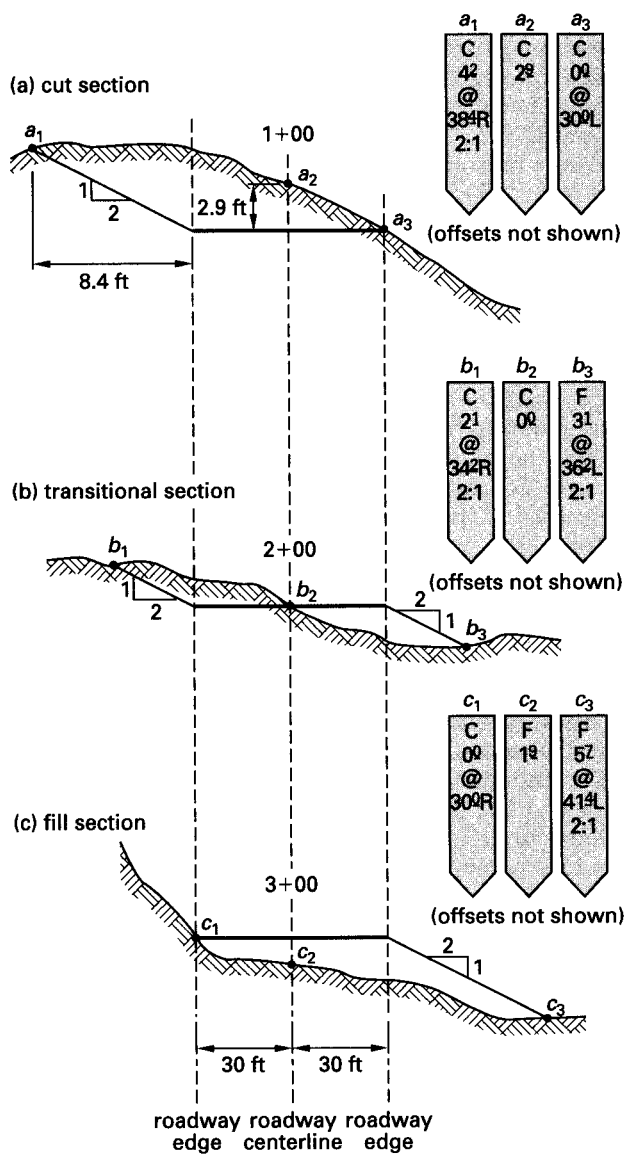
In addition to indicating the grade point, the front of slope stakes are marked to indicate the nature of the earthwork (i.e., "C" for "cut" and "F" for "fill"), the offset distance, the type of line being staked, the distance from the centerline or control line, the slope to finished grade, and the elevation difference between the grade point and the finished grade. Distances from the centerline can be marked "L" or "R" to indicate whether the stake points are to the left or the right of centerline when looking up-station. The station is marked on the stake back.

For example, a stake's front face markings "C 4.2 FG @ 38.4L CL 2:1" would be interpreted as "cut with 2:1 slope is required; stake set point is 4.2 ft above the finished grade; stake is 38.4 ft to the left of the centerline of the roadway." The use of FG is optional.

Slope stakes can be driven vertically or at an angle, depending on convention. When driven at an angle, slope stakes slant outward, pointing away from the earthwork, when fill is required; and they slope inward, toward the earthwork, when a cut is required. Stakes are set with the front face toward the construction.

Hubs and other ground stakes without offsets are not used with fill stakes, since they would be covered during construction. For shallow and moderate fills, a fill stake alone is used. A crow's foot may be marked on the stake to indicate the approximate finished grade, or the top of the stake may be set to coincide with the approximate finished grade. For deeper fills, offset stakes are required.

Not all earthwork produces a straight slope. Some earthwork results in a smooth-curved ground surface between two lateral points. The points where the grading begins and ends are marked "BSR" (*begin slope rounding*) and "ESR" (*end slope rounding*), rather than the analogous grade point.



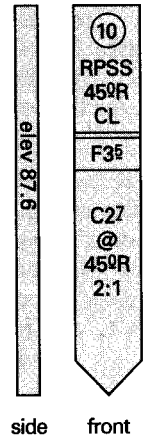


Figure 80.6 *Slope Stakes Along a Highway*

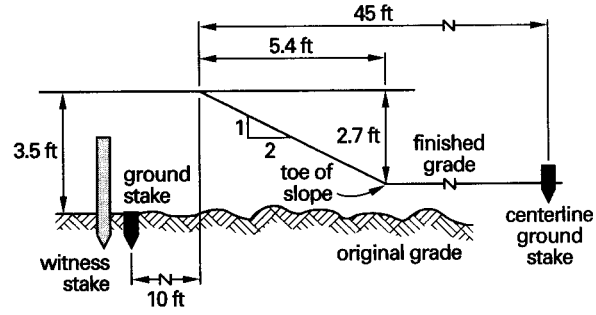
A line of stakes at adjacent grade or ESR points is known as a *daylight line*. Therefore, the term *daylight stake* can be used when referring to the stakes marking the grade or ESR points.

Example 80.1

While checking the work of a surveying crew along a highway, you encounter the ground stake and its accompanying witness stake as shown. What is the elevation at the toe of the slope documented by the witness stake?



Solution

The witness stake indicates that the ground stake is a reference point slope stake located 45.0 ft to the right of centerline when looking up-station. The elevation of the ground stake, marked on the side of the witness stake, is 87.6 ft. The earthwork starts out with a 3.5 ft fill. Then, the earth is cut away at a 2:1 slope until the finished grade is reached, 2.7 ft below.

The elevation at the toe of the slope is the same as the elevation of the finished grade.

$$\begin{aligned}\text{elev}_{\text{slope toe}} &= \text{elev}_{\text{ground stake}} + \text{fill} - \text{cut} \\ &= 87.6\text{ ft} + 3.5\text{ ft} - 2.7\text{ ft} = 88.4\text{ ft}\end{aligned}$$

8. ESTABLISHING SLOPE STAKE MARKINGS

The markings on a construction stake are determined from a survey of the natural ground surface. This survey requires two individuals: one, the *leveler* or *instrument person*, to work the instrument, and the other, the *rod person*, to hold the leveling rod. The elevation of the instrument (or the elevation of the ground at the instrument location) and the height of the instrument above the ground must be known if actual elevations are

to be marked on a stake. The term "height of the instrument" (HI) is the elevation of the instrument above the reference datum.

$$\begin{aligned}\text{HI} &= \text{elev}_{\text{ground}} + \begin{matrix}\text{instrument height}\\ \text{above the ground}\end{matrix}\\ &= \text{elev}_{\text{ground}} + \text{ground rod}\end{aligned} \qquad 80.9$$

The *rod reading*, or *ground rod*, is the sighting made through a leveling instrument at the rod held vertically at the grade point. The *grade rod*, short for *grade rod reading* and *rod reading for grade*, is the reading that would be observed on an imaginary rod held on the finished grade elevation. The grade rod is calculated from the planned grade elevation and the height of the instrument.

$$\text{grade rod} = \text{HI} - \text{elev}_{\text{grade}} \qquad 80.10$$

The distance, h, marked on a construction stake, or the cut or fill, is the distance between natural and finished grade elevations and is easily calculated from the ground and grade rods. The cut or fill stake marking is the difference between grade and ground rod elevations. The actual steps taken to calculate the stake marking depend on whether the earthwork is a cut or a fill and whether the instrument is above or below the finished grade. Drawing a diagram will clarify the algebraic steps and prevent sign errors.

$$h = \text{grade rod} - \text{ground rod} \qquad 80.11$$

The distance from grade point to centerline or other control is also written on the stake. If w is the width of the finished surface, s is the side slope ratio (as horizontal:vertical), and h is the cut or fill at the grade point, then the horizontal distance, d, from the grade point to the centerline stake of the finished surface is calculated using Eq. 80.12. In the field, the stake location is found by trial and error.

$$d = \frac{w}{2} + hs \qquad 80.12$$

1. DEFINITIONS

activity: any subdivision of a project whose execution requires time and other resources.

critical path: a path connecting all activities that have minimum or zero slack times. The critical path is the longest path through the network.

duration: the time required to perform an activity. All durations are *normal durations* unless otherwise referred to as *crash durations*.

event: the beginning or completion of an activity.

event time: actual time at which an event occurs.

float: same as slack time.

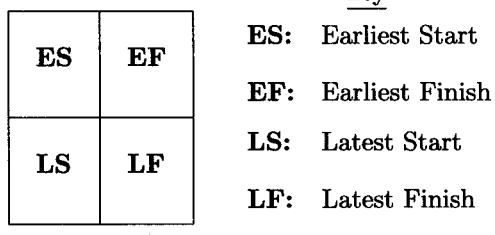
slack time: the minimum time that an activity can be delayed without causing the project to fall behind schedule. Slack time is always minimum or zero along the critical path.

2. INTRODUCTION

Critical path techniques are used to graphically represent the multiple relationships between stages in a complicated project. The graphical network shows the *precedence relationships* between the various activities.

The graphical network can be used to control and monitor the progress, cost, and resources of a project. A critical path technique will also identify the most critical activities in the project.

Critical path techniques use *directed graphs* to represent a project. These graphs are made up of *arcs* (arrows) and *nodes* (junctions). The placement of the arcs and nodes completely specifies the precedences of the project. Durations and precedences are usually given in a *precedence table (matrix)*.



3. ACTIVITY-ON-NODE NETWORKS: THE CRITICAL PATH METHOD

One technique is known as the *critical path method*, CPM. This deterministic method is applicable when all activity durations are known in advance. CPM is usually represented as an *activity-on-node* model since arcs are used to specify precedence and the nodes actually represent the activities. Events are not represented on the graph, other than as the heads and tails of the arcs. Two *dummy nodes* taking zero time may be used to specify the start and finish of the project.

4. SOLVING A CPM PROBLEM

The solution to a critical path method problem reveals the earliest and latest times that an activity can be started and finished. It also identifies the *critical path* and generates the *slack times* for each activity.

The following procedure may be used to solve a CPM problem. To facilitate the solution, each node should be replaced by a square that has been quartered. The compartments have the meanings indicated by the key.

step 1: Place the project start time or date in the **ES** and **EF** positions of the start activity. The start time is zero for relative calculations.

step 2: Consider any unmarked activity, all of whose predecessors have been marked in the **EF** and **ES** positions. (Go to step 4 if there are none.) Mark in its **ES** position the largest number marked in the **EF** position of those predecessors.

step 3: Add the activity time to the **ES** time and write this in the **EF** box. Go to step 2.

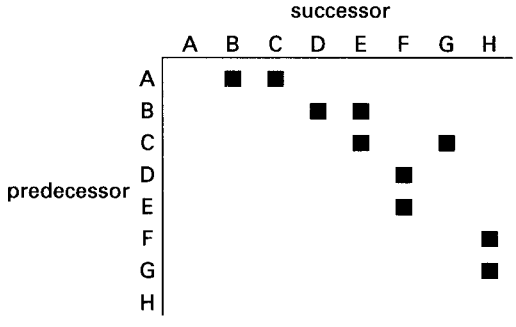
step 4: Place the value of the latest finish date in the **LS** and **LF** boxes of the finish mode.

step 5: Consider unmarked predecessors whose successors have all been marked. Their **LF** is the smallest **LS** of the successors. Go to step 7 if there are no unmarked predecessors.

step 6: The **LS** for the new node is **LF** minus its activity time. Go to step 5.

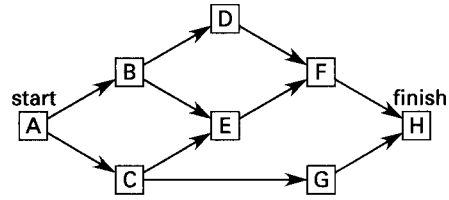
step 7: The slack time for each node is **LS**−**ES** or **LF**−**EF**.

step 8: The critical path encompasses nodes for which the slack time equals **LS**−**ES** from the start node. There may be more than one critical path.



Example 81.1

Using the precedence table given, construct the precedence matrix and draw an activity-on-node network.

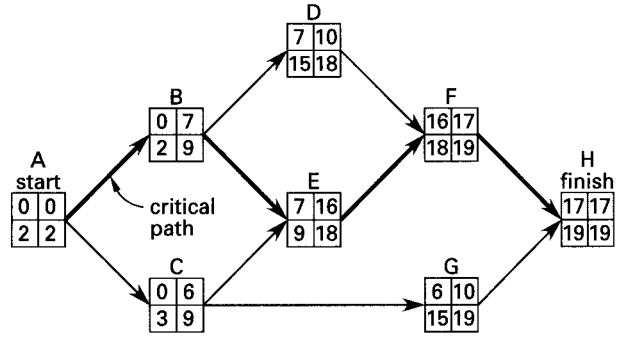


activity	duration (days)	predecessors
A, start	0	–
B	7	A
C	6	A
D	3	B
E	9	B,C
F	1	D,E
G	4	C
H, finish	0	F,G

Solution

The precedence matrix is

The activity-on-node network is



Example 81.2

Complete the network for the previous example and find the critical path. Assume the desired completion date is in 19 days.

Solution

The critical path is shown with darker lines.

5. ACTIVITY-ON-BRANCH NETWORKS

In an *activity-on-branch* network, the arcs represent the activities, which are labeled with letters of the alphabet, and the nodes represent events, which are numbered. The activity durations may appear in parentheses near the activity letter.

The activity-on-branch method is complicated by the frequent requirement for *dummy activities* and nodes to maintain precedence. Consider the following part of a precedence table.

activity	predecessors
L	–
M	–
N	L,M
P	M

Note that activity P depends on the completion of only M. Figure 81.1(a) is an activity-on-branch representation of this precedence. However, N depends on the completion of both L and M. It would be incorrect to draw the network as Fig. 81.1(b) since the activity N appears twice. To represent the project, the dummy activity X must be used, as shown in Fig. 81.1(c).

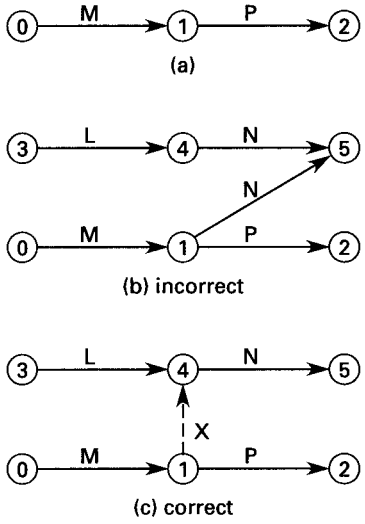


Figure 81.1 *Activity-on-Branch Networks*

If two activities have the same starting and ending events, a dummy node is required to give one activity a uniquely identifiable completion event. This is illustrated in Fig. 81.2(b).

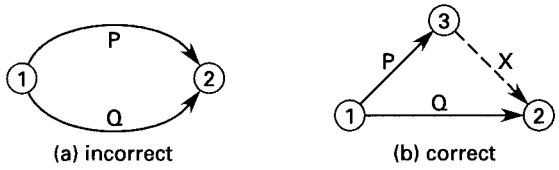

Figure 81.2 *Use of a Dummy Node*

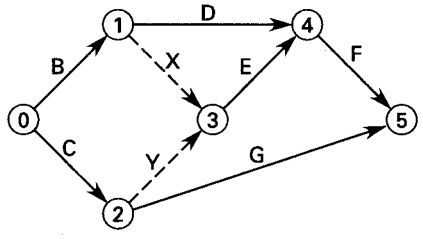

The solution method for an activity-on-branch problem is essentially the same as for the activity-on-node problem, requiring forward and reverse passes to determine earliest and latest dates.

Example 81.3

Represent the project in Ex. 81.1 as an activity-on-branch network.

Solution

event	event description
0	start project
1	finish B, start D
2	finish C, start G
3	finish B and C, start E
4	finish D and E, start F
5	finish F and G

6. STOCHASTIC CRITICAL PATH MODELS

Stochastic models differ from deterministic models only in the way in which the activity durations are found. Whereas durations are known explicitly for the deterministic model, the time for a stochastic activity is distributed as a random variable.

This stochastic nature complicates the problem greatly since the actual distribution is often unknown. Such problems are solved as a deterministic model using the mean of an assumed duration distribution as the activity duration.

The most common stochastic critical path model is PERT, which stands for *program evaluation and review technique*. In PERT, all duration variables are assumed to come from a *beta distribution*, with mean and standard deviation given by Eqs. 81.1 and 81.2, respectively.

$$\mu = \tfrac{1}{6}(t_{\text{minimum}} + 4t_{\text{most likely}} + t_{\text{maximum}}) \qquad 81.1$$

$$\sigma = \tfrac{1}{6}(t_{\text{maximum}} - t_{\text{minimum}}) \qquad 81.2$$

The project *completion time* for large projects is assumed to be normally distributed with mean equal to the critical path length and with overall variance equal to the sum of the variances along the critical path.

The probability that a project duration will exceed some length (D) can be found from Eq. 81.3. z is the standard normal variable.

$$p\{\text{duration} > D\} = p\{t > z\} \qquad 81.3$$

$$z = \frac{D - \mu_{\text{critical path}}}{\sigma_{\text{critical path}}} \qquad 81.4$$

Example 81.4

The mean times and variances for activities along a PERT critical path are given. What is the probability that the project's completion time will be (a) less than 14 days, (b) more than 14 days, (c) more than 23 days, and (d) between 14 and 23 days?

activity mean time (days)	activity standard deviation (days)
9	1.3
4	0.5
7	2.6

Solution

The most likely completion time is the sum of the mean activity times.

$$\begin{aligned}\mu_{\text{critical path}} &= 9 \text{ days} + 4 \text{ days} + 7 \text{ days} \\ &= 20 \text{ days}\end{aligned}$$

The variance of the project's completion times is the sum of the variances along the critical path. Variance, σ^2, is the square of the standard deviation, σ.

$$\begin{aligned}(\sigma_{\text{critical path}})^2 &= (1.3 \text{ days})^2 + (0.5 \text{ days})^2 \\ &\quad + (2.6 \text{ days})^2 \\ &= 8.7 \text{ days}^2 \\ \sigma_{\text{critical path}} &= \sqrt{8.7 \text{ days}^2} \\ &= 2.95 \text{ days} \quad \text{[use 3 days]}\end{aligned}$$

The standard normal variable corresponding to 14 days is given by Eq. 81.4.

$$\begin{aligned}z &= \frac{D - \mu_{\text{critical path}}}{\sigma_{\text{critical path}}} \\ &= \frac{14 \text{ days} - 20 \text{ days}}{3 \text{ days}} = -2.0\end{aligned}$$

The area under the standard normal curve is 0.4772 for $0.0 < z < -2.0$. Since the normal curve is symmetrical, the negative sign is irrelevant in determining the area.

The standard normal variable corresponding to 23 days is given by Eq. 81.4.

$$\begin{aligned}z &= \frac{D - \mu_{\text{critical path}}}{\sigma_{\text{critical path}}} \\ &= \frac{23 \text{ days} - 20 \text{ days}}{3 \text{ days}} = 1.0\end{aligned}$$

The area under the standard normal curve is 0.3413 for $0.0 < z < 1.0$.

(a) $p\{\text{duration} < 14\} = p\{z < -2.0\} = 0.5 - 0.4772$
$= 0.0228\ (2.28\%)$

(b) $p\{\text{duration} > 14\} = p\{z > -2.0\} = 0.4772 + 0.5$
$= 0.9772\ (97.72\%)$

(c) $p\{\text{duration} > 23\} = p\{z > 1.0\} = 0.5 - 0.3413$
$= 0.1587\ (15.87\%)$

(d) $p\{14 < \text{duration} < 23\} = p\{-2.0 < z < 1.0\}$
$= 0.4772 + 0.3413$
$= 0.8185\ (81.85\%)$

PRACTICE PROBLEMS

1. The activities that constitute a project are listed. The project starts at $t = 0$. (a) Draw the critical path network. (b) Indicate the critical path. (c) What is the earliest finish? (d) What is the latest finish? (e) What is the slack along the critical path? (f) What is the float along the critical path?

activity	predecessors	successors	duration
start	–	A	0
A	start	B,C,D	7
B	A	G	6
C	A	E,F	5
D	A	G	2
E	C	H	13
F	C	H,I	4
G	D,B	I	18
H	E,F	finish	7
I	F,G	finish	5
finish	H,I	–	0

Answers: (b) A-B-G-I; (c) 36; (d) 36; (e) 0; (f) 0

2. PERT activities constituting a short project are listed with their characteristic completion times. If the project starts at $t = 15$, what is the probability that the project will be completed on or before $t = 42$?

activity	predecessors	successors	t_{min}	t_{likely}	t_{max}
start	–	A	0	0	0
A	start	B,D	1	2	5
B	A	C	7	9	20
C	B	D	5	12	18
D	A,C	finish	2	4	7
finish	D	–	0	0	0

Answer: 28.6%

3. Listed is a set of activities and sequence requirements to start a warehouse construction project. Prepare a CPM project diagram.

activity	letter code	code of immediate predecessor
move-in	A	
job layout	B	A
excavations	C	B
make-up forms	D	A
shop drawing, order rebar	E	A
erect forms	F	C,D
rough in plumbing	G	F
install rebar	H	E,F
pour, finish concrete	I	G,H

4. Activities constituting a bridge construction project are listed. (a) Draw the CPM network showing the critical path. (b) Compute ES, EF, LS, and LF for each of the activities. Assume a target time for completing the project that, for the bridge, is 3 days after the EF time.

job number		immediate predecessors	time (days)
a	start		0
b		a	4
c		b	2
d		c	4
e		d	6
f		c	1
g		f	2
h		f	3
i		d	2
j		d,g	4
k		i,j,h	10
l		k	3
m		l	1
n		l	2
o		l	3
p		e	2
q		p	1
r		c	1
s		o,t	2
t		m,n	3
u		t	1
v		q,r	2
w		v	5
x	finish	s,u,w	0

5. Prepare a PERT diagram for the activities and sequence requirements given in Prob. 4.

6. Listed is a set of activities, sequence requirements, and estimated activity times required for the renewal of a pipeline.

(a) Prepare a PERT project diagram.

activity	letter code	code of immediate predecessor	activity time requirement (days)
assemble crew for job	A		10
use old line to build inventory	B	D	28
measure and sketch old line	C	A	2
develop materials list	D	C	1
erect scaffold	E	D	2
procure pipe	F	D	30
procure valves	G	D	45
deactivate old line	H	B	1
remove old line	I	E,H	6
prefabricate new pipe	J	F	5
place valves	K	I,G	1
place new pipe	L	I,J	6
weld pipe	M	L	2
connect valves	N	K,M	1
insulate	O	N	4
pressure test	P	K	1
remove scaffold	Q	O,P	1
clean up and turn over to operating crew	R	O,Q	1

(b) There is additional information in the form of optimistic, most likely, and pessimistic time estimates for the project. Compute the expected mean time, t_m, and the variance, σ^2, for the activities. Which activities have the greatest uncertainty in their completion schedules?

activity code	optimistic time ($t_{\min}$)	most likely time (t_{ml})	pessimistic time ($t_{\max}$)
A	8	10	12
B	26	26.5	36
C	1	2	3
D	0.5	1	1.5
E	1.5	1.63	4
F	28	28	40
G	40	42.5	60
H	1	1	1
I	4	6	8
J	4	4.5	8
K	0.5	0.9	2
L	5	5.25	10
M	1	2	3
N	0.5	1	1.5
O	3	3.75	6
P	1	1	1
Q	1	1	1
R	1	1	1

(c) Suppose that, due to penalties in the contract, each day the pipeline renewal project can be shortened is worth $100. Which of the following possibilities would you follow and why?

- Shorten t_{m} of activity B by 4 days at a cost of $100.
- Shorten t_{ml} of activity G by 5 days at a cost of $50.
- Shorten t_{m} of activity O by 2 days at a cost of $150.
- Shorten t_{m} of activity O by 2 days by drawing resources from activity N, thereby lengthening its t_e by 2 days.

82 Construction and Jobsite Safety

1. Introduction 82-1
2. Trenching and Excavation 82-1
3. Chemical Hazards 82-1
4. Confined Spaces and Hazardous Atmospheres 82-2
5. Power Line Hazards 82-2
6. Fall and Impact Protection 82-2
7. Noise 82-2

1. INTRODUCTION

Common sense can go a long way in preventing many jobsite accidents. However, scheduling, economics, lack of concern, carelessness, and laxity are often more likely to guide actions than common sense. For that reason, the "science" of accident prevention is highly regulated. Workers' safety is regulated by the federal Occupational Safety and Health Act (OSHA). State divisions (e.g., Cal-OSHA) are charged with enforcing federal and state safety regulations in the United States. Other countries may have more restrictive standards.

All of the federal OSHA regulations are published in the Congressional Federal Register (CFR). The two main categories of standards are the "1910 standards," which apply to general industry, and the "1926 standards," which apply to the construction industry.

This chapter covers only a minuscule portion of the standards and safety issues facing civil engineers and construction workers. Only the briefest descriptions of these complex issues and the regulations that govern them are provided.

2. TRENCHING AND EXCAVATION

Soils are classified as stable rock and types A, B, or C, with type C being the most unstable. Type A soils are cohesive soils with unconfined compressive strengths of 1.5 tons per square foot (tsf) (144 kPa) or greater. Type B soils are cohesive soils with compressive strengths of 0.5 to 1.5 tsf (48 to 144 kPa) and some granular soils. Type C soils are cohesive soils with compressive strengths less than 0.5 tsf (48 to 144 kPa), and some granular soils. Soils classified as types A and B may need to be reclassified as type C following rain and flooding [OSHA 1926.652 App. A to Subpart P].

Except for excavations entirely in stable rock, excavations deeper than 5 ft (1.5 m) in all types of earth must be protected from cave-in and collapse [OSHA 1926.652]. Excavations less than 5 ft (1.5 m) deep are usually exempt but may also need to be protected when inspection indicates that hazardous ground movement is possible.

Timber and aluminum shoring (hydraulic, pneumatic, and screw-jacked) and trench shields that meet the requirements of OSHA 1926.652 App. C to Subpart P may be used in excavations up to 20 ft deep.

Sloping and benching the trench walls may be substituted for shoring. For long-term use, the maximum allowable slope (H:V) for type A soils is $^3/_4$:1 (53° from the horizontal). For type B soils, it is 1:1 (45°). For type C soils, it is $1^1/_2$:1 (34°). These slopes shall be reduced 50% if the soil shows signs of distress. Sloped walls in excavations deeper than 20 ft (6 m) must be designed by a professional engineer. Greater slopes are permitted for short-term usage in excavations less than 12 ft (3.67 m) deep.

In trenches 4 ft (1.2 m) deep or more, ladders, stairways, or ramps are required with a maximum lateral spacing of 25 ft (7.5 m) [OSHA 1926.651(b)(2)].

Spoils and other equipment that could fall into a trench or excavation must be kept at least 2 ft from the edge of a trench unless secured in some other fashion [OSHA 1926.651(l)].

3. CHEMICAL HAZARDS

OSHA's Hazard Communication Standard [OSHA 1910.1200] requires that the dangers of all chemicals purchased, used, or manufactured be known to employees. The hazards are communicated in a variety of ways, including labeling containers, training employees, and providing ready access to *material safety data sheets* (MSDSs).

OSHA has suggested a nonmandatory standard form for the MSDS, but other forms are acceptable as long as they contain the same (or more) information. The information contained on an MSDS consists of following categories.

Chemical identity: the identity of the substance as it appears on the label.

Section I: Manufacturer's name and contact information: manufacturer's name, address, telephone number, and emergency phone number; date the

MSDS was prepared; and an optional signature of the preparer.

Section II: Hazardous ingredients/identity information: a list of the hazardous components by chemical identity and other common names; OSHA *permissible exposure limit* (PEL), ACGIH *threshold level value* (TLV), and other recommended exposure limits; percentage listings of the hazardous components is optional.

Section III: Physical/chemical characteristics: boiling point, vapor pressure, vapor density, specific gravity, melting point, evaporation rate, solubility in water, physical appearance, and odor.

Section IV: Fire and explosion hazard data: flash point (and method used to determine it), flammability limits, extinguishing media, special fire-fighting procedures, and unusual fire and explosion hazards.

Section V: Reactivity data: stability, conditions to avoid, incompatibility (materials to avoid), hazardous decomposition or by-products, and hazardous polymerization (and conditions to avoid).

Section VI: Health hazard data: routes of entry into the body (inhalation, skin, ingestion), health hazards (acute = immediate, or chronic = builds up over time), carcinogenicity (NTP, IARC monographs, OSHA regulated), signs and symptoms of exposure, medical conditions generally aggravated by exposure, and emergency and first-aid procedures.

Section VII: Precautions for safe handling and use: steps to be taken in case the material is released or spilled, waste disposal method, precautions to be taken in handling or storage, and other precautions.

Section VIII: Control measures: respiratory protection (type to be specified), ventilation (local, mechanical exhaust, special, or other), protective gloves, eye protection, other protective clothing or equipment, and work/hygienic practices.

Section IX: Special precautions and comments: safe storage and handling, types of labels or markings for containers, and Department of Transportation (DOT) policies for handling the material.

4. CONFINED SPACES AND HAZARDOUS ATMOSPHERES

Employees entering confined spaces (e.g., excavations, sewers, tanks) must be properly trained, supervised, and equipped. Atmospheres in confined spaces must be monitored for oxygen content and other harmful contaminants. Oxygen content must be maintained at 19.5% or higher unless a breathing apparatus is provided. Employees entering deep confined excavations must wear harnesses with lifelines [OSHA 1926.651].

5. POWER LINE HAZARDS

Employees operating cranes or other overhead material-handling equipment (e.g., concrete boom trucks, backhoe arms, and raised dumptruck boxes) must be aware of the possibility of inadvertent power line contact. Prior to operation, the site must be thoroughly inspected for the danger of power line contact. OSHA provides specific minimum requirements for safe operating distances. For example, for lines of 50 kV or less, all parts of the equipment must be kept at least 10 ft (3 m) from the power line [OSHA 1926.550(a)(15)]. A good rule of thumb for higher voltages is a clearance of 35 ft (10.5 m). However, the exact OSHA clearance requirement can be calculated from Eq. 82.1.

$$\text{line clearance} = 3\text{ m} + (10.2\text{ mm})(\#\text{kV over 50 kV}) \quad \text{[SI]} \quad 82.1(a)$$

$$\text{line clearance} = 10\text{ ft} + (0.4\text{ in})(\#\text{kV over 50 kV}) \quad \text{[U.S.]} \quad 82.1(b)$$

6. FALL AND IMPACT PROTECTION

Fall protection can take the form of barricades, walkways, bridges (with guardrails), nets, and fall-arrest systems. Personal fall-arrest systems include lifelines, lanyards, and deceleration devices. Such equipment is attached to an anchorage at one end and to the body-belt or body hardness at the other. All equipment is to be properly used, certified, and maintained. Employees are to be properly trained in the equipment's use and operation.

Employees must be protected from impalement hazards from exposed rebar [OSHA 1926.701(b)]. A widely used method for covering rebar ends has been plastic *mushroom caps*, often orange or yellow in color. However, OSHA no longer considers plastic caps adequate for anything more than scratch protection. Commercially available steel-reinforced caps and wooden troughs capable of withstanding a 250 lbm/10 ft drop test without breakthrough can still be used.

Head protection, usually in the form of a helmet (*hard-hat*), is part of a worker's *personal protective equipment* (PPE). Head protection is required where there is a danger of head injuries from impact, flying or falling objects, electrical shock, or burns [OSHA 1910.132(a) and (c)]. Head protection should be nonconductive when there is electrical or thermal danger [OSHA 1910.335(a)(1)(iv)].

7. NOISE

OSHA sets maximum limits on daily sound exposure. The "all-day" 8 hr noise level limit is 90 dBA. This is higher than the maximum level permitted in other countries (e.g., 85 dBA in Germany and Japan). In the

United States, employees may not be exposed to steady sound levels above 115 dBA, regardless of the duration. Impact sound levels are limited to 140 dBA.

Hearing protection, educational programs, periodic examinations, and other actions are required for workers whose 8 hr exposure is more than 85 dBA or whose noise dose exceeds 50% of the *action levels*.

Table 82.1 *Typical Permissible Noise Exposure Levels*[a]

sound level (dBA)	exposure (hr/day)
90	8
92	6
95	4
97	3
100	2
102	$1\frac{1}{2}$
105	1
110	$\frac{1}{2}$
115	$\frac{1}{4}$ or less

1. ELECTRIC CHARGE

The charge on an electron is one *electrostatic unit* (esu). Since an esu is very small, electrostatic charges are more conveniently measured in *coulombs* (C). One coulomb is approximately 6.24×10^{18} esu. Another unit of charge, the *faraday*, is sometimes encountered in the description of ionic and plating processes. One faraday is equal to one mole of electrons, approximately 96,500 C.

2. CURRENT

Current, I, is the movement of electrons. By historical convention, current moves in a direction opposite to the flow of electrons (i.e., current flows from the positive terminal to the negative terminal). Current is measured in *amperes* (A) and is the time rate change in charge.

$$I = \frac{dQ}{dt} \qquad 83.1$$

3. VOLTAGE SOURCES

A net *voltage*, V, causes electrons to move, hence the common synonym *electromotive force* (emf).[1] With *direct-current* (DC) voltage sources, the voltage may vary in amplitude, but not in polarity. In simple problems where a battery serves as the voltage source, the magnitude is also constant.

With *alternating-current* (AC) voltage sources, the magnitude and polarity both vary with time. Due to the method of generating electrical energy, AC voltages are typically sinusoidal.

4. RESISTIVITY AND RESISTANCE

Resistance is the property of a *resistor* or resistive circuit to impede current flow.[2] A circuit with zero resistance is a *short circuit*, whereas an *open circuit* has infinite resistance. Adjustable resistors are known as *potentiometers* and *rheostats*.

Resistance of a circuit element depends on the *resistivity*, ρ (in Ω-in or Ω·cm), of the material and the geometry of the current path through the element. The area, A, of circular conductors is often measured in *circular mils*, abbreviated *cmils*, the area of a 0.001 in diameter circle.

$$R = \frac{\rho l}{A} \qquad 83.2$$

$$A_{\text{cmils}} = \left(\frac{d_{\text{in}}}{0.001}\right)^2 \qquad 83.3$$

$$A_{\text{in}^2} = (7.854 \times 10^{-7})(A_{\text{cmils}}) \qquad 83.4$$

Resistivity depends on temperature. For most conductors, resistivity increases linearly with temperature. The resistivity of standard *IACS (International Annealed Copper Standard)* copper wire at 20°C is approximately

$$\begin{aligned} \rho_{\text{IACS Cu,20°C}} &= 1.7241 \times 10^{-6}\ \Omega\text{·cm} \\ &= 0.67879 \times 10^{-6}\ \Omega\text{-in} \\ &= 10.371\ \Omega\text{-cmil/ft} \end{aligned} \qquad 83.5$$

Example 83.1

What is the resistance of a parallelepiped (1 cm × 1 cm × 1 m long) of IACS copper if current flows between the two smaller faces?

Solution

From Eqs. 83.2 and 83.5, the resistance is

$$\begin{aligned} R = \frac{\rho l}{A} &= \frac{(1.7241 \times 10^{-6}\ \Omega\text{·cm})(1\text{ m})\left(100\ \frac{\text{cm}}{\text{m}}\right)}{(1\text{ cm})(1\text{ cm})} \\ &= 1.724 \times 10^{-4}\ \Omega \end{aligned}$$

5. CONDUCTIVITY AND CONDUCTANCE

The reciprocals of resistivity and resistance are *conductivity* (σ) and *conductance* (G), respectively. The unit of conductance is the *siemens* (S).[3]

$$\sigma = \frac{1}{\rho} \qquad 83.6$$

$$G = \frac{1}{R} \qquad 83.7$$

Percent conductivity is the ratio of a substance's conductivity to the conductivity of standard IACS copper. (See Sec. 4.)

$$\begin{aligned} \%\text{ conductivity} &= \frac{\sigma}{\sigma_{\text{Cu}}} \times 100\% \\ &= \frac{\rho_{\text{Cu}}}{\rho} \times 100\% \end{aligned} \qquad 83.8$$

[1] The symbol E (derived from the name electromotive force) has been commonly used to represent voltage induced by electromagnetic induction.

[2] *Resistance* is not the same as *inductance* (Sec. 20), which is the property of a device to impede a *change* in current flow.

[3] The siemens is the inverse of an ohm and is the same as the obsolete unit, the *mho*.

6. OHM'S LAW

The *voltage drop*, also known as the *IR drop*, across a circuit or circuit element with resistance R is given by *Ohm's law*.[4]

$$V = IR \quad \text{[DC circuits]} \qquad 83.9$$

$$v(t) = i(t)R \quad \text{[AC circuits]} \qquad 83.10$$

7. POWER IN DC CIRCUITS

The *power*, P (in watts), dissipated across two terminals with resistance R and voltage drop V is given by *Joule's law*, Eq. 83.11.

$$P = IV = I^2R = \frac{V^2}{R} = V^2G \quad \text{[DC circuits]} \qquad 83.11$$

$$P(t) = i(t)v(t) = i(t)^2R = \frac{v(t)^2}{R} = v(t)^2G \quad \text{[AC circuits]} \qquad 83.12$$

8. ELECTRICAL CIRCUIT SYMBOLS

Figure 83.1 illustrates symbols typically used to diagram electrical circuits in this book.

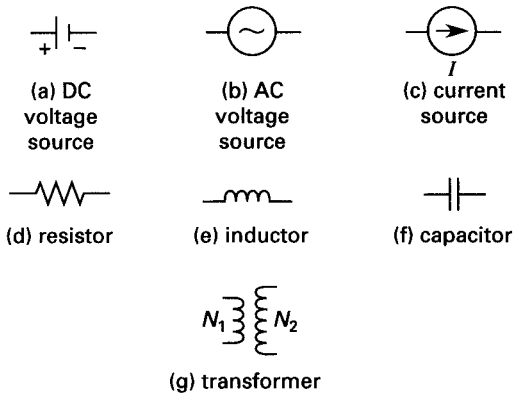

Figure 83.1 *Symbols for Electrical Circuit Elements*

9. RESISTORS IN COMBINATION

Resistors in series are added to obtain the total (equivalent) resistance of a circuit.

$$R_e = R_1 + R_2 + R_3 + \cdots \quad \text{[series]} \qquad 83.13$$

Resistors in parallel are combined by adding their reciprocals. This is a direct result of the fact that conductances in parallel add.

$$G_e = G_1 + G_2 + G_3 + \cdots \quad \text{[parallel]} \qquad 83.14$$

$$\frac{1}{R_e} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots \quad \text{[parallel]} \qquad 83.15$$

[4]This book uses the convention that uppercase letters represent fixed, maximum, or effective values, and lowercase letters represent values that change with time.

For two resistors in parallel, the equivalent resistance is

$$R_e = \frac{R_1R_2}{R_1 + R_2} \quad \text{[two parallel resistors]} \qquad 83.16$$

10. SIMPLE SERIES CIRCUITS

Figure 83.2 illustrates a simple series DC circuit and its equivalent circuit.

- The current is the same through all circuit elements.

$$I = I_{R_1} = I_{R_2} = I_{R_3} \qquad 83.17$$

- The equivalent resistance is the sum of the individual resistances.

$$R_e = R_1 + R_2 + R_3 \qquad 83.18$$

- The equivalent applied voltage is the sum of all voltage sources (polarities considered).

$$V_e = \pm V_1 \pm V_2 \qquad 83.19$$

- The sum of all of the voltage drops across the components in the circuit (a *loop*) is equal to the equivalent applied voltage. This fact is known as *Kirchhoff's voltage law*.

$$V_e = \Sigma IR_j = I\Sigma R_j = IR_e \qquad 83.20$$

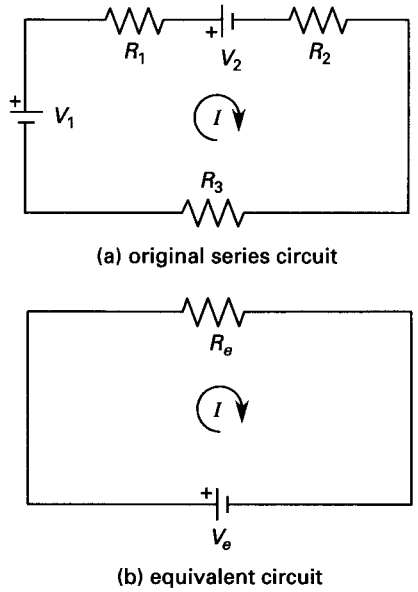

Figure 83.2 *Simple Series DC Circuit and Its Equivalent*

11. SIMPLE PARALLEL CIRCUITS

Figure 83.3 illustrates a simple parallel DC circuit with one voltage source and its equivalent circuit.

- The voltage drop is the same across all legs.

$$V = V_{R_1} = V_{R_2} = V_{R_3} = I_1 R_1 = I_2 R_2 = I_3 R_3 \quad 83.21$$

- The reciprocal of the equivalent resistance is the sum of the reciprocals of the individual resistances.

$$\frac{1}{R_e} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} \quad 83.22$$

$$G_e = G_1 + G_2 + G_3 \quad 83.23$$

- The sum of all of the leg currents is equal to the total current. This fact is an extension of *Kirchhoff's current law*: The current flowing out of a connection (*node*) is equal to the current flowing into it.

$$I = I_1 + I_2 + I_3 = \frac{V}{R_1} + \frac{V}{R_2} + \frac{V}{R_3} = V(G_1 + G_2 + G_3) \quad 83.24$$

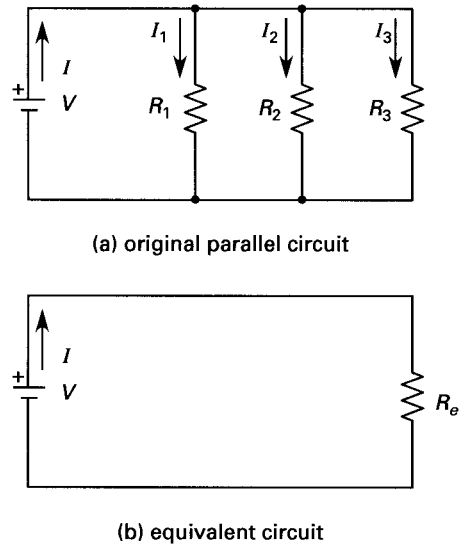

Figure 83.3 *Simple Parallel DC Circuit and Its Equivalent*

12. VOLTAGE AND CURRENT DIVIDERS

Figure 83.4(a) illustrates a *voltage divider circuit*. The voltage across resistor 2 is

$$V_2 = V\left(\frac{R_2}{R_1 + R_2}\right) \quad 83.25$$

Figure 83.4(b) illustrates a *current divider circuit*. The current through resistor 2 is

$$I_2 = I\left(\frac{R_1}{R_1 + R_2}\right) \quad 83.26$$

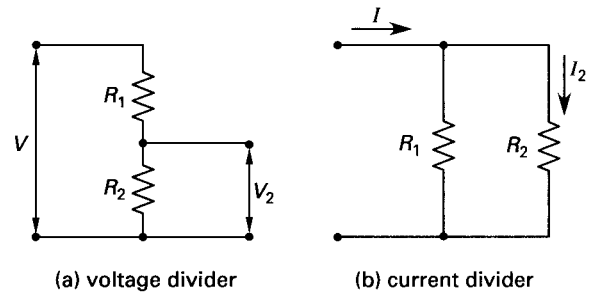

Figure 83.4 *Divider Circuits*

13. AC VOLTAGE SOURCES

The term *alternating current* (AC) almost always means that the current is produced from the application of a voltage with sinusoidal waveform.[5] Sinusoidal variables can be specified without loss of generality as either sines or cosines. If a sine waveform is used, Eq. 83.27 gives the instantaneous voltage as a function of time. V_m is the *maximum value*, also known as the *amplitude*, of the sinusoid. If $v(t)$ is not zero at $t = 0$, a *phase angle*, θ, must be included.

$$v(t) = V_m \sin(\omega t + \theta) \quad \text{[trigonometric form]} \quad 83.27$$

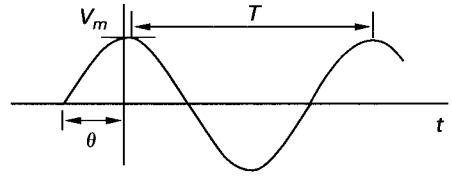

Figure 83.5 *Sinusoidal Waveform*

Figure 83.5 illustrates the *period*, T, of the waveform. The *frequency*, f (also known as *linear frequency*), of the sinusoid is the reciprocal of the period and is expressed in hertz (Hz).[6] *Angular frequency*, ω, in radians per second (rad/s), can also be specified.

$$f = \frac{1}{T} = \frac{\omega}{2\pi} \quad 83.28$$

$$\omega = 2\pi f = \frac{2\pi}{T} \quad 83.29$$

[5]Other alternating waveforms commonly encountered in commercial applications are the square, triangular, and sawtooth waveforms.

[6]In the United States, the standard frequency is 60 Hz. In Japan, the British Isles and Commonwealth countries, continental Europe, and some Mediterranean, Near Eastern, African, and South American countries, the standard is 50 Hz.

14. MAXIMUM, EFFECTIVE, AND AVERAGE VALUES

The *maximum value* (see Fig. 83.5), V_m, of a sinusoidal voltage is usually not specified in commercial and residential power systems. The *effective value*, also known as the *root-mean-square (rms) value*, is usually specified when referring to single- and three-phase voltages.[7] A DC current equal in magnitude to the effective value of a sinusoidal AC current produces the same heating effect as the sinusoid. The scale reading of a typical AC current meter is proportional to the effective current.

$$V_{\text{eff}} = \frac{V_m}{\sqrt{2}} \approx 0.707V_m \qquad 83.30$$

The *average value* of a symmetrical sinusoidal waveform is zero. However, the average value of a rectified sinusoid (or the average value of a sinusoid taken over half of the cycle) is $V_{\text{ave}} = 2V_m/\pi$. A DC current equal to the average value of a *rectified AC current* has the same electrolytic action (e.g., capacitor charging, plating, and ion formation) as the rectified sinusoid.[8]

15. IMPEDANCE

Simple alternating current circuits can be composed of three different types of passive circuit components—resistors, inductors, and capacitors. Each type of component affects both the magnitude of the current flowing as well as the phase angle (Sec. 23) of the current. For both individual components and combinations of components, these two effects are quantified by the *impedance*, **Z**. Impedance is a complex quantity with a magnitude (in ohms) and an associated *impedance angle*, ϕ. It is usually written in *phasor (polar) form* (e.g., $\mathbf{Z} \equiv Z\angle\phi$).

Multiple impedances in a circuit combine in the same manner as resistances: Impedances in series add; reciprocals of impedances in parallel add. However, the addition must use complex (i.e., vector) arithmetic.

16. REACTANCE

Impedance, like any complex quantity, can also be written in rectangular form. In this case, impedance is written as the complex sum of the resistive (R) and reactive (X) components, both having units of ohms. The resistive and reactive components combine trigonometrically in the impedance triangle. The reactive component, X, is known as the *reactance*.

$$\mathbf{Z} \equiv R \pm jX \qquad 83.31$$

$$R = Z\cos\phi \quad \text{[resistive part]} \qquad 83.32$$

$$X = Z\sin\phi \quad \text{[reactive part]} \qquad 83.33$$

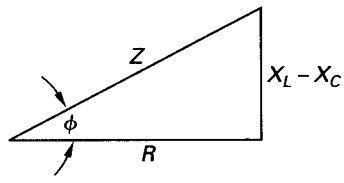

Figure 83.6 *Impedance Triangle of a Complex Circuit*

17. ADMITTANCE

The reciprocal of impedance is the complex quantity *admittance*, **Y**. Admittance can be used to analyze parallel circuits, since admittances of parallel circuit elements add together.

$$\mathbf{Y} = \frac{1}{\mathbf{Z}} \equiv \frac{1}{Z\angle\phi} \qquad 83.34$$

The reciprocal of the resistive part of the impedance is the *conductance*, G, with units of siemens, S. The reciprocal of the reactive part of impedance is the *susceptance*, B.

$$G = \frac{1}{R} \qquad 83.35$$

$$B = \frac{1}{X} \qquad 83.36$$

18. RESISTORS IN AC CIRCUITS

An ideal resistor, with resistance R, has no inductance or capacitance. The magnitude of the impedance is equal to the resistance, R, in ohms. The impedance angle is zero. Therefore, current and voltage are in phase in a purely resistive circuit.

$$\mathbf{Z}_R \equiv R\angle 0^\circ \equiv R + j0 \qquad 83.37$$

19. CAPACITORS

A *capacitor* stores electrical charge. The charge on a capacitor is proportional to its *capacitance*, C (in farads, F), and voltage.[9]

$$Q = CV \qquad 83.38$$

An ideal capacitor has no resistance or inductance. The magnitude of the impedance is the *capacitive reactance*, X_C, in ohms. The impedance angle is $-\pi/2$ (-90°). Therefore, current leads the voltage by 90° in a purely capacitive circuit.

$$\mathbf{Z}_C \equiv X_C\angle -90^\circ \equiv 0 - jX_C \qquad 83.39$$

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi fC} \qquad 83.40$$

[7]The standard U.S. 110 V household voltage (also commonly referred to as 115 V, 117 V, and 120 V) is an effective value. This is sometimes referred to as the *nominal system voltage* or just *system voltage*. Other standard voltages used around the world, expressed as effective values, are 208 V, 220 V, 230 V, 240 V, 480 V, 550 V, 575 V, and 600 V.

[8]A *rectified waveform* has had all of its negative values converted to positive values of equal absolute value.

[9]Since a farad is a very large unit of capacitance, most capacitors are measured in microfarads, μF.

20. INDUCTORS

An ideal *inductor*, with an *inductance* L (in henries, H), has no resistance or capacitance. The magnitude of the impedance is the *inductive reactance*, X_L, in ohms. The impedance angle is $\pi/2$ (90°). Therefore, current lags the voltage by 90° in a purely inductive circuit.

$$\mathbf{Z}_L \equiv X_L\angle 90^\circ \equiv 0 + jX_L \qquad 83.41$$

$$X_L = \omega L = 2\pi f L \qquad 83.42$$

21. TRANSFORMERS

Transformers are used to change voltages, isolate circuits, and match impedances. Transformers usually consist of two coils of wire wound on magnetically permeable cores. One coil, designated as the *primary coil*, serves as the input; the other coil, the *secondary coil*, is the output. The primary current produces a magnetic flux in the core; the magnetic flux, in turn, induces a voltage in the secondary coil. In an *ideal transformer* (*loss-less transformer* or *100% efficient transformer*), the coils have no electrical resistance, and all magnetic flux lines pass through both coils.

The ratio of the numbers of primary to secondary coil windings is the *turns ratio (ratio of transformation)*, a. If the turns ratio is greater than 1.0, the transformer decreases voltage and is a *step-down transformer*. If the turns ratio is less than 1.0, the transformer increases voltage and is a *step-up transformer*.

$$a = \frac{N_p}{N_s} \qquad 83.43$$

In an ideal transformer, the power transferred from the primary side equals the power received by the secondary side.

$$I_p V_p = I_s V_s \qquad 83.44$$

$$a = \frac{V_p}{V_s} = \frac{I_s}{I_p} = \sqrt{\frac{Z_p}{Z_s}} \qquad 83.45$$

22. OHM'S LAW FOR AC CIRCUITS

Ohm's law (Sec. 6) can be written in phasor (polar) form. Voltage and current can be represented by their maximum, effective (rms), or average values. However, both must be represented in the same manner.

$$\mathbf{V} = \mathbf{IZ} \qquad 83.46$$

$$V = IZ \quad \text{[magnitudes only]} \qquad 83.47$$

$$\phi_V = \phi_I + \phi_Z \quad \text{[angles only]} \qquad 83.48$$

23. PHASE ANGLE

The current and current phase angle of a circuit are determined by using Ohm's law (Sec. 6) in phasor form. The current *phase angle*, ϕ_I, is the angular difference between when the current and voltage waveforms peak.

$$\mathbf{I} = \frac{\mathbf{V}}{\mathbf{Z}} \qquad 83.49$$

$$I = \frac{V}{Z} \quad \text{[magnitudes only]} \qquad 83.50$$

$$\phi_I = \phi_V - \phi_Z \quad \text{[angles only]} \qquad 83.51$$

Example 83.2

An inventor's black box is connected across standard household voltage (110 V rms). The current drawn is 1.7 A with a lagging phase angle of 14° with respect to the voltage. What is the impedance of the black box?

Solution

From Eq. 83.49,

$$\mathbf{Z} = \frac{\mathbf{V}}{\mathbf{I}} = \frac{110\ \text{V}\angle 0^\circ}{1.7\ \text{A}\angle 14^\circ}$$

$$= 64.71\ \Omega\angle -14^\circ$$

24. POWER IN AC CIRCUITS

In a purely resistive circuit, all of the current drawn contributes to dissipated energy. The flow of current causes resistors to increase in temperature, and heat is transferred to the environment.

In a typical AC circuit containing inductors and capacitors as well as resistors, some of the current drawn does not cause heating.[10] Rather, the current charges capacitors and creates magnetic fields in inductors. Since the voltage alternates in polarity, capacitors alternately charge and discharge. Thus, energy is repeatedly drawn and returned by capacitors. Similarly, energy is repeatedly drawn and returned by inductors as their magnetic fields form and collapse.

Current through resistors in AC circuits causes heating, just as in DC circuits. The power dissipated is represented by the *real power* vector, **P**. Current through capacitors and inductors contributes to reactive power, represented by the *reactive power* vector, **Q**. Reactive power does not contribute to heating. For convenience, both real and reactive power are considered to be complex (vector) quantities, with magnitudes and associated angles. Real and reactive power combine as vectors into the *complex power* vector, **S**, as shown in Fig. 83.7. The angle, ϕ, is known as the overall *impedance angle*.

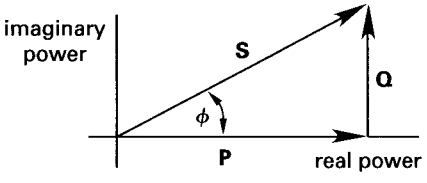

Figure 83.7 *Complex Power Triangle (lagging)*

[10]The notable exception is a *resonant circuit* in which the inductive and capacitive reactances are equal. In that case, the circuit is purely resistive in nature.

The magnitude of real power is known as the *average power*, P, and is measured in watts. The magnitude of the reactive power vector is known as *reactive power*, Q, and is measured in VARs (volt-amps-reactive). The magnitude of the complex power vector is the *apparent power*, S, measured in VAs (volt-amps). The apparent power is easily calculated from measurements of the line current and line voltage.

$$S = I_{\text{eff}} V_{\text{eff}} = \tfrac{1}{2} I_m V_m \qquad 83.52$$

25. POWER FACTOR

The complex power triangle shown in Fig. 83.7 is congruent to the impedance triangle (Fig. 83.6), and the *power angle*, ϕ, is identical to the overall impedance angle.

$$S^2 = P^2 + Q^2 \qquad 83.53$$

$$P = S \cos\phi \qquad 83.54$$

$$Q = S \sin\phi \qquad 83.55$$

$$\phi = \arctan\left(\frac{Q}{P}\right) \qquad 83.56$$

The *power factor*, pf (also occasionally referred to as the *phase factor*), for a sinusoidal voltage is $\cos\phi$. By convention, the power factor is usually given in percent value rather than by its equivalent decimal value. For a purely resistive circuit, pf = 100%; for a purely reactive circuit, pf = 0.

$$\text{pf} = \frac{P}{S} \qquad 83.57$$

Since the cosine is positive for both positive and negative angles, the terms "leading" and "lagging" are used to describe the nature of the circuit. In a circuit with a *leading power factor* (i.e., in a *leading circuit*), the load is primarily capacitive in nature. In a circuit with a *lagging power factor* (i.e., in a *lagging circuit*), the load is primarily inductive in nature.

26. COST OF ELECTRICAL ENERGY

Except for large industrial users, electrical meters at service locations usually measure and record real power only. Electrical utilities charge on the basis of the total energy used. Energy usage, commonly referred to as the *usage* or *demand*, is measured in kilowatt-hours, abbreviated kWh or kW-hr.

$$\text{cost} = (\text{cost per kW-hr}) \times E_{\text{kW-hr}} \qquad 83.58$$

The cost per kW-hr may not be a single value but may be tiered so that cost varies with cumulative usage. The lowest rate is the *baseline rate*.[11] To encourage conservation, the incremental cost of energy increases with increases in monthly usage.[12] To encourage cutbacks during the day, the cost may also increase during periods of peak demand.[13] The increase in cost for usage during peak demand may be accomplished by varying the rate, additively, or by use of a *peak demand multiplier*. There may also be different rates for summer and winter usage.

Although only real power is dissipated, reactive power contributes to total current. (Reactive power results from the current drawn in supplying the magnetization energy in motors and charges on capacitors.) Therefore, the distribution system (wires, transformers, etc.) must be sized to carry the total current, not just the current supplying the heating effect. When real power alone is measured at the service location, the power factor is routinely monitored and its effect is built into the charge per kW-hr. This has the equivalent effect of charging the user for apparent power usage.

Example 83.3

A small office normally uses 700 kW-hr per month of electrical energy. The company adds a 1.5 kW heater (to be used at the rate of 1000 kW-hr/month) and a 5 hp motor with a mechanical efficiency of 90% (to be used 240 hr/month). What is the incremental cost of adding the heater and motor? The tiered rate structure is

electrical usage (kW-hr)	rate ($/kW-hr)
less than 350	0.1255
350 to 999	0.1427
1000 to 3999	0.1693

Solution

Motors are rated by their real power output, which is less than their real power demand. The incremental electrical usage per month is

$$1000 \text{ kW-hr} + \frac{(5 \text{ hp})\left(0.7457 \dfrac{\text{kW}}{\text{hp}}\right) \times (240 \text{ hr})}{0.90} = 1994 \text{ kW-hr}$$

The cumulative monthly electrical usage is

$$700 \text{ kW-hr} + 1994 \text{ kW-hr} = 2694 \text{ kW-hr}$$

The company was originally in the second tier. The new usage will be billed partially at the second and third tier rates.

[11] There might also be a *lifeline rate* for low-income individuals with very low usage.

[12] There are different rate structures for different categories of users. While increased use within certain categories of users (e.g., residential) results in a higher cost per kW-hr, larger users in another category may pay substantially less per kW-hr due to their volume "buying power."

[13] The day may be divided into *peak periods, partial-peak periods,* and *off-peak periods.*

The incremental cost is

$$(999 \text{ kW-hr} - 700 \text{ kW-hr})\left(0.1427 \frac{\$}{\text{kW-hr}}\right) + (2694 \text{ kW-hr} - 999 \text{ kW-hr})\left(0.1693 \frac{\$}{\text{kW-hr}}\right) = \$329.63$$

27. POWER FACTOR CORRECTION

Inasmuch as apparent power is paid for but only real power is used to drive motors or provide light and heating, it may be possible to reduce electrical utility charges by reducing the power angle without changing the real power. This strategy, known as *power factor correction*, is routinely accomplished by changing the circuit reactance in order to reduce the reactive power. The change in reactive power needed to change the power angle from ϕ_1 to ϕ_2 is

$$\Delta Q = P(\tan \phi_1 - \tan \phi_2) \qquad 83.59$$

When a circuit is capacitive (i.e., leading), induction motors (Sec. 39) can be connected across the line to improve the power factor. In the more common situation, when a circuit is inductive (i.e., lagging), capacitors or synchronous capacitors (Sec. 41) can be added across the line. The size (in farads) of capacitor required is

$$C = \frac{\Delta Q}{\pi f V_m^2} \quad [V_m \text{ maximum}] \qquad 83.60$$

$$C = \frac{\Delta Q}{2\pi f V_{\text{eff}}^2} \quad [V_{\text{eff}} \text{ effective}] \qquad 83.61$$

Capacitors for power factor correction are generally rated in kVA. Equation 83.59 can be used to find that rating.

Example 83.4

A 60 Hz, 5 hp induction motor draws 53 A (rms) at 117 V (rms) with a 78.5% electrical-to-mechanical energy conversion efficiency. What capacitance should be connected across the line to increase the power factor to 92%?

Solution

The apparent power is found from the observed voltage and the current. Use Eq. 83.52.

$$S = IV = \frac{(53 \text{ A})(117 \text{ V})}{1000 \frac{\text{VA}}{\text{kVA}}} = 6.201 \text{ kVA}$$

The real power drawn from the line is calculated from the real work done by the motor. Use Eq. 83.72.

$$P_{\text{electrical}} = \frac{P_{\text{out}}}{\eta} = \frac{(5 \text{ hp})\ (0.7457 \text{ kW/hp})}{0.785} = 4.750 \text{ kW}$$

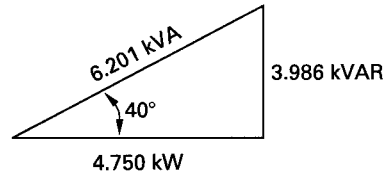
The reactive power and power angle are calculated from the real and apparent powers.

$$Q_1 = \sqrt{S^2 - P^2} = \sqrt{(6.201 \text{ kVA})^2 - (4.750 \text{ kW})^2} = 3.986 \text{ kVAR}$$

From Eq. 83.53,

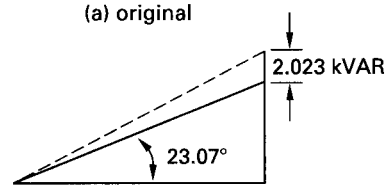
$$\phi_1 = \arccos\left(\frac{4.750 \text{ kW}}{6.201 \text{ kVA}}\right) = 40.00^\circ$$

The desired power factor angle is



$$\phi_2 = \arccos(0.92) = 23.07^\circ$$

The reactive power after the capacitor is installed is given by Eq. 83.56.



$$Q_2 = P \tan \phi_2 = (4.750 \text{ kW})(\tan 23.07^\circ) = 2.023 \text{ kVAR}$$

The required capacitance is found from Eq. 83.61.

$$C = \frac{\Delta Q}{2\pi f V_{\text{eff}}^2} = \frac{(3.986 \text{ kVAR} - 2.023 \text{ kVAR})\left(1000 \frac{\text{VAR}}{\text{kVAR}}\right)}{(2\pi)(60 \text{ Hz})(117 \text{ V})^2} = 3.8 \times 10^{-4} \text{ F } (380\ \mu\text{F})$$

(a) original

(b) corrected

28. THREE-PHASE ELECTRICITY

Smaller electric loads, such as household loads, are served by single-phase power. The power company delivers a sinusoidal voltage of fixed frequency and amplitude connected between two wires—a phase wire and a neutral wire. Large electric loads, large buildings, and industrial plants are served by three-phase power. Three voltage signals are connected between three phase wires and a single neutral wire. The phases have equal

frequency and amplitude, but they are out of phase by 120° (electrical) with each other. Such *three-phase systems* use smaller conductors to distribute electricity.[14] Thus, for the same delivered power, three-phase distribution systems have lower losses and are more efficient.

Three-phase motors provide a more uniform torque than do single-phase motors whose torque production pulsates.[15] Three-phase induction motors require no additional starting windings or associated switches. When rectified, three-phase voltage has a smoother waveform.

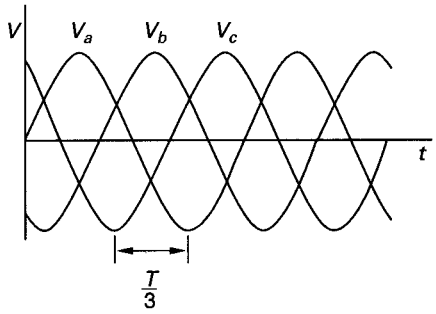


Figure 83.8 *Three-Phase Voltage*

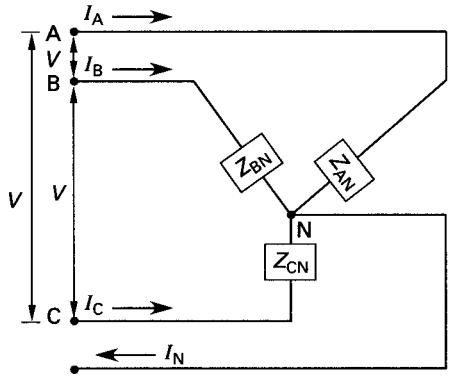
29. THREE-PHASE LOADS

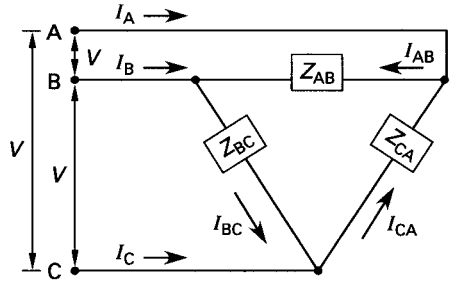
Three impedances are required to fully load a three-phase voltage source. In three-phase motors and other devices, these impedances are three separate motor windings. Similarly, three-phase transformers have three separate sets of primary and secondary windings.

The impedances in a three-phase system are said to be *balanced loads* when they are identical in magnitude and angle. The voltages, line currents, and real, apparent, and reactive powers are all identical in a balanced system. Also, the power factor is the same for each phase. Therefore, only one phase of a balanced system needs to be analyzed (i.e., a *one-line analysis*).



30. LINE AND PHASE VALUES

The *line current*, I_l, is the current carried by the distribution lines (wires). The *phase current*, I_p, is the current flowing through each of the three separate loads (i.e., the phase) in the motor or device. Line and phase currents are both vector quantities.



Depending on how the motor or device is internally wired, the line and phase currents may or may not be the same. Figure 83.9 illustrates delta- and wye-connected loads. For balanced *wye-connected loads*, the line and phase currents are the same. For balanced *delta-connected loads*, they are not.

$$I_p = I_l \quad \text{[wye]} \qquad 83.62$$

$$I_p = \frac{I_l}{\sqrt{3}} \quad \text{[delta]} \qquad 83.63$$

(a) wye-connected loads

(b) delta-connected loads

Figure 83.9 *Wye- and Delta-Connected Loads*

Similarly, the *line voltage*, V_l (same as *line-to-line voltage*, commonly referred to as the *terminal voltage*), and *phase voltage*, V_p, may not be the same. With balanced delta-connected loads, the full line voltage appears across each phase. With balanced wye-connected loads, the line voltage appears across two loads.

$$V_p = \frac{V_l}{\sqrt{3}} \quad \text{[wye]} \qquad 83.64$$

$$V_p = V_l \quad \text{[delta]} \qquad 83.65$$

31. INPUT POWER THREE-PHASE SYSTEMS

Each impedance in a balanced system dissipates the same real *phase power*, P_p. The power dissipated in a balanced three-phase system is three times the phase power and is calculated in the same manner for both delta- and wye-connected loads.

$$P_t = 3P_p = 3V_pI_p \cos\phi$$
$$= \sqrt{3}V_lI_l \cos\phi \qquad 83.66$$

[14]The uppercase Greek letter phi is often used as an abbreviation for the word "phase." For example, "3Φ" would be interpreted as "three-phase."

[15]Single-phase motors require auxiliary windings for starting, since one phase alone cannot get the magnetic field rotating.

The real power component is sometimes referred to as "power in kW." Apparent power is sometimes referred to as "kVA value" or "power in kVA."

$$S_t = 3S_p = 3V_pI_p = \sqrt{3}V_lI_l \quad 83.67$$

32. ROTATING MACHINES

Rotating machines are categorized as AC and DC machines. Both categories include machines that use electrical power (i.e., motors) and those that generate electrical power (alternators and generators).[16] Machines can be constructed in either single-phase or polyphase configurations, although single-phase machines may be inferior in terms of economics and efficiency. (See Sec. 28.)

Large AC motors are almost always three-phase. However, since the phases are balanced, it is necessary to analyze one phase only of the motor. Torque and power are divided evenly among the three phases.

33. REGULATION

Rotating machines (motors and alternators), as well as power supplies, are characterized by changes in voltage and speed under load. *Voltage regulation* is defined as

$$\text{VR} = \frac{\text{no-load voltage} - \text{full-load voltage}}{\text{full-load voltage}} \times 100\% \quad 83.68$$

Speed regulation is defined as

$$\text{SR} = \frac{\text{no-load speed} - \text{full-load speed}}{\text{full-load speed}} \times 100\% \quad 83.69$$

34. TORQUE AND POWER

For rotating machines, torque and power are basic operational parameters. It takes mechanical power to turn an alternator or generator. A motor converts electrical power into mechanical power. In SI units, power is given in watts (W) and kilowatts (kW). One horsepower (hp) is equivalent to 0.7457 kilowatts. The relationship between torque and power is

$$T_{\text{ft-lbf}} = (5252)\left(\frac{P_{\text{horsepower}}}{n_{\text{rpm}}}\right) \quad 83.70$$

$$T_{\text{N·m}} = (9549)\left(\frac{P_{\text{kW}}}{n_{\text{rpm}}}\right) \quad 83.71$$

There are many important torque parameters for motors. The *starting torque* (also known as *static torque, break-away torque,* and *locked-rotor torque*) is the turning effort exerted by the motor when starting from rest. *Pull-up torque (acceleration torque)* is the minimum torque developed during the period of acceleration from rest to full speed. *Pull-in torque* (as developed in synchronous motors) is the maximum torque that brings the motor back to synchronous speed (Sec. 39). *Nominal pull-in torque* is the torque that is developed at 95% of synchronous speed.

The *full-load torque (steady-state torque)* occurs at the rated speed and horsepower. Full-load torque is supplied to the load on a continuous basis. The full-load torque establishes the temperature increase that the motor must be able to withstand without deterioration. The *rated torque* is developed at rated speed and rated horsepower. The maximum torque that the motor can develop at its synchronous speed is the *pull-out torque. Breakdown torque* is the maximum torque that the motor can develop without stalling (i.e., without coming rapidly to a complete stop).

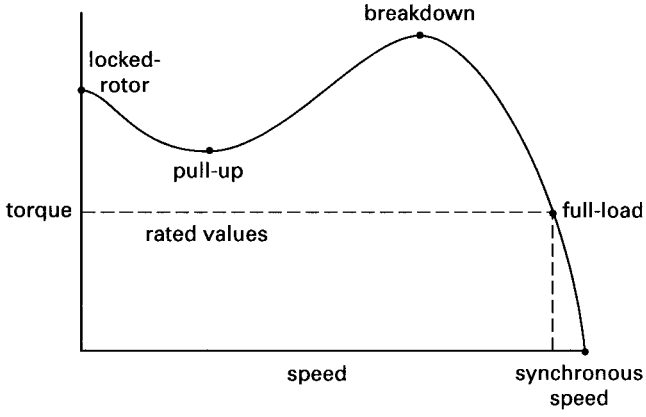


Figure 83.10 *Induction Motor Torque-Speed Characteristic (typical of design B frames)*

Motors are rated according to their output power (*rated power* or *brake power*). Thus, a 5 hp motor will normally deliver a full five horsepower when running at its rated speed. While the rated power is not affected by the motor's energy conversion efficiency, η, the electrical power input to the motor is.

$$P_{\text{electrical}} = \frac{P_{\text{rated}}}{\eta} \quad 83.72$$

Table 83.1 lists standard motor sizes by rated horsepower.[17] The rated horsepower should be greater than the calculated brake power requirements. Since the rated power is the power actually produced, motors are not selected on the basis of their efficiency or electrical power input. The smaller motors listed in Table 83.1 are generally single-phase motors. The larger motors listed are three-phase motors.

[16] An *alternator* produces AC potential. A *generator* produces DC potential.

[17] For economics, standard motor sizes should be specified.

Table 83.1 *Typical Standard Motor Sizes (horsepower)*[a]

$\frac{1}{8}$	$\frac{1}{6}$	$\frac{1}{4}$	$\frac{1}{3}$	$\frac{1}{2}$	$\frac{3}{4}$			
1	$1\frac{1}{2}$	2	3	5	$7\frac{1}{2}$			
10	15	20	25	30	40	50	60	75
100	125	150	200	250				

(Multiply hp by 0.7457 to obtain kW.)
[a] $\frac{1}{8}$ hp and $\frac{1}{6}$ hp motors are less common.

35. NEMA MOTOR CLASSIFICATIONS

Motors are classified by their NEMA design type—A, B, C, D, and F.[18,19] These designs are collectively referred to as *NEMA frame motors*. All NEMA motors of a given frame size are interchangeable as to bolt holes, shaft diameter, height, length, and various other dimensions.

- Frame design A: three-phase, squirrel-cage motor with high locked-rotor (starting) current but also higher breakdown torques; capable of handling intermittent overloads without stalling; 1 to 3% slip at full load.
- Frame design B: three-phase, squirrel-cage motor capable of withstanding full-voltage starting; locked-rotor and breakdown torques suitable for most applications; 1 to 3% slip at full load; often designated for "normal" usage; the most common design.[20]
- Frame design C: three-phase, squirrel-cage motor capable of withstanding full-voltage starting; high locked-rotor torque for special applications (e.g., conveyors and compressors); 1 to 3% slip at full load.
- Frame design D: three-phase, squirrel-cage motor capable of withstanding full-voltage starting; develops 275% locked-rotor torque for special applications; high breakdown torque; depending on design, 5 to 13% slip at full load; commonly known as a *high-slip motor*; used for cranes, hoists, oil well pump jacks, and valve actuators.
- Frame design F: three-phase, squirrel-cage motor with low starting current and low starting torque; used to meet applicable regulations regarding starting current; limited availability.

36. NAMEPLATE VALUES

A *nameplate* is permanently affixed to each motor's housing or frame. This nameplate is embossed or engraved with the *rated values* of the motor (*nameplate values* or *full-load values*). Nameplate information may include some or all of the following: voltage,[21] frequency,[22] number of phases, rated power (output power), running speed, duty cycle (Sec. 38), locked-rotor and breakdown torques, starting current, current drawn at rated load (in kVA/hp), ambient temperature, temperature rise at rated load, temperature rise at service factor (Sec. 37), insulation rating, power factor, efficiency, frame size, and enclosure type.

It is important to recognize that the rated power of the motor is the actual output power (i.e., power delivered to the load), not the input power. Only the electrical power input is affected by the motor efficiency. (See Eq. 83.72.)

Nameplates are also provided on transformers. Transformer nameplate information includes the two winding voltages (either of which can be the primary winding), frequency, and kVA rating. Apparent power in kVA, not real power, is used in the rating because heating is proportional to the square of the supply current. As with motors, continuous operation at the rated values will not result in excessive heat build-up.

37. SERVICE FACTOR

The horsepower and torque ratings listed on the nameplate of an AC motor can be maintained on a continuous basis without overheating. However, motors can be operated at slightly higher loads without exceeding a safe temperature rise.[23] The ratio of the safe to rated loads (horsepower or torque) is the *service factor*, sf, usually expressed as a decimal.

$$\text{sf} = \frac{\text{maximum safe load}}{\text{nameplate load}} \qquad 83.73$$

Service factors vary from 1.15 to 1.4, with the lower values being applicable to the larger, more efficient motors. Typical values of service factor are 1.4 (up to $\frac{1}{8}$ hp motors), 1.35 ($\frac{1}{6}$ to $\frac{1}{3}$ hp motors), 1.25 ($\frac{1}{2}$ to 1 hp motors), and 1.15 (1 or $1\frac{1}{2}$ to 200 hp).

When running above the rated load, the motor speed, temperature, power factor, full-load current, and efficiency will differ from the nameplate values. However, the locked-rotor and breakdown torques will remain the same, as will the starting current.

Active current is proportional to torque, and hence, is proportional to the horsepower developed (Eq. 83.75).

[18] NEMA stands for the National Electrical Manufacturers Association.
[19] There is no type E.
[20] Design B is estimated to be used in 90% of all applications.
[21] Standard NEMA nameplate voltages (effective) are 200 V, 230 V, 460 V, and 575 V. NEMA motors are capable of operating in a range of only ±10% of their rated voltages. Thus, 230 V motors should not be used on 208 V systems.
[22] While some 60 Hz motors (notably those intended for 230 V operation) can be used at 50 Hz, most others (e.g., those intended for 200 V operation) are generally not suitable for use at 50 Hz.
[23] Higher temperatures have a deteriorating effect on the winding insulation. A general rule of thumb is that a motor loses two or three hours of useful life for each hour run at the service factor load.

The active current (line or phase) drawn is also proportional to the service factor. The current drawn per phase is given by Eq. 83.75.[24]

$$I_{\text{active}} = I_l(\text{pf}) \tag{83.74}$$

$$I_{\text{actual},p} = \frac{(\text{sf})P_{\text{rated},p}}{V\eta(\text{pf})} = \frac{P_{\text{actual},p}}{V\eta(\text{pf})} \quad \text{[per phase; } P \text{ in watts]} \tag{83.75}$$

Equation 83.75 can also be used when a motor is developing less than its rated power. In this case, the service factor can be considered as the fraction of the rated power being developed.

Example 83.5

What is the approximate phase current drawn by a three-phase, 75 hp, 230 V (rms) motor running at 88% power factor and its rated load?

Solution

No information is given about the efficiency, which is taken as 100%. The service factor is 1.00 because the motor is running at its rated load. From Eq. 83.75, the approximate phase current is

$$I_p = \frac{(\text{sf})P_p}{V_p\eta(\text{pf})} = \frac{(1.00)\left(\frac{75 \text{ hp}}{3 \text{ phases}}\right)\left(0.7457 \frac{\text{kW}}{\text{hp}}\right)\left(1000 \frac{\text{W}}{\text{kW}}\right)}{(230 \text{ V})(1.00)(0.88)} = 92.1 \text{ A} \quad \text{[per phase]}$$

38. DUTY CYCLE

Motors are categorized according to their *duty cycle: continuous-duty* (24 hr/day); *short-time duty* (15 to 30 min); and *special-duty* (application specific).

39. INDUCTION MOTORS

The three-phase induction motor is by far the most frequently used motor in industry. In an induction motor, the magnetic field rotates at the synchronous speed. The *synchronous speed* can be calculated from the number of poles and frequency. The frequency, f, is either 60 Hz (in the United States) or 50 Hz (in Europe and other locations). The number of poles, p, must be even.[25] The most common motors have 2, 4, and 6 poles.

$$n_{\text{synchronous}} = \frac{120f}{p} \quad \text{[rpm]} \tag{83.76}$$

Due to friction and other factors, rotors (and hence, the motor shafts) in induction motors run slightly slower than their synchronous speeds. The percentage difference is known as the *slip*, s. Slip is seldom greater than 10%, and it is usually much less than that. 4% is a typical value.

$$s = \frac{n_{\text{synchronous}} - n_{\text{actual}}}{n_{\text{synchronous}}} \tag{83.77}$$

The rotor's actual speed is[26]

$$n_{\text{actual}} = (1 - s)n_{\text{synchronous}} \tag{83.78}$$

Induction motors are usually specified in terms of the *kVA ratings*. The kVA rating is not the same as the motor power in kilowatts, although one can be calculated from the other if the motor's power factor is known. The power factor generally varies from 0.8 to 0.9 depending on the motor size.

$$\text{kVA rating} = \frac{P_{\text{kW}}}{\text{pf}} \tag{83.79}$$

$$P_{\text{kW}} = 0.7457P_{\text{mechanical,hp}} \tag{83.80}$$

Induction motors can differ in the manner in which their rotors are constructed. A *wound rotor* is similar to an armature winding in a dynamo. Wound rotors have high-torque and soft-starting capabilities. There are no wire windings at all in a *squirrel-cage* rotor. Most motors use squirrel-cage rotors. Typical torque-speed characteristics of a design B induction motor are shown in Fig. 83.10.

Example 83.6

A pump is driven by a three-phase induction motor running at its rated values. The motor's nameplate lists the following rated values: 50 hp, 440 V, 92% lagging power factor, 90% efficiency, 60 Hz, and 4 poles. The motor's windings are delta-connected. The pump efficiency is 80%. When running under the pump load, the slip is 4%. What are the (a) total torque developed, (b) torque developed per phase, and (c) line current?

[24] It is important to recognize the difference between the rated (i.e., nameplate) power and the actual power developed. The actual power should not be combined with the service factor, since the actual power developed is the product of the rated power and the service factor.

[25] There are various forms of Eq. 83.76. As written, the speed is given in rpm, and the number of poles, p, is twice the number of *pole pairs*. When the synchronous speed is specified as f/p, it is understood that the speed is in revolutions per second (rps) and p is the number of pole *pairs*.

[26] Some motors (i.e., *integral gear motors*) are manufactured with integral speed reducers. Common standard output speeds are 37, 45, 56, 68, 84, 100, 125, 155, 180, 230, 280, 350, 420, 520, and 640 rpm. While the integral gear motor is more compact, lower in initial cost, and easier to install than a separate motor with belt drive, coupling, and guard, the separate motor and reducer combination may nevertheless be preferred for its flexibility, especially in replacing and maintaining the motor.

Solution

(a) The synchronous speed is given by Eq. 83.76.

$$n_{\text{synchronous}} = \frac{120f}{p} = \frac{(120)(60\text{ Hz})}{4} = 1800\text{ rpm}$$

From Eq. 83.78, the rotor speed is

$$n_{\text{actual}} = (1-s)n_{\text{synchronous}} = (1-0.04)(1800\text{ rpm}) = 1728\text{ rpm}$$

Since the motor is running at its rated values, the motor delivers 50 hp to the pump. The pump's efficiency is irrelevant. From Eq. 83.70, the total torque developed by all three phases is

$$T_t = (5252)\left(\frac{P_{\text{horsepower}}}{n_{\text{rpm}}}\right) = \frac{\left(5252\ \frac{\text{ft-lbf}}{\text{hp-min}}\right)(50\text{ hp})}{1728\text{ rpm}} = 152.0\text{ ft-lbf}\quad\text{[total]}$$

(b) The torque developed per phase is one third of the total torque developed.

$$T_p = \frac{T_t}{3} = \frac{152.0\text{ ft-lbf}}{3\text{ phases}} = 50.67\text{ ft-lbf}\quad\text{[per phase]}$$

(c) The total electrical input power is given by Eq. 83.72.

$$P_{\text{electrical}} = \frac{P_{\text{rated}}}{\eta} = \frac{(50\text{ hp})\left(0.7457\ \frac{\text{kW}}{\text{hp}}\right)}{0.90} = 41.43\text{ kW}\quad\text{[total]}$$

Since the power factor is less than 1.0, more current is being drawn than is being converted into useful work. From Eq. 83.79, the apparent power in kVA per phase is

$$S_{\text{kVA}} = \frac{P_{\text{kW}}}{\text{pf}} = \frac{41.43\text{ kW}}{(3)(0.92)} = 15.01\text{ kVA}\quad\text{[per phase]}$$

The phase current is given by Eq. 83.52.

$$I = \frac{S}{V} = \frac{(15.01\text{ kVA})\left(1000\ \frac{\text{VA}}{\text{kVA}}\right)}{440\text{ V}} = 34.11\text{ A}$$

Since the motor's windings are delta-connected across the three lines, the line current is

$$I_l = \sqrt{3}I_p = (\sqrt{3})(34.11\text{ A}) = 59.08\text{ A}$$

40. TYPICAL INDUCTION MOTOR PERFORMANCE

The following rules of thumb can be used for initial estimates of induction motor performance.

- At 1800 rpm, a motor will develop a torque of 3 ft-lbf/hp.
- At 1200 rpm, a motor will develop a torque of 4.5 ft-lbf/hp.
- At 550 V, a three-phase motor will draw 1 A/hp.
- At 440 V, a three-phase motor will draw 1.25 A/hp.
- At 220 V, a three-phase motor will draw 2.5 A/hp.
- At 220 V, a single-phase motor will draw 5 A/hp.
- At 110 V, a single-phase motor will draw 10 A/hp.

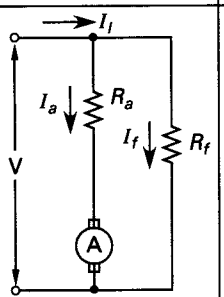
41. SYNCHRONOUS MOTORS

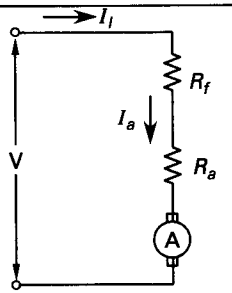
Synchronous motors are essentially dynamo alternators operating in reverse. The stator field frequency is fixed, so regardless of load, the motor runs only at a single speed—the synchronous speed given by Eq. 83.76. Stalling occurs when the motor's counter-torque is exceeded. For some equipment that must be driven at constant speed, such as large air or gas compressors, the additional complexity of synchronous motors is justified.

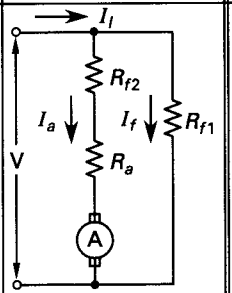
Power factor can be adjusted manually by varying the field current. With *normal excitation* field current, the power factor is 1.0. With *over-excitation*, the power factor is leading, and the field current is greater than normal. With *under-excitation*, the power factor is lagging, and the field current is less than normal.

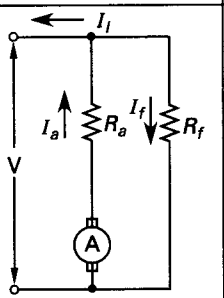
Since a synchronous motor can be adjusted to draw leading current, it can be used for power factor correction. A synchronous motor used purely for power factor correction is referred to as a *synchronous capacitor* or *synchronous condenser*. A power factor of 80% is often specified or used with synchronous capacitors.

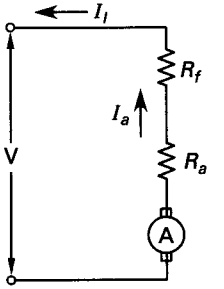
42. DC MACHINES

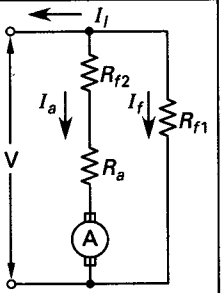












DC motors and generators can be wired in one of three ways: series, shunt, and compound. Operational characteristics are listed in Table 83.2. Equations 83.70 and 83.71 can be used to calculate torque and power.

43. CHOICE OF MOTOR TYPES

Squirrel-cage induction motors are commonly chosen because of their simple construction, low maintenance, and excellent efficiencies.[27] A wound-rotor induction

[27]The larger the motor and the higher the speed, the higher the efficiency. Large 3600 rpm induction motors have excellent performance.

PROFESSIONAL PUBLICATIONS, INC.

motor should be used only if it is necessary to achieve a low starting kVA, controllable kVA, controllable torque, or variable speed.[28]

While induction motors are commonly used, synchronous motors are suitable for many applications normally handled by a NEMA design B squirrel-cage motor. They have adjustable power factors and higher efficiency. Their initial cost may also be less.

Selecting a motor type is greatly dependent on the power, torque, and speed requirements of the rotating load. Table 83.3, Fig. 83.11, and Apps. 83.A and 83.B can be used as starting points in the selection process.

Table 83.3 *Recommended Motor Voltage and Power Ranges*

voltage	horsepower
direct current	
115	0 to 30 (max)
230	0 to 200 (max)
550 or 600	$\frac{1}{2}$ and upward
alternating current, one-phase	
110, 115, or 120	0 to $1\frac{1}{2}$
220, 230, or 240	0 to 10
440 or 550	5 to 10[a]
alternating current, two- and three-phase	
110, 115, or 120	0 to 15
208, 220, 230, or 240	0 to 200
440 or 550	0 to 500
2200 or 2300	40 and upward
4000	75 and upward
6600	400 and upward

(Multiply hp by 0.7457 to obtain kW.)

44. LOSSES IN ROTATING MACHINES

Losses in rotating machines are typically divided into the following categories: armature copper losses, field copper losses, mechanical losses (including friction and windage), core losses (including hysteresis losses, eddy current losses, and brush resistance losses), and stray losses.

Copper losses (also known as I^2R *losses*) are real power losses due to wire and winding resistance.

$$P_{Cu} = \Sigma I^2 R \qquad 83.81$$

[28]A constant-speed motor with a slip coupling could also be used.

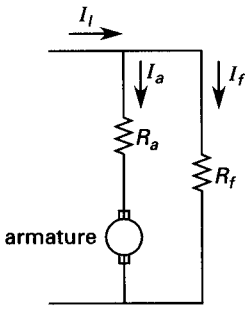
[a]Adapted from *Mechanical Engineering*, Design Manual NAVFAC DM-3, Department of the Navy, © 1972.

Figure 83.11 *Motor Rating According to Speed*[a] *(general guidelines)*

Core losses (also known as *iron losses*) are constant losses that are independent of the load and, for that reason, are also known as *open-circuit* and *no-load losses*.

Mechanical losses (also known as *rotational losses*) include brush and bearing friction and *windage* (air friction). (Windage is a no-load loss but is not an electrical core loss.) Mechanical losses are determined by measuring the power input at the rated speed and with no load.

Stray losses are due to non-uniform current distribution in the conductors. Stray losses are approximately 1% for DC machines and zero for AC machines.



45. EFFICIENCY OF ROTATING MACHINES

Only real power is used to compute the efficiency of a rotating machine. This efficiency is sometimes referred to as *overall efficiency* and *commercial efficiency*.

$$\eta = \frac{\text{output power}}{\text{input power}} = \frac{\text{output power}}{\text{output power} + \text{power losses}} = \frac{\text{input power} - \text{power losses}}{\text{input power}} \qquad 83.82$$

Example 83.7

A DC shunt motor draws 40 A at 112 V when fully loaded. When running without a load at the same speed, it draws only 3 A at 106 V. The field resistance is 100 Ω, and the armature resistance is 0.125 Ω. (a) What is the efficiency of the motor? (b) What power (in hp) does the motor deliver at full load?

Solution

(a) The field current is given by Eq. 83.9.

$$I_f = \frac{V}{R_f} = \frac{112\ V}{100\ \Omega} = 1.12\ \text{A}$$

The total full-load line current is known to be 40 A. The full-load armature current is

$$I_a = I_l - I_f = 40\ \text{A} - 1.12\ \text{A} = 38.88\ \text{A}$$

The field copper loss is given by Eq. 83.11.

$$P_{\text{Cu},f} = I_f^2 R_f = (1.12\ \text{A})^2(100\ \Omega) = 125.4\ \text{W}$$

The armature copper loss is given by Eq. 83.11.

$$P_{\text{Cu},a} = I_a^2 R_a = (38.88\ \text{A})^2(0.125\ \Omega) = 189.0\ \text{W}$$

The total copper loss is

$$P_{\text{Cu},t} = P_{\text{Cu},f} + P_{\text{Cu},a} = 125.4\ \text{W} + 189.0\ \text{W} = 314.4\ \text{W}$$

Stray power is determined from the no-load conditions. At no load, the field current is given by Eq. 83.9.

$$I_f = \frac{V}{R_f} = \frac{106\ \text{V}}{100\ \Omega} = 1.06\ \text{A}$$

At no load, the armature current is

$$I_a = I_l - I_f = 3\ \text{A} - 1.06\ \text{A} = 1.94\ \text{A}$$

The stray power loss is

$$P_{\text{stray}} = V_l I_a - I_a^2 R_a = (106\ \text{V})(1.94\ \text{A}) - (1.94\ \text{A})^2(0.125\ \Omega) = 205.2\ \text{W}$$

The stray power loss is assumed to be independent of the load. The total losses at full load are

$$P_{\text{loss}} = P_{\text{Cu},t} + P_{\text{stray}} = 314.4\ \text{W} + 205.2\ \text{W} = 519.6\ \text{W}$$

The power input to the motor when fully loaded is

$$P_{\text{input}} = I_l V_l = (40\ \text{A})(112\ \text{V}) = 4480\ \text{W}$$

The efficiency is

$$\eta = \frac{\text{input power} - \text{power losses}}{\text{input power}} = \frac{4480\ \text{W} - 519.6\ \text{W}}{4480\ \text{W}} = 0.884\ \ (88.4\%)$$

(b) The real power (in hp) delivered at full load is

$$P_{\text{real}} = \text{input power} - \text{power losses} = \frac{4480\ \text{W} - 519.6\ \text{W}}{\left(1000\ \frac{\text{W}}{\text{kW}}\right)\left(0.7457\ \frac{\text{kW}}{\text{hp}}\right)} = 5.3\ \text{hp}$$

46. HIGH-EFFICIENCY MOTORS AND DRIVES

A premium, energy-efficient motor will have approximately 50% of the losses of a conventional motor. Due to the relatively high overall efficiency enjoyed by all motors, however, this translates into only a 5% increase in overall efficiency.

High-efficiency motors are often combined with *variable-frequency drives* (VFDs) to achieve continuous-variable speed control.[29] VFDs can substantially reduce the power drawn by the process. For example, with a motor-driven pump or fan, the motor can be slowed down instead of closing a valve or damper when the flow requirements decrease. Since the required motor horsepower varies with the cube root of the speed, for processes that do not always run at full-flow (fluid pumping, metering, flow control, etc.), the energy savings can be substantial.

A VFD uses an electronic controller to produce a variable-frequency signal that is not an ideal sine wave. This results in additional heating (e.g., an increase of 20 to 40%) from copper and core losses in the motor. In pumping applications, though, the process load drops off faster than additional heat is produced. Thus, the process power savings dominate.

Most low- and medium-power motors implement VFD with DC voltage intermediate circuits, a technique known as *voltage-source inversion*. Voltage-source inversion is further subdivided into *pulse-width modulation* (PWM) and *pulse-amplitude modulation* (PAM).

Under VFD control, the motor torque is approximately proportional to the applied voltage and drawn current but inversely proportional to the applied frequency.

$$T \propto \frac{VI}{f} \qquad 83.83$$

[29] Prior to VFDs, there were two common ways to change the speed of an induction motor: (a) increasing the slip, and (b) changing the number of pole-pairs. Increasing the slip was accomplished by under-magnetizing the motor so that it received less input voltage than it was built for. Dropping or adding the number of active poles resulted in the speed changing by a factor of 2 (or ½).

[1]Measurement of fluid pressure is covered in Chap. 15; measurement of fluid flow is covered in Chap. 17.

1. ACCURACY

A measurement is said to be *accurate* if it is substantially unaffected by (i.e., is insensitive to) all variation outside of the measurer's control.

For example, suppose a rifle is aimed at a point on a distant target and several shots are fired. The target point represents the "true value" of a measurement—the value that should be obtained. The impact points

represent the measured values—what is obtained. The distance from the centroid of the points of impact to the target point is a measure of the alignment accuracy between the barrel and the sights. This difference between the true and measured values is known as the measurement *bias.*

2. PRECISION

Precision is not synonymous with *accuracy.* Precision is concerned with the repeatability of the measured results. If a measurement is repeated with identical results, the experiment is said to be precise. The average distance of each impact from the centroid of the impact group is a measure of precision. Thus, it is possible to take highly precise measurements and still have a large bias.

Most measurement techniques (e.g., taking multiple measurements and refining the measurement methods or procedures) that are intended to improve accuracy actually increase the precision.

Sometimes the term *reliability* is used with regard to the precision of a measurement. A *reliable measurement* is the same as a *precise estimate.*

3. STABILITY

Stability and *insensitivity* are synonymous terms. (Conversely, *instability* and *sensitivity* are synonymous.) A stable measurement is insensitive to minor changes in the measurement process.

Example 84.1

At 65°F (18°C), the centroid of an impact group on a rifle target is 2.1 in (5.3 cm) from the sight-in point. At 80°F (27°C), the distance is 2.3 in (5.8 cm). What is the sensitivity to temperature?

SI Solution

$$\begin{aligned}\text{sensitivity to temperature} &= \frac{\Delta \text{ measurement}}{\Delta \text{ temperature}} \\ &= \frac{5.8 \text{ cm} - 5.3 \text{ cm}}{27°\text{C} - 18°\text{C}} \\ &= 0.0556 \text{ cm/°C}\end{aligned}$$

Customary U.S. Solution

$$\begin{aligned}\text{sensitivity to temperature} &= \frac{\Delta \text{ measurement}}{\Delta \text{ temperature}} \\ &= \frac{2.3 \text{ in} - 2.1 \text{ in}}{80°\text{F} - 65°\text{F}} \\ &= 0.0133 \text{ in/°F}\end{aligned}$$

4. CALIBRATION

Calibration is used to determine or verify the scale of the measurement device. In order to calibrate a measurement device, one or more known values of the quantity to be measured (temperature, force, torque, etc.) are applied to the device and the behavior of the device is noted. (If the measurement device is linear, it may be adequate to use just a single calibration value. This is known as *single-point calibration.*)

Once a measurement device has been calibrated, the calibration signal should be reapplied as often as necessary to prove the reliability of the measurements. In some electronic measurement equipment, the calibration signal is applied continuously.

5. ERROR TYPES

Measurement errors can be categorized as *systematic (fixed) errors, random (accidental) errors, illegitimate errors,* and *chaotic errors.*

Systematic errors, such as improper calibration, use of the wrong scale, and incorrect (though consistent) technique, are essentially constant or similar in nature over time. *Loading error* is a systematic error and occurs when the act of measuring alters the true value.[2] Some *human errors,* if present in each repetition of the measurement, are also systematic. Systematic errors can be reduced or eliminated by refinement of the experimental method.

Random errors are caused by random and irregular influences generally outside the control of the measurer. Such errors are introduced by fluctuations in the environment, changes in the experimental method, and variations in materials and equipment operation. Since the occurrence of these errors is irregular, their effects can be reduced or eliminated by multiple repetitions of the experiment.

There is no reason to expect or tolerate *illegitimate errors* (e.g., errors in computations and other blunders). These are essentially mistakes that can be avoided through proper care and attention.

Chaotic errors, such as resonance, vibration, or experimental "noise," essentially mask or entirely invalidate the experimental results. Unlike the random errors previously mentioned, chaotic disturbances are sufficiently large to reduce the experimental results to meaninglessness.[3] Chaotic errors must be eliminated.

[2]For example, inserting an air probe into a duct will change the flow pattern and velocity around the probe.

[3]Much has been written in recent years about *chaos theory.* This theory holds that, for many processes, the ending state is dependent on imperceptible differences in the starting state. Future weather conditions and the landing orientation of a finely balanced spinning top are often used as examples of states that are greatly affected by their starting conditions.

6. ERROR MAGNITUDES

If a single measurement is taken of some quantity whose true value is known, the *error* is simply the difference between the true and measured values. However, the true value is never known in an experiment, and measurements are usually taken several times, not just once. Therefore, many conventions exist for estimating the unknown error.[4]

When most experimental quantities are measured, the measurements tend to cluster around some "average value." The measurements will be distributed according to some distribution, such as linear, normal, Poisson, and so on. The measurements can be graphed in a *histogram* and the distribution inferred. Usually the data will be normally distributed.[5]

Certain error terms used with normally distributed data have been standardized. These are listed in Table 84.1.

Table 84.1 *Normal Distribution Error Terms*

term	number of standard deviations	percent certainty	approximate odds of being incorrect
probable error	0.6745	50	1 in 2
mean deviation	0.6745	50	1 in 2
standard deviation	1.000	68.3	1 in 3
one-sigma error	1.000	68.3	1 in 3
90% error	1.6449	90	1 in 10
two-sigma error	2.000	95	1 in 20
three-sigma error	3.000	99.7	1 in 370
maximum error[a]	3.29	99.9+	1 in 1000

[a]The true maximum error is theoretically infinite.

7. POTENTIOMETERS

A *potentiometer (potentiometer transducer, variable resistor)* is a resistor with a sliding third contact. It converts linear or rotary motion into a variable resistance (voltage).[6] It consists of a resistance oriented in a linear or angular manner and a variable-position contact point known as the *tap*. A voltage is applied across the entire resistance, causing current to flow through the resistance. The voltage at the tap will vary with tap position.

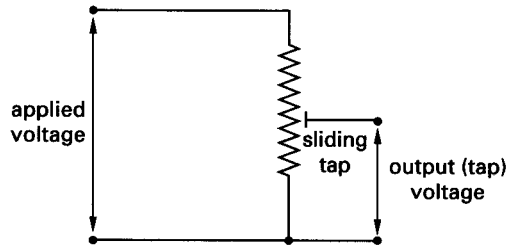

Figure 84.1 *Potentiometer*

8. TRANSDUCERS

Physical quantities are often measured with transducers (*detector-transducers*). A *transducer* converts the measured quantity to a second quantity that is measured. For example, a Bourdon tube pressure gage converts pressure to angular displacement; a strain gage converts stress to resistance change. Transducers are primarily mechanical in nature (e.g., pitot tube, spring devices, Bourdon tube pressure gage) or electrical in nature (e.g., thermocouple, strain gage, moving-core transformer).

9. SENSORS

While the term "transducer" is commonly used for devices that respond to mechanical input (force, pressure, torque, etc.), the term *sensor* is commonly applied to devices that respond to varying chemical conditions.[7] For example, an electrochemical sensor might respond to a specific gas, compound, or ion (known as a *target substance* or *species*). Two types of electrochemical sensors are in use today: potentiometric and amperometric.

Potentiometric sensors generate a measurable voltage at their terminals. In electrochemical sensors taking advantage of half-cell reactions at electrodes, the generated voltage is proportional to the absolute temperature, T, and is inversely proportional to the number of electrons, n, taking part in the chemical reaction at the half-cell. In Eq. 84.1, p_1 is the partial pressure of the target substance at the measurement electrode; p_2 is the partial pressure of the target substance at the reference electrode.

$$V \propto \left(\frac{T_{\text{absolute}}}{n}\right) \ln\left(\frac{p_1}{p_2}\right) \qquad 84.1$$

Amperometric sensors (also known as *voltammetric sensors*) generate a measurable current at their terminals. In the conventional electrochemical sensors known as *diffusion-controlled cells*, a high-conductivity acid or alkaline liquid electrolyte is used with a gas-permeable membrane that transmits ions from the outside to the inside of the sensor. A reference voltage is applied to two terminals within the electrolyte, and the current generated at a (third) sensing electrode is measured.

[4]This may be a good time to review the material in Chap. 11.

[5]The results of all numerical experiments are not automatically normally distributed. The throw of a die (one of two dice) is linearly distributed. Emissive power of a heated radiator is skewed with respect to wavelength. However, the means of sets of experimental data generally will be normally distributed, even if the raw measurements are not.

[6]There is a voltage-balancing device that shares the name *potentiometer (potentiometer circuit)*. An unknown voltage source can be measured by adjusting a calibrated voltage until a null reading is obtained on a voltage meter. The applications are sufficiently different that no confusion occurs when the "pot is adjusted."

[7]The categorization is common but not universal. The terms "transducer," "sensor," and "pickup" are often used loosely.

The maximum current generated is known as the *limiting current.* Current is proportional to the concentration (C) of the target substance, the permeability (P), the exposed sensor (membrane) area (A), and the number of electrons transferred per molecule detected (n). The current is inversely proportional to the membrane thickness (t).

$$I \propto \frac{nPCA}{t} \qquad 84.2$$

10. VARIABLE-INDUCTANCE TRANSDUCERS

Inductive transducers contain a wire coil and a moving permeable *core.*[8] As the core moves, the flux linkage through the coil changes. The change in inductance affects the overall impedance of the detector circuit.

The *differential transformer* or *linear variable differential transformer* (LVDT) is an important type of *variable-inductance transducer.* It converts linear motion into a change in voltage. The transformer is supplied with a low AC voltage. When the core is centered between the two secondary windings, the LVDT is said to be in its *null position.*

Movement of the core changes the magnetic flux linkage between the primary and secondary windings. Over a reasonable displacement range, the output voltage is proportional to the displacement of the core from the null position, hence the description "linear." The voltage changes phase (by 180°) as the core passes through the null position.

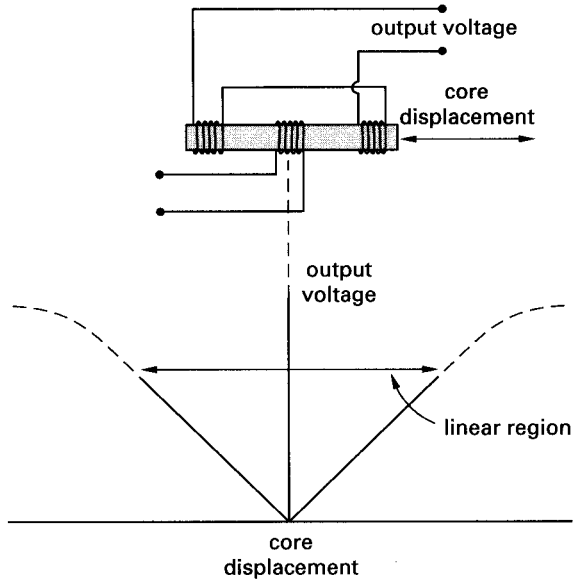

Figure 84.2 *Linear Variable Differential Transformer Schematic and Performance Characteristic*

[8]The term *core* is used even if the cross sections of the coil and core are not circular.

Sensitivity of a LVDT is measured in mV/in (mV/cm) of core movement. The sensitivity and output voltage depend on the frequency of the applied voltage (i.e., the *carrier frequency*) and are directly proportional to the magnitude of the applied voltage.

11. VARIABLE-RELUCTANCE TRANSDUCERS

A *variable-reluctance transducer (pickup)* is essentially a permanent magnet and a coil in the vicinity of the process being monitored.[9] There are no moving parts in this type of transducer. However, some of the magnet's magnetic flux passes through the surroundings, and the presence or absence of the process changes the coil voltage. Two typical applications of variable-reluctance pickups are measuring liquid levels and determining the rotational speed of a gear.

12. VARIABLE-CAPACITANCE TRANSDUCERS

In *variable-capacitance transducers*, the capacitance of a device can be modified by changing the plate separation, plate area, or dielectric constant of the medium separating the plates.

13. OTHER ELECTRICAL TRANSDUCERS

The *piezoelectric effect* is the name given to the generation of an electrical voltage when placed under stress.[10] *Piezoelectric transducers* generate a small voltage when stressed (strained). Since voltage is developed during the application of changing strain but not while strain is constant, piezoelectric transducers are limited to dynamic applications. Piezoelectric transducers may suffer from low voltage output, instability, and limited ranges in operating temperature and humidity.

The *photoelectric effect* is the generation of an electrical voltage when a material is exposed to light.[11] Devices using this effect are known as *photocells, photovoltaic cells, photosensors,* or *light-sensitive detectors,* depending on the applications. The sensitivity need not be to light in the visible spectrum. Photoelectric detectors can be made that respond to infrared and ultraviolet radiation. The magnitude of the voltage (or of the

[9]*Reluctance* depends on the area, length, and permeability of the medium through which the magnetic flux passes.

[10]Quartz, table sugar, potassium sodium tartarate (Rochelle salt), and barium titanate are examples of piezoelectric materials. Quartz is commonly used to provide a stable frequency in electronic oscillators. Barium titanate is used in some ultrasonic cleaners and sonar-like equipment.

[11]While the *photogenerative (photovoltaic)* definition is the most common definition, the term "photoelectric" can also be used with *photoconductive devices* (those whose resistance changes with light) and *photoemissive devices* (those that emit light when a voltage is applied).

current in an attached circuit) depends on the amount of illumination. If the cell is reverse-biased by an external battery, its operation is similar to a constant-current source.[12]

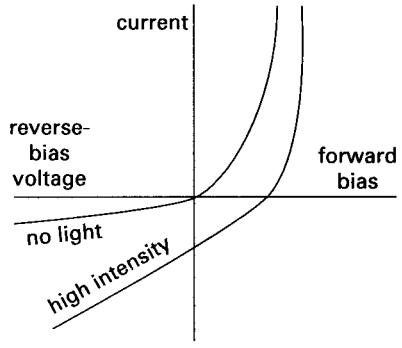

Figure 84.3 *Photovoltaic Device Characteristic Curves*

14. PHOTOSENSITIVE CONDUCTORS

Cadmium sulfide and *cadmium selenide* are two compounds that decrease in resistance when exposed to light. Cadmium sulfide is most sensitive to light in the 5000Å to 6000Å (0.5 to 0.6 μm) range, while cadmium selenide shows peak sensitivities in the 7000Å to 8000Å range (0.7 to 0.8 μm). These compounds are used in *photosensitive conductors*. Due to hysteresis, photosensitive conductors do not react instantaneously to changes in intensity.[13] High-speed operation requires high light intensities and careful design.

15. RESISTANCE TEMPERATURE DETECTORS

Resistance temperature detectors (RTDs), also known as *resistance thermometers*, make use of changes in their resistance to determine changes in temperature. A fine wire is wrapped around a form and protected with glass or a ceramic coating. Nickel and copper are commonly used for industrial RTDs. Platinum is used when precision resistance thermometry is required. RTDs are connected through resistance bridges (Sec. 19) to compensate for lead resistance.

Resistance in most conductors increases with temperature. The resistance at a given temperature can be calculated from the *coefficients of thermal resistance*, α and β.[14] The variation of resistance with temperature is nonlinear, though β is small and is often insignificant over short temperature ranges. Therefore, a linear relationship is often assumed and only α is used. In Eq. 84.3, R_{ref} is the resistance at the reference temperature, T_{ref}, usually 100 Ω at 32°F (0°C).

$$R_T \approx R_{\text{ref}}(1 + \alpha\Delta T + \beta\Delta T^2) \qquad 84.3$$

$$\Delta T = T - T_{\text{ref}} \qquad 84.4$$

In commercial RTDs, α is referred to by the literal term *alpha-value*. There are two applicable alpha values for platinum, depending on the purity. Commercial platinum RTDs produced in the United States generally have alpha values of 0.00392 1/°C, while RTDs produced in Europe and other countries generally have alpha values of 0.00385 1/°C.

16. THERMISTORS

Thermistors are temperature-sensitive semiconductors constructed from oxides of manganese, nickel, and cobalt and from sulfides of iron, aluminum, and copper. Thermistor materials are encapsulated in glass or ceramic materials to prevent penetration of moisture. Unlike RTDs, the resistance of thermistors decreases as the temperature increases.

Thermistor temperature-resistance characteristics are exponential. Depending on the brand, material, and construction, β typically varies between 3400 K and 3900 K.

$$R = R_o e^k \qquad 84.5$$

$$k = \beta\left(\frac{1}{T} - \frac{1}{T_o}\right) \quad [T \text{ in K}] \qquad 84.6$$

Thermistors can be connected to measurement circuits with copper wire and soldered connections. Compensation of lead wire effects is not required because resistance of thermistors is very large, far greater than the resistance of the leads. Since the negative temperature characteristic makes it difficult to design customized detection circuits, some thermistor and instrumentation standardization has occurred. The most common thermistors have resistances of 2252 Ω at 77°F (25°C), and most instrumentation is compatible with them. Other standardized resistances are 5000 Ω and 10,000 Ω at 25°C.

Thermistors typically are less precise and more unpredictable than metallic resistors. Since resistance varies exponentially, most thermistors are suitable for use only up to approximately 550°F (290°C).

[12] A semiconductor device is *reverse-biased* when a negative battery terminal is connected to a *p*-type semiconductor material in the device, or when a positive battery terminal is connected to an *n*-type semiconductor material.

[13] *Hysteresis* is the tendency for the transducer to continue to respond (i.e., indicate) when the load is removed. Alternatively, hysteresis is the difference in transducer outputs when a specific load is approached from above and from below. Hysteresis is usually expressed in percent of the full-load reading during any single calibration cycle.

[14] Higher-order terms (third, fourth, etc.) are used when extreme accuracy is required.

Table 84.2 *Typical Resistivities and Coefficients of Thermal Resistance*[a]

conductor	resistivity[b] (Ω·cm)	$\alpha^{c,d}$ (1/°C)
alumel[e]	28.1×10^{-6}	0.0024 @ 212°F (100°C)

[m]95% Pt, 5% Ir
[n]90% platinum, 10% rhodium

17. THERMOCOUPLES

A *thermocouple* consists of two wires of dissimilar metals joined at both ends.[15] One set of ends, typically called a *junction*, is kept at a known *reference temperature* while the other junction is exposed to the unknown temperature.[16] In a laboratory, the reference junction is often maintained at the *ice point*, 32°F (0°C), in an ice/water bath for convenience in later analysis. In commercial applications, the reference temperature can be any value, with appropriate compensation being made.

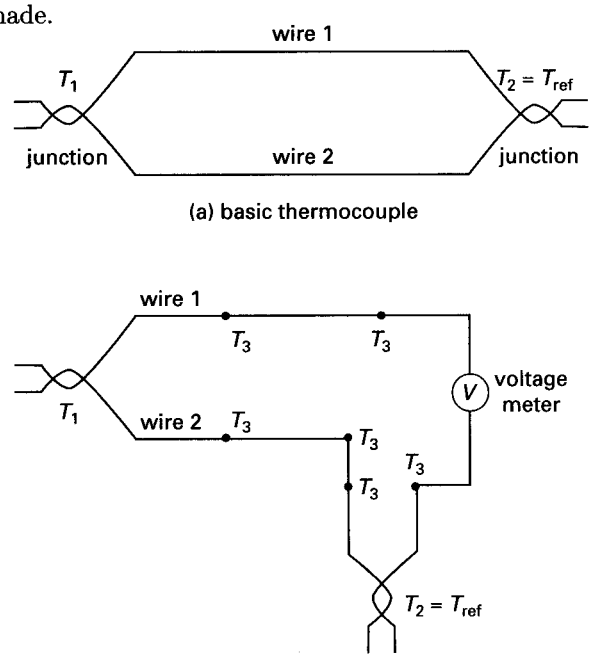

Figure 84.4 *Thermocouple*

Thermocouple materials, standard ANSI designations, and approximate useful temperature ranges are given in Table 84.3.[17] The "usable" temperature range can be much larger than the useful range. The most significant factors limiting the useful temperature range, sometimes referred to as the *error limits range*, are linearity, the rate at which the material will erode due to oxidation at higher temperatures, irreversible magnetic effects above magnetic critical points, and longer stabilization periods at higher temperatures.

A voltage is generated when the temperatures of the two junctions are different. This phenomenon is known as the *Seebeck effect.*[18] Referring to the polarities of

[15]The joint may be made by simply twisting the ends together. However, to achieve a higher mechanical strength and a better electrical connection, the ends should be soldered, brazed, or welded.

[16]The *ice point* is the temperature at which liquid water and ice are in equilibrium. Other standardized temperature references are: *oxygen point*, −297.346°F (90.19K); *steam point*, 212.0°F (373.16K); *sulfur point*, 832.28°F (717.76K); *silver point*, 1761.4°F (1233.96K); and *gold point*, 1945.4°F (1336.16K).
[17]It is not uncommon to list the two thermocouple materials with "vs." (as in *versus*). For example, a copper/constantan thermocouple might be designated as "copper vs. constantan."
[18]The inverse of the Seebeck effect, that current flowing through a junction of dissimilar metals will cause either heating or cooling, is the *Peltier effect*, though the term is generally used in regard to cooling applications. An extension of the Peltier effect, known as the *Thompson effect*, is that heat will be carried along the conductor. Both the Peltier and Thompson effects occur simultaneously with the Seebeck effect. However, the Peltier and Thompson effects are so minuscule that they can be disregarded.

Table 84.3 *Typical Temperature Ranges of Thermocouple Materials*[a]

materials	ANSI designation	useful range, °F (°C)
copper-constantan	T	−300 to 700 (−180 to 370)
chromel-constantan	E	32 to 1600 (0 to 870)
iron-constantan[b]	J	32 to 1400 (0 to 760)

[a] Actual values will depend on wire gauge, atmosphere (oxidizing or reducing), use (continuous or intermittent), and manufacturer.
[b] Nonoxidizing atmospheres only.
[c] Approximate usable temperature range. Error limit range is less.

the voltage generated, one metal is known as the *positive element* while the other is the *negative element.* The generated voltage is small, and thermocouples are calibrated in μV/°F or μV/°C. An amplifier may be required to provide usable signal levels, although thermocouples can be connected in series (a *thermopile*) to increase the value.[19] The accuracy (referred to as the *calibration*) of thermocouples is approximately 1/2 to 3/4%, though manufacturers produce thermocouples with various guaranteed accuracies.

The voltage generated by a thermocouple is given by Eq. 84.7. Since the *thermoelectric constant*, k_T, varies with temperature, thermocouple problems are solved with published tables of total generated voltage versus temperature. (See App. 84.A.)

$$V = k_T(T - T_{\text{ref}}) \qquad 84.7$$

Generation of thermocouple voltage in a measurement circuit is governed by three laws. The *law of homogeneous circuits* states that the temperature distribution along one or both of the thermocouple leads is irrelevant. Only the junction temperatures contribute to the generated voltage.

The *law of intermediate metals* states that an intermediate length of wire placed within one leg or at the junction of the thermocouple circuit will not affect the voltage generated as long as the two new junctions are at the same temperature. This law permits the use of a measuring device, soldered connections, and extension leads.

The *law of intermediate temperatures* states that if a thermocouple generates voltage V_1 when its junctions are at T_1 and T_2, and it generates voltage V_2 when its junctions are at T_2 and T_3, then it will generate voltage $V_1 + V_2$ when its junctions are at T_1 and T_3.

Example 84.2

A type-K (chromel-alumel) thermocouple produces a voltage of 10.79 mV. The "cold" junction is kept at 32°F (0°C) by an ice bath. What is the temperature of the hot junction?

Solution

Since the cold junction temperature corresponds to the reference temperature, the hot junction temperature is read directly from App. 84.A as 510°F.

Example 84.3

A type-K (chromel-alumel) thermocouple produces a voltage of 10.87 mV. The "cold" junction is at 70°F. What is the temperature of the hot junction?

Solution

Use the law of intermediate temperatures. From App. 84.A, the thermoelectric constant for 70°F is 0.84 mV. If the cold junction had been at 32°C, the generated voltage would have been higher. The corrected reading is

$$10.87 \text{ mV} + 0.84 \text{ mV} = 11.71 \text{ mV}$$

The temperature corresponding to this voltage is 550°F.

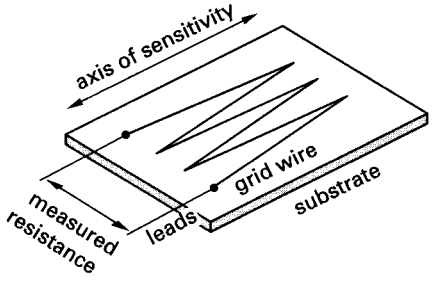
Example 84.4

A type-T (copper-constantan) thermocouple is connected directly to a voltage meter. The temperature of the meter's screw-terminals is measured by a nearby thermometer as 70°F. The thermocouple generates 5.262 mV. What is the temperature of its hot junction?

Solution

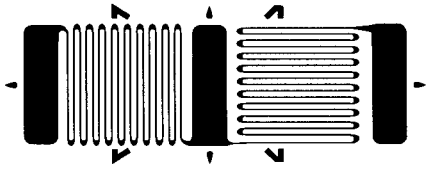
There are two connections at the meter. However, both connections are at the same temperature, so the meter can be considered to be a length of different wire, and the law of intermediate metals applies. Since the meter connections are not at 32°F, the law of intermediate temperatures applies. The corrected voltage is

$$5.262 \text{ mV} + 0.832 \text{ mV} = 6.094 \text{ mV}$$



From App. 84.A, 6.094 mV corresponds to 280°F.

[19] There is no special name for a combination of thermocouples connected in parallel.



18. STRAIN GAGES

A *bonded strain gage* is a metallic resistance device that is cemented to the surface of the unstressed member.[20] The gage consists of a metallic conductor (known as the *grid*) on a backing (known as the *substrate*).[21] The substrate and grid experience the same strain as the surface of the member. The resistance of the gage changes as the member is stressed due to changes in conductor cross section and intrinsic changes in resistivity with strain. Temperature effects must be compensated for by the circuitry or by using a second unstrained gage as part of the bridge measurement system. (See Sec. 19.)

When simultaneous strain measurements in two or more directions are needed, it is convenient to use a commercial *rosette strain gage.* A rosette consists of two or more *grids* properly oriented for application as a single unit.

(a) folded-wire strain gage

(b) commercial two-element rosette

Figure 84.5 *Strain Gage*

The *gage factor (strain sensitivity factor)*, GF, is the ratio of the fractional change in resistance to the fractional change in length (strain) along the detecting axis of the gage. The gage factor is a function of the gage material. It can be calculated from the grid material's properties and configuration. The higher the gage factor, the greater the sensitivity of the gage. From a practical standpoint, however, the gage factor and gage resistance are provided by the gage manufacturer. Only the change in resistance is measured.

$$\mathrm{GF} = 1 + 2\nu + \frac{\dfrac{\Delta\rho}{\rho_o}}{\dfrac{\Delta L}{L_o}}$$

$$= \frac{\dfrac{\Delta R_g}{R_g}}{\dfrac{\Delta L}{L_o}}$$

$$= \frac{\dfrac{\Delta R_g}{R_g}}{\epsilon} \qquad 84.8$$

Table 84.4 *Approximate Gage Factors*[a]

material	GF
constantan	2.0
iron, soft	4.2
isoelastic	3.5
manganin	0.47
monel	1.9
nichrome	2.0
nickel	−12[b]
platinum	4.8
platinum-iridium	5.1

[a]Other properties of strain gage materials are listed in Table 84.2.
[b]Value depends on amount of preprocessing and cold working.

Constantan and isoelastic wires along with metal foil with gage factors of approximately 2 and initial resistances of less than 1000 Ω (typically 120 Ω, 350 Ω, 600 Ω, and 700 Ω) are commonly used. In practice, the gage factor and initial gage resistance, R_g, are specified by the manufacturer of the gage. Once the strain sensitivity factor is known, the strain, ϵ, can be determined from the change in resistance. Strain is often reported in units of μin/in (μm/m) and is given the name *microstrain.*

$$\epsilon = \frac{\Delta R_g}{(\mathrm{GF})R_g} \qquad 84.9$$

Theoretically, a strain gage should not respond to strain in its transverse direction. However, the turn-around end-loops are also made of strain-sensitive material, and the end-loop material contributes to a nonzero sensitivity to strain in the transverse direction. Equation 84.10 defines the *transverse sensitivity factor*, K_t, which is of academic interest in most problems. The transverse sensitivity factor is seldom greater than 2%.

$$K_t = \frac{(\mathrm{GF})_{\text{transverse}}}{(\mathrm{GF})_{\text{longitudinal}}} \qquad 84.10$$

[20]A *bonded strain gage* is constructed by bonding the conductor to the surface of the member. An *unbonded strain gage* is constructed by wrapping the conductor tightly around the member or between two points on the member.

Strain gages on rotating shafts are usually connected through *slip rings* to the measurement circuitry.

[21]The grids of strain gages were originally of the folded-wire variety. For example, nichrome wire with a total resistance under 1000 Ω was commonly used. Modern strain gages are generally of the foil type manufactured by printed circuit techniques. Semiconductor gages are also used when extreme sensitivity (i.e., gage factors in excess of 100) is required. However, semiconductor gages are extremely temperature-sensitive.

Example 84.5

A strain gage with a nominal resistance of 120 Ω and gage factor of 2.0 is used to measure a strain of 1 μin/in. What is the change in resistance?

Solution

From Eq. 84.9,

$$\Delta R_g = (\mathrm{GF}) R_g \epsilon$$
$$= (2.0)(120\ \Omega)\left(1 \times 10^{-6}\ \frac{\text{in}}{\text{in}}\right) = 2.4 \times 10^{-4}\ \Omega$$

19. WHEATSTONE BRIDGES

The *Wheatstone bridge* shown in Fig. 84.6 is one type of *resistance bridge.*[22] The bridge can be used to determine the unknown resistance of a resistance transducer (e.g., thermistor or resistance-type strain gage), say R_1 in Fig. 84.6. The potentiometer is adjusted (i.e., the bridge is "balanced") until no current flows through the meter or until there is no voltage across the meter (hence the name *null indicator*).[23,24] When the bridge is balanced and no current flows through the meter leg, Eqs. 84.11 through 84.14 are applicable.

$$I_2 = I_4 \quad \text{[balanced]} \qquad 84.11$$
$$I_1 = I_3 \quad \text{[balanced]} \qquad 84.12$$
$$V_1 + V_3 = V_2 + V_4 \quad \text{[balanced]} \qquad 84.13$$
$$\frac{R_1}{R_2} = \frac{R_3}{R_4} \quad \text{[balanced]} \qquad 84.14$$

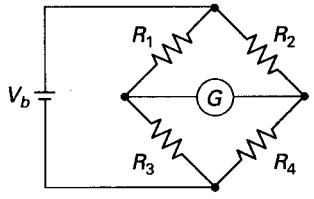


Figure 84.6 *Series-Balance Wheatstone Bridge*

Since any one of the four resistances can be the unknown, up to three of the remaining resistances can be fixed or adjustable, and the battery and meter can be connected to either of two diagonal corners, it is sometimes confusing to apply Eq. 84.14 literally. However, the following bridge law statement can be used to help formulate the proper relationship: *When a series Wheatstone bridge is null-balanced, the ratio of resistance of any two adjacent arms equals the ratio of resistance of the remaining two arms, taken in the same sense.* In this statement, "taken in the same sense" means that both ratios must be formed reading either left to right, right to left, top to bottom, or bottom to top.

20. STRAIN GAGE DETECTION CIRCUITS

The resistance of a strain gage can be measured by placing the gage in either a ballast circuit or bridge circuit. A *ballast circuit* consists of a voltage source (V_b) of less than 10 V (typical), a current-limiting ballast resistance (R_b), and the strain gage of known resistance (R_g) in series. This is essentially a voltage-divider circuit. (See Chap. 83.) The change in voltage (ΔV_g) across the strain gage is measured. The strain (ϵ) can be determined from Eq. 84.15.

$$\Delta V_g = \frac{(\mathrm{GF})\epsilon V_b R_b R_g}{(R_b + R_g)^2} \qquad 84.15$$

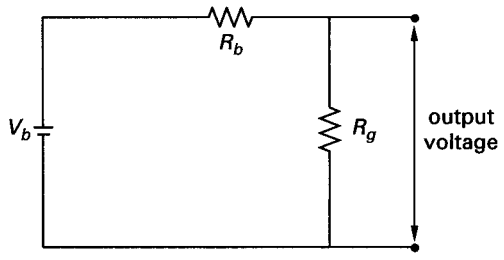

Figure 84.7 *Ballast Circuit*

Ballast circuits do not provide temperature compensation, nor is their sensitivity adequate for measuring static strain. Ballast circuits, where used, are often limited to measurement of transient strains. A bridge detection circuit overcomes these limitations.

Figure 84.8 illustrates how a strain gage can be used with a resistance bridge. Gage 1 measures the strain, while *dummy gage* 2 provides temperature compensation.[25] The meter voltage is a function of the input (battery) voltage and the resistors. (As with bridge circuits, the input voltage is typically less than 10 V.) The variable resistance is used for balancing the bridge prior to the strain. When the bridge is balanced, V_{meter} is zero.

When the gage is strained, the bridge becomes unbalanced. Assuming the bridge is initially balanced, the voltage at the meter (known as the *voltage deflection*

[22]Other types of resistance bridges are the *differential series balance bridge, shunt balance bridge,* and *differential shunt balance bridge.* These differ in the manner in which the adjustable resistor is incorporated into the circuit.

[23]This gives rise to the alternate names of *zero-indicating bridge* and *null-indicating bridge.*

[24]The unknown resistance can also be determined from the amount of voltage unbalance shown by the meter reading, in which case, the bridge is known as a *deflection bridge* rather than a null-indicating bridge. Deflection bridges are described in Sec. 20.

[25]This is a "quarter-bridge" or "1/4-bridge" configuration, as described in Sec. 22. The strain gage used for temperature compensation is not active.

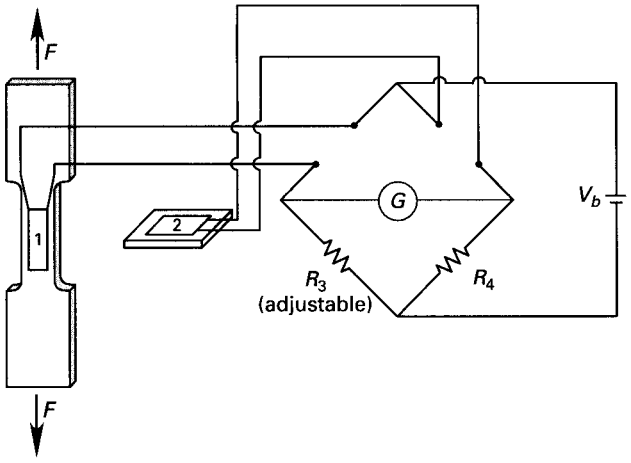

Figure 84.8 *Strain Gage in Resistance Bridge*

from the null condition) will be[26]

$$V_{\text{meter}} = V_b\left(\frac{R_1}{R_1+R_3} - \frac{R_2}{R_2+R_4}\right) \quad [\tfrac{1}{4}\text{-bridge}] \qquad 84.16$$

For a single strain gage in a resistance bridge and neglecting lead resistance, the voltage deflection is related to the strain by Eq. 84.17.

$$V_{\text{meter}} = \frac{(\text{GF})\epsilon V_b}{4+2(\text{GF})\epsilon} \approx \tfrac{1}{4}(\text{GF})\epsilon V_b \quad [\tfrac{1}{4}\text{-bridge}] \qquad 84.17$$

21. STRAIN GAGE IN UNBALANCED RESISTANCE BRIDGE

A resistance bridge does not need to be balanced prior to use as long as an accurate digital voltmeter is used in the detection circuit. The voltage ratio difference, ΔVR, is defined as the fractional change in the output voltage from the unstrained to the strained condition.

$$\Delta\text{VR} = \left(\frac{V_{\text{meter}}}{V_b}\right)_{\text{strained}} - \left(\frac{V_{\text{meter}}}{V_b}\right)_{\text{unstrained}} \qquad 84.18$$

If the only resistance change between the strained and unstrained conditions is in the strain gage and lead resistance is disregarded, the fractional change in gage resistance for a single strain gage in a resistance bridge is

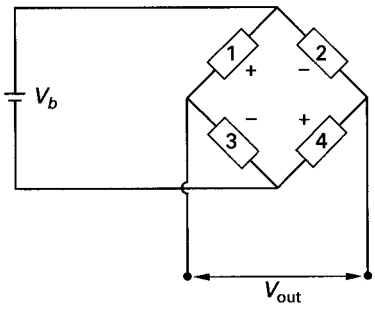
$$\frac{\Delta R_g}{R_g} = \frac{-4\Delta(\text{VR})}{1+2\Delta(\text{VR})} \quad [\tfrac{1}{4}\text{-bridge}] \qquad 84.19$$

Since the fractional change in gage resistance also occurs in the definition of the gage factor (Eq. 84.9), the strain is

$$\epsilon = \frac{-4\Delta\text{VR}}{(\text{GF})(1+2\Delta\text{VR})} \quad [\tfrac{1}{4}\text{-bridge}] \qquad 84.20$$

[26]Equation 84.16 applies to the unstrained condition as well. However, if the gage is unstrained and the bridge is balanced, the bracketed resistance term is zero.

22. BRIDGE CONSTANT



The voltage deflection can be doubled (or quadrupled) by using two (or four) strain gages in the bridge circuit. The larger voltage deflection is more easily detected, resulting in more accurate measurements.

Use of multiple strain gages is generally limited to configurations where symmetrical strain is available on the member. For example, a beam in bending experiences the same strain on the top and bottom faces. Therefore, if the temperature-compensation strain gage shown in Fig. 84.8 is bonded to the bottom of the beam, the resistance change would double.

The *bridge constant* (BC) is the ratio of the actual voltage deflection to the voltage deflection from a single gage. Depending on the number and orientation of the gages used, bridge constants of 1.0, 1.3, 2.0, 2.6, and 4.0 may be encountered (for materials with a Poisson's ratio of 0.3).

Figure 84.9 illustrates how (up to) four strain gages can be connected in a Wheatstone bridge circuit. The total strain indicated will be the algebraic sum of the four strains detected. For example, if all four strains are equal in magnitude, ϵ_1 and ϵ_4 are tensile (i.e., positive), and ϵ_2 and ϵ_3 are compressive (i.e., negative), then the bridge constant would be 4.

$$\epsilon_t = \epsilon_1 - \epsilon_2 - \epsilon_3 + \epsilon_4 \qquad 84.21$$

[a]The 45° orientations shown are figurative. Actual gage orientation can be in any direction.

Figure 84.9 *Wheatstone Bridge Strain Gage Circuit*[a]

23. STRESS MEASUREMENTS IN KNOWN DIRECTIONS

Strain gages are the most frequently used method of determining stress in a member. Stress can be calculated from strain, or the measurement circuitry can be calibrated to give the stress directly.

For stress in only one direction (i.e., the *uniaxial stress* case), such as a simple bar in tension, only one strain gage is required. The stress can be calculated from *Hooke's law.*

$$\sigma = E\epsilon \qquad 84.22$$

When a surface, such as that of a pressure vessel, experiences simultaneous stresses in two directions (the *biaxial stress* case), the strain in one direction affects the strain in the other direction.[27] Therefore, two strain gages are needed, even if the stress in only one direction is needed. The strains actually measured by the gages are known as the *net strains.*

$$\epsilon_x = \frac{\sigma_x - \nu\sigma_y}{E} \qquad 84.23$$

$$\epsilon_y = \frac{\sigma_y - \nu\sigma_x}{E} \qquad 84.24$$

The stresses are determined by solving Eqs. 84.23 and 84.24 simultaneously.

$$\sigma_x = \frac{E(\epsilon_x + \nu\epsilon_y)}{1 - \nu^2} \qquad 84.25$$

$$\sigma_y = \frac{E(\epsilon_y + \nu\epsilon_x)}{1 - \nu^2} \qquad 84.26$$

Figure 84.9 shows how four strain gages can be interconnected in a bridge circuit. Figure 84.10 shows how (up to) four strain gages would be physically oriented on a test specimen to measure different types of stress. Not all four gages are needed in all cases. If four gages are used, the arrangement is said to be a *full bridge.* If only one or two gages are used, the terms *quarter-bridge* (1/4-bridge) and *half-bridge* (1/2-bridge), respectively, apply.

In the case of up to four gages applied to detect bending strain (Fig. 84.10(a)), the bridge constant (BC) can be 1.0 (one gage in position 1), 2.0 (two gages in positions 1 and 2), or 4.0 (all four gages). The relationships between the stress, strain, and applied force are

$$\sigma = E\epsilon = \frac{E\epsilon_t}{\text{BC}} \qquad 84.27$$

$$\sigma = \frac{Mc}{I} = \frac{Mh}{2I} \qquad 84.28$$

$$I = \frac{bh^3}{12} \quad \text{[rectanglar section]} \qquad 84.29$$

For axial strain (Fig. 84.10(b)) and a material with a Poisson's ratio of 0.3, the bridge constant can be 1.0 (one gage in position 1), 1.3 (two gages in positions 1 and 2), 2.0 (two gages in positions 1 and 3), or 2.6 (all four gages).

$$\sigma = E\epsilon = \frac{E\epsilon_t}{\text{BC}} \qquad 84.30$$

$$\sigma = \frac{F}{A} \qquad 84.31$$

$$A = bh \quad \text{[rectanglular section]} \qquad 84.32$$

[27] Thin-wall pressure vessel theory shows that the hoop stress is twice the longitudinal stress. However, the ratio of circumferential to longitudinal strains is closer to 4:1 than to 2:1.

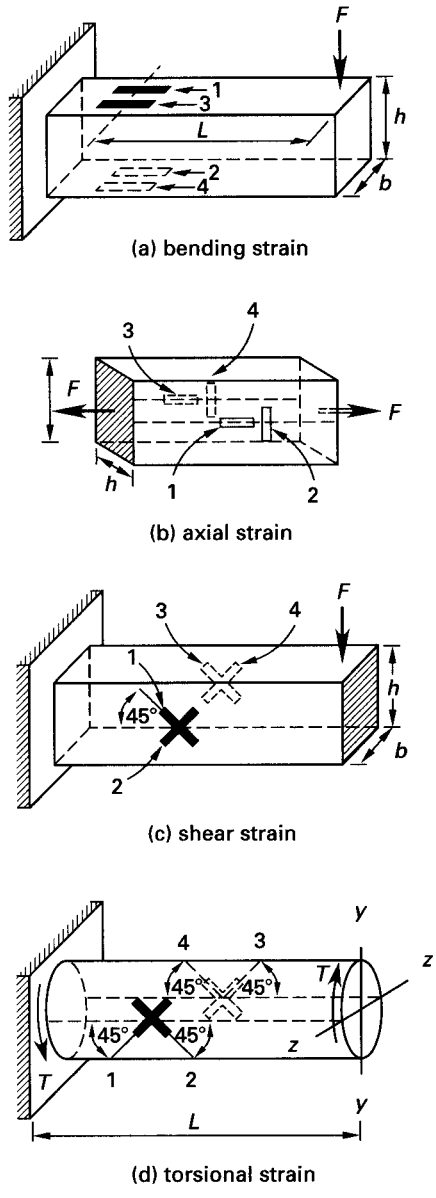


Figure 84.10 *Orientation of Strain Gages*

For shear strain (Fig. 84.10(c)) and a material with a Poisson's ratio of 0.3, the bridge constant can be 2.0 (two gages in positions 1 and 2) or 4.0 (all four gages). The shear strain is twice the axial strain at 45°.

$$\tau = G\gamma = 2G\epsilon = \frac{2G\epsilon_t}{\text{BC}} \qquad 84.33$$

$$\tau = \frac{FQ}{bI} \qquad 84.34$$

$$\gamma = 2\epsilon \quad \text{[at 45°]} \qquad 84.35$$

$$Q_{\max} = \frac{bh^2}{8} \quad \text{[rectanglar section]} \qquad 84.36$$

$$G = \frac{E}{2(1+\nu)} \qquad 84.37$$

Systems, Mgmt., and Professional

For torsional strain (Fig. 84.10(d)) and a material with a Poisson's ratio of 0.3, the bridge constant can be 2.0 (two gages in positions 1 and 2) or 4.0 (all four gages). The shear strain is twice the axial strain at 45°.

$$\tau = G\gamma = 2G\epsilon = \frac{2G\epsilon_t}{\mathrm{BC}} \qquad 84.38$$

$$\tau = \frac{Tr}{J} = \frac{Td}{2J} \qquad 84.39$$

$$\gamma = 2\epsilon \quad [\text{at } 45°] \qquad 84.40$$

$$J = \frac{\pi d^4}{32} \quad [\text{solid circular}] \qquad 84.41$$

$$\phi = \frac{TL}{JG} \qquad 84.42$$

$$G = \frac{E}{2(1+\nu)} \qquad 84.43$$

24. STRESS MEASUREMENTS IN UNKNOWN DIRECTIONS

In order to calculate the maximum stresses (i.e., the principal stresses) on the surface shown in Sec. 23, the gages were oriented in the known directions of the principal stresses.

In most cases, however, the directions of the principal stresses are not known. Therefore, rosettes of at least three gages are used to obtain information in a third direction. Rosettes of three gages (*rectangular* and *equiangular (delta) rosettes*) are used for this purpose. *T-delta rosettes* include a fourth strain gage to refine and validate the results of the three primary gages. Table 84.5 can be used to calculate the principal stresses.

25. LOAD CELLS

Load cells are used to measure force. A load cell is a transducer that converts a tensile or compressive force into an electrical signal. Though the details of the load cell vary with the application, the basic elements are (a) a member that is strained by the force and (b) a strain detection system (e.g., strain gage). The force is calculated from the observed deflection, y. In Eq. 84.44, the spring constant, k, is known as the load cell's *deflection constant.*

$$F = ky \qquad 84.44$$

Because of their low cost and simple construction, *bending beam load cells* are the most common variety of load cell. Two strain gages, one on the top and the other mounted on the bottom of a cantilever bar, are used. *Shear beam load cells* (which detect force by measuring the shear stress) can be used where the shear does not vary considerably with location, as in the web of an I-beam cross section.[28] The common S-shaped load cell constructed from a machined steel block can be instrumented as either a bending beam or shear beam load cell.

Load cell applications are categorized into classes, with class III (using a single load cell) being the most common. Commercial load cells meet standardized limits on errors due to temperature, nonlinearity, and hysteresis. The *temperature effect on output* (TEO) is typically stated in percentage change per 100°F (55.5°C) change in temperature.

Nonlinearity errors are reduced in proportion to the load cell's derating (i.e., using the load cell to measure forces less than its rated force). For example, a 2:1 derating will reduce the nonlinearity errors by 50%. Hysteresis is not normally reduced by derating.

The overall error of force measurement can be reduced by a factor of $1/\sqrt{n}$ (where n is the number of load cells that share the load equally) by using more than one load cell. Conversely, the applied force can vary by $\sqrt{n}$ times the known accuracy of a single load cell without decreasing the error.

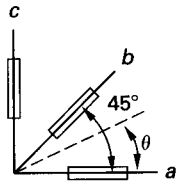
26. DYNAMOMETERS

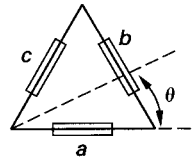
Torque from large motors and engines is measured by a *dynamometer. Absorption dynamometers* (e.g., the simple *friction brake, Prony brake, water brake,* and *fan brake*) dissipate energy as the torque is measured. Opposing torque in pumps and compressors must be supplied by a *driving dynamometer*, which has its own power input. *Transmission dynamometers* (e.g., *torque meters, torsion dynamometers*) use strain gages to sense torque. They do not absorb or provide energy.

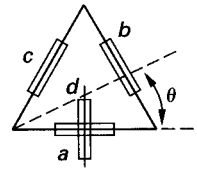
Using a brake dynamometer involves measuring a force, a moment arm, and the angular speed of rotation. The familiar torque-power-speed relationships are used with absorption dynamometers.

$$T = Fr \qquad 84.45$$

$$P_{\text{ft-lbf/min}} = 2\pi T_{\text{ft-lbf}} n_{\text{rpm}} \qquad 84.46$$







$$P_{\text{kW}} = \frac{T_{\text{N·m}} n_{\text{rpm}}}{9549} \quad [\text{SI}] \qquad 84.47(a)$$

$$P_{\text{hp}} = \frac{2\pi F_{\text{lbf}} r_{\text{ft}} n_{\text{rpm}}}{33{,}000} = \frac{2\pi T_{\text{ft-lbf}} n_{\text{rpm}}}{33{,}000} \quad [\text{U.S.}] \qquad 84.47(b)$$

[28] While shear in a rectangular beam varies parabolically with distance from the neutral axis, shear in the web of an I-beam is essentially constant at F/A. The flanges carry very little of the shear load.

Other advantages of the shear beam load cell include protection from the load and environment, high side load rejection, lower creep, faster RTZ (return to zero) after load removal, and higher tolerance of vibration, dynamic forces, and noise.

Table 84.5 *Stress-Strain Relationships for Strain Gage Rosettes*[a]

type of rosette	 rectangular	 equiangular (delta)	 *T*-delta
principal strains, ϵ_p, ϵ_q	$\frac{1}{2}\left(\epsilon_a + \epsilon_c \pm \sqrt{2(\epsilon_a - \epsilon_b)^2 + 2(\epsilon_b - \epsilon_c)^2}\right)$	$\frac{1}{3}\left(\epsilon_a + \epsilon_b + \epsilon_c \pm \sqrt{2(\epsilon_a - \epsilon_b)^2 + 2(\epsilon_b - \epsilon_c)^2 + 2(\epsilon_c - \epsilon_a)^2}\right)$	$\frac{1}{2}\left(\epsilon_a + \epsilon_d \pm \sqrt{(\epsilon_a - \epsilon_d)^2 + \left(\frac{4}{3}\right)(\epsilon_b - \epsilon_c)^2}\right)$
principal stresses, σ_1, σ_2	$\left(\frac{E}{2}\right)\left(\frac{\epsilon_a + \epsilon_c}{1-\nu} \pm \frac{1}{1+\nu} \times \sqrt{2(\epsilon_a - \epsilon_b)^2 + 2(\epsilon_b - \epsilon_c)^2}\right)$	$\left(\frac{E}{3}\right)\left(\frac{\epsilon_a + \epsilon_b + \epsilon_c}{1-\nu} \pm \frac{1}{1+\nu} \times \sqrt{2(\epsilon_a - \epsilon_b)^2 + 2(\epsilon_b - \epsilon_c)^2 + 2(\epsilon_c - \epsilon_a)^2}\right)$	$\left(\frac{E}{2}\right)\left(\frac{\epsilon_a + \epsilon_d}{1-\nu} \pm \frac{1}{1+\nu} \times \sqrt{(\epsilon_a - \epsilon_d)^2 + \left(\frac{4}{3}\right)(\epsilon_b - \epsilon_c)^2}\right)$
maximum shear, τ_{max}	$\left(\frac{E}{2(1+\nu)}\right) \times \sqrt{2(\epsilon_a - \epsilon_b)^2 + 2(\epsilon_b - \epsilon_c)^2}$	$\left(\frac{E}{3(1+\nu)}\right) \times \sqrt{2(\epsilon_a - \epsilon_b)^2 + 2(\epsilon_b - \epsilon_c)^2 + 2(\epsilon_c - \epsilon_a)^2}$	$\left(\frac{E}{2(1+\nu)}\right) \times \sqrt{(\epsilon_a - \epsilon_d)^2 + \left(\frac{4}{3}\right)(\epsilon_b - \epsilon_c)^2}$
$\tan 2\theta^b$	$\frac{2\epsilon_b - \epsilon_a - \epsilon_c}{\epsilon_a - \epsilon_c}$	$\frac{\sqrt{3}(\epsilon_c - \epsilon_b)}{2\epsilon_a - \epsilon_b - \epsilon_c}$	$\left(\frac{2}{\sqrt{3}}\right)\left(\frac{\epsilon_c - \epsilon_b}{\epsilon_a - \epsilon_d}\right)$
$0 < \theta < +90°$	$\epsilon_b > \frac{\epsilon_a + \epsilon_c}{2}$	$\epsilon_c > \epsilon_b$	$\epsilon_c > \epsilon_b$

[a] θ is measured in the counterclockwise direction from the a-axis of the rosette to the axis of the algebraically larger stress.
[b] θ is the angle from gage A axis to axis of maximum normal stress.

Some brakes and dynamometers are constructed with a "standard" brake arm whose length is 5.252 ft. In that case, the horsepower calculation conveniently reduces to

$$P_{\text{hp}} = \frac{F_{\text{lbf}} n_{\text{rpm}}}{1000} \quad \text{["standard arm" brake]} \qquad 84.48$$

If an absorption dynamometer uses a DC generator to dissipate energy, the generated voltage (V in volts) and line current (I in amps) are used to determine the power. Equations 84.47 and 84.48 are used to determine the torque.

$$P_{\text{hp}} = \frac{IV}{\eta\left(1000\ \frac{\text{W}}{\text{kW}}\right)\left(0.7457\ \frac{\text{W}}{\text{hp}}\right)} \quad \text{[absorption]} \qquad 84.49$$

For a driving dynamometer using a DC motor,

$$P_{\text{hp}} = \frac{IV\eta}{\left(1000\ \frac{\text{W}}{\text{kW}}\right)\left(0.7457\ \frac{\text{W}}{\text{hp}}\right)} \quad \text{[driving]} \qquad 84.50$$

Torque can be measured directly by a *torque meter* mounted to the power shaft. Either the angle of twist (ϕ) or the shear strain (τ/G) are measured. The torque in a solid shaft of diameter d and length L is

$$T = \frac{JG\phi}{L} = \left(\frac{\pi}{32}\right) d^4 \left(\frac{G\phi}{L}\right) = \left(\frac{\pi}{16}\right) d^3 \tau \quad \text{[solid round]} \qquad 84.51$$

27. INDICATOR DIAGRAMS

Indicator diagrams are plots of pressure versus volume and are encountered in the testing of reciprocating engines. In the past, indicator diagrams were actually drawn on an *indicator card* wrapped around a drum through a mechanical linkage of arms and springs. This method is mechanically complex and is not suitable for rotational speeds above 2000 rpm. Modern records of pressure and volume are produced by signals from electronic transducers recorded in real time by computers.

Analysis of indicator diagrams produced by mechanical devices requires knowing the spring constant, also known as the *spring scale*. The *mean effective pressure* (MEP) is calculated by dividing the area of the diagram by the width of the plot and then multiplying by the spring constant.

n	at time n
t	at time t

1. IRRELEVANT CHARACTERISTICS

In its simplest form, an *engineering economic analysis* is a study of the desirability of making an investment.[1] The decision-making principles in this chapter can be applied by individuals as well as by companies. The nature of the spending opportunity or industry is not important. Farming equipment, personal investments, and multimillion dollar factory improvements can all be evaluated using the same principles.

Similarly, the applicable principles are largely insensitive to the monetary units. Although *dollars* are used in this chapter, it is equally convenient to use British pounds, Japanese yen, or German marks.

Finally, this chapter may give the impression that investment alternatives must be evaluated on a year-by-year basis. Actually, the *effective period* can be defined as a day, month, century, or any other convenient period of time.

2. MULTIPLICITY OF SOLUTION METHODS

Most economic conclusions can be reached in more than one manner. There are usually several different analyses that will eventually result in identical answers.[2] Other than the pursuit of elegant solutions in a timely manner, there is no reason to favor one procedural method over another.[3]

3. PRECISION AND SIGNIFICANT DIGITS

The full potential of electronic calculators will never be realized in engineering economic analyses. Considering that calculations are based on estimates of far-future cash flows and that unrealistic assumptions (no inflation, identical cost structures of replacement assets, etc.) are routinely made, it makes little sense to carry cents along in calculations.

The calculations in this chapter have been designed to illustrate and review the principles presented. Because of this, greater precision than is normally necessary in everyday problems may be used. Though used, such precision is not warranted.

Unless there is some compelling reason to strive for greater precision, the following rules are presented for use in reporting final answers to engineering economic analysis problems.

- Omit fractional parts of the dollar (i.e., cents).
- Report and record a number to a maximum of four significant digits unless the first digit of that number is 1, in which case, a maximum of five significant digits should be written. For example,

\$49	not	\$49.43
\$93,450	not	\$93,453
\$1,289,700	not	\$1,289,673

4. NONQUANTIFIABLE FACTORS

An engineering economic analysis is a quantitative analysis. Some factors cannot be introduced as numbers into the calculations. Such factors are known as *nonquantitative factors, judgment factors*, and *irreducible factors.* Typical nonquantifiable factors are

- preferences
- political ramifications
- urgency
- goodwill
- prestige
- utility
- corporate strategy
- environmental effects
- health and safety rules
- reliability
- political risks

[1] This subject is also known as *engineering economics* and *engineering economy.* There is very little, if any, true economics in this subject.

[2] Because of round-off errors, particularly when factors are taken from tables, these different calculations will produce slightly different numerical results (e.g., \$49.49 versus \$49.50). However, this type of divergence is well known and accepted in engineering economic analysis.

[3] This does not imply that approximate methods, simplifications, and rules of thumb are acceptable.

Since these factors are not included in the calculations, the policy is to disregard the issues entirely. Of course, the factors should be discussed in a final report. The factors are particularly useful in breaking ties between competing alternatives that are economically equivalent.

5. YEAR-END CONVENTION

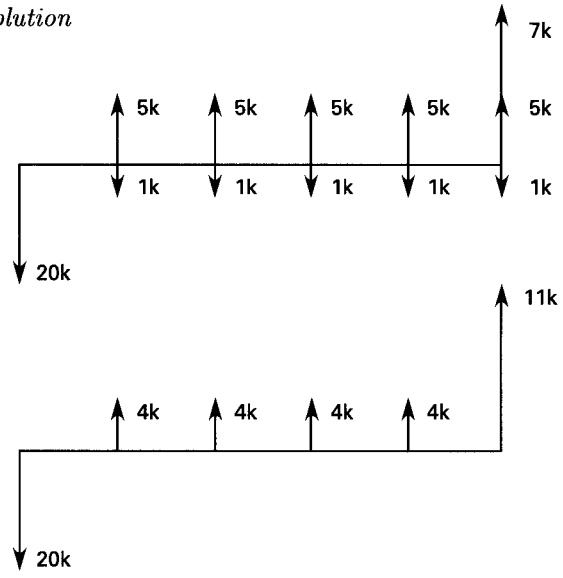
Except in short-term transactions, it is simpler to assume that all receipts and disbursements (cash flows) take place at the end of the year in which they occur.[4] This is known as the *year-end convention.* The exceptions to the year-end convention are initial project cost (purchase cost), trade-in allowance, and other cash flows that are associated with the inception of the project at $t = 0$.

On the surface, such a convention appears grossly inappropriate since repair expenses, interest payments, corporate taxes, and so on seldom coincide with the end of a year. However, the convention greatly simplifies engineering economic analysis problems, and it is justifiable on the basis that the increased precision associated with a more rigorous analysis is not warranted (due to the numerous other simplifying assumptions and estimates initially made in the problem).

There are various established procedures, known as *rules* or *conventions*, imposed by the Internal Revenue Service on U.S. taxpayers. An example is the *half-year rule*, which permits only half of the first-year depreciation to be taken in the first year of an asset's life when certain methods of depreciation are used. These rules are subject to constantly changing legislation and are not covered in this book. The implementation of such rules is outside the scope of engineering practice and is best left to accounting professionals.

6. CASH FLOW DIAGRAMS

Although they are not always necessary in simple problems (and they are often unwieldy in very complex problems), *cash flow diagrams* can be drawn to help visualize and simplify problems having diverse receipts and disbursements.



The following conventions are used to standardize cash flow diagrams.

- The horizontal (time) axis is marked off in equal increments, one per period, up to the duration (or *horizon*) of the project.
- Two or more transfers in the same period are placed end-to-end, and these may be combined.
- Expenses incurred before $t = 0$ are called *sunk costs.* Sunk costs are not relevant to the problem unless they have tax consequences in an after-tax analysis.
- *Receipts* are represented by arrows directed upward. *Disbursements* are represented by arrows directed downward. The arrow length is proportional to the magnitude of the cash flow.

Example 85.1

A mechanical device will cost \$20,000 when purchased. Maintenance will cost \$1000 each year. The device will generate revenues of \$5000 each year for five years, after which the salvage value is expected to be \$7000. Draw and simplify the cash flow diagram.

Solution

7. TYPES OF CASH FLOWS

To evaluate a real-world project, it is necessary to present the project's cash flows in terms of standard cash flows that can be handled by engineering economic analysis techniques. The standard cash flows are single payment cash flow, uniform series cash flow, gradient series cash flow, and the infrequently encountered exponential gradient series cash flow.

A *single payment cash flow* can occur at the beginning of the time line (designated as $t = 0$), at the end of the time line (designated as $t = n$), or at any time in between.

The *uniform series cash flow* consists of a series of equal transactions starting at $t = 1$ and ending at $t = n$. The symbol A is typically given to the magnitude of each individual cash flow.[5]

[4] A *short-term transaction* typically has a lifetime of five years or less and has payments or compounding that are more frequent than once per year.

[5] Notice that the cash flows do not begin at $t = 0$. This is an important concept with all of the series cash flows. This convention has been established to accommodate the timing of annual maintenance (and similar) cash flows for which the year-end convention is applicable.

The *gradient series cash flow* starts with a cash flow (typically given the symbol G) at $t = 2$ and increases by G each year until $t = n$, at which time the final cash flow is $(n - 1)G$.

An *exponential gradient series cash flow* is based on a phantom value (typically given the symbol E_0) at $t = 0$ and grows or decays exponentially according to the following relationship.[6]

$$\text{amount at time } t = E_t = E_0(1+g)^t \quad [t = 1, 2, 3, \ldots, n] \quad 85.1$$

In Eq. 85.1, g is the *exponential growth rate*, which can be either positive or negative. Exponential gradient cash flows are rarely seen in economic justification projects assigned to engineers.[7]

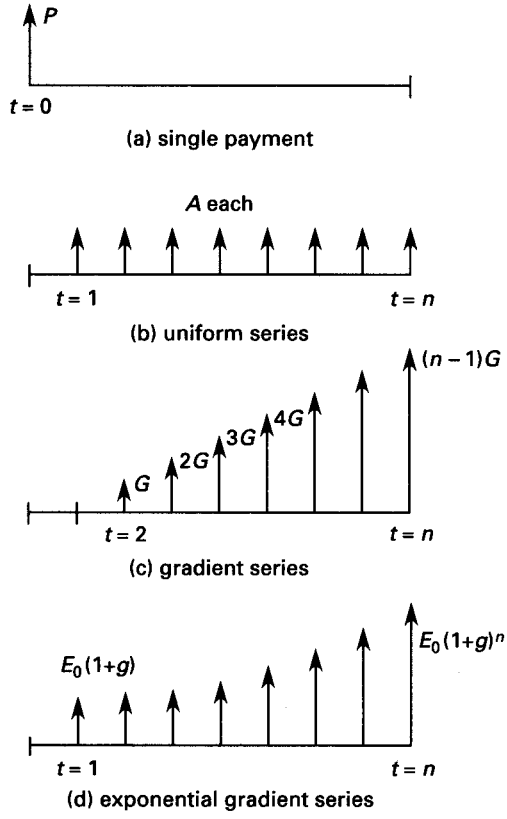


Figure 85.1 *Standard Cash Flows*

8. TYPICAL PROBLEM TYPES

There is a wide variety of problem types that, collectively, are considered to be engineering economic analysis problems.

By far, the majority of engineering economic analysis problems are *alternative comparisons*. In these problems, two or more mutually exclusive investments compete for limited funds. A variation of this is a *replacement/retirement analysis*, which is repeated each year to determine if an existing asset should be replaced. Finding the percentage return on an investment is a *rate of return problem*, one of the alternative comparison solution methods.

Investigating interest and principal amounts in loan payments is a *loan repayment problem*. An *economic life analysis* will determine when an asset should be retired. In addition, there are miscellaneous problems involving economic order quantity, learning curves, break-even points, product costs, and so on.

9. IMPLICIT ASSUMPTIONS

Several assumptions are implicitly made when solving engineering economic analysis problems. Some of these assumptions are made with the knowledge that they are or will be poor approximations of what really will happen. The assumptions are made, regardless, for the benefit of obtaining a solution.

The most common assumptions are the following.

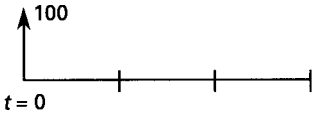
- The year-end convention is applicable.
- There is no inflation now, nor will there be any during the lifetime of the project.
- Unless otherwise specifically called for, a before-tax analysis is needed.
- The effective interest rate used in the problem will be constant during the lifetime of the project.
- Nonquantifiable factors can be disregarded.
- Funds invested in a project are available and are not urgently needed elsewhere.
- Excess funds continue to earn interest at the effective rate used in the analysis.

This last assumption, like most of the assumptions listed, is almost never specifically mentioned in the body of a solution. However, it is a key assumption when comparing two alternatives that have different initial costs.

For example, suppose two investments, one costing \$10,000 and the other costing \$8000, are to be compared at 10%. It is obvious that \$10,000 in funds is available, otherwise the costlier investment would not be under consideration. If the smaller investment is chosen, what is done with the remaining \$2000? The last assumption yields the answer: the \$2000 is "put to work" in some investment earning (in this case) 10%.

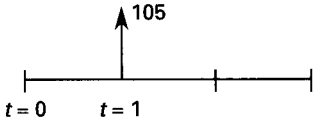
[6]Notice the convention for an exponential cash flow series: The first cash flow E_0 is at $t = 1$, as in the uniform annual series. However, the first cash flow is $E_0(1 + g)$. The cash flow of E_0 at $t = 0$ is absent (i.e., is a *phantom cash flow*).

[7]For one of the few discussions on exponential cash flow, see *Capital Budgeting*, Robert V. Oakford, The Ronald Press Company, New York, 1970.



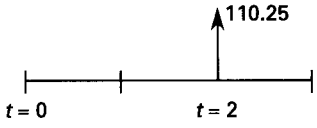
10. EQUIVALENCE

Industrial decision makers using engineering economic analysis are concerned with the magnitude and timing of a project's cash flow as well as with the total profitability of that project. In this situation, a method is required to compare projects involving receipts and disbursements occurring at different times.



By way of illustration, consider \$100 placed in a bank account that pays 5% effective annual interest at the end of each year. After the first year, the account will have grown to \$105. After the second year, the account will have grown to \$110.25.

Assume that you will have no need for money during the next two years, and any money received will immediately go into your 5% bank account. Then, which of the following options would be more desirable?



option a: \$100 now

option b: \$105 to be delivered in one year.

option c: \$110.25 to be delivered in two years

As illustrated, none of the options is superior under the assumptions given. If the first option is chosen, you will immediately place \$100 into a 5% account, and in two years the account will have grown to \$110.25. In fact, the account will contain \$110.25 at the end of two years regardless of the option chosen. Therefore, these alternatives are said to be *equivalent.*

Equivalence may or may not be the case, depending on the interest rate. Thus, an alternative that is acceptable to one decision maker may be unacceptable to another. The interest rate that is used in actual calculations is known as the *effective interest rate.*[8] If compounding is once a year, it is known as the *effective annual interest rate.* However, effective quarterly, monthly, daily, and so on, interest rates are also used.

The fact that \$100 today grows to \$105 in one year (at 5% annual interest) is an example of what is known as the *time value of money* principle. This principle simply articulates what is obvious: Funds placed in a secure investment will increase to an equivalent future amount. The procedure for determining the present investment from the equivalent future amount is known as *discounting.*

11. SINGLE-PAYMENT EQUIVALENCE

The equivalence of any present amount, P, at $t = 0$, to any future amount, F, at $t = n$, is called the *future worth* and can be calculated from Eq. 85.2.

$$F = P(1+i)^n \qquad 85.2$$

The factor $(1 + i)^n$ is known as the single payment *compound amount factor* and has been tabulated in App. 85.B for various combinations of i and n.

Similarly, the equivalence of any future amount to any present amount is called the *present worth* and can be calculated from Eq. 85.3.

$$P = F(1+i)^{-n} = \frac{F}{(1+i)^n} \qquad 85.3$$

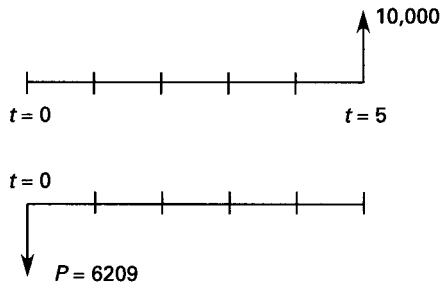
The factor $(1 + i)^{-n}$ is known as the *single payment present worth factor.*[9]

The interest rate used in Eqs. 85.2 and 85.3 must be the effective rate per period. Also, the basis of the rate (annually, monthly, etc.) must agree with the type of period used to count n. Thus, it would be incorrect to use an effective annual interest rate if n was the number of compounding periods in months.

Example 85.2

How much should you put into a 10% (effective annual rate) savings account in order to have \$10,000 in five years?

Solution



This problem could also be stated: What is the equivalent present worth of \$10,000 five years from now if money is worth 10% per year?

$$\begin{aligned} P &= F(1+i)^{-n} = (\$10{,}000)(1+0.10)^{-5} \\ &= \$6209 \end{aligned}$$

The factor 0.6209 would usually be obtained from the tables.

[8]The adjective *effective* distinguishes this interest rate from other interest rates (e.g., nominal interest rates) that are not meant to be used directly in calculating equivalent amounts.

[9]The *present worth* is also called the *present value* and *net present value.* These terms are used interchangeably and no significance should be attached to the terms *value, worth,* and *net.*

12. STANDARD CASH FLOW FACTORS AND SYMBOLS

Equations 85.2 and 85.3 may give the impression that solving engineering economic analysis problems involves a lot of calculator use, and, in particular, a lot of exponentiation. Such calculations may be necessary from time to time, but most problems are simplified by the use of tabulated values of the factors.

Rather than actually writing the formula for the compound amount factor (which converts a present amount to a future amount), it is common convention to substitute the standard functional notation of $(F/P, i\%, n)$. Thus, the future value in n periods of a present amount would be symbolically written as

$$F = P(F/P, i\%, n) \qquad 85.4$$

Similarly, the present worth factor has a functional notation of $(P/F, i\%, n)$. The present worth of a future amount n periods hence would be symbolically written as

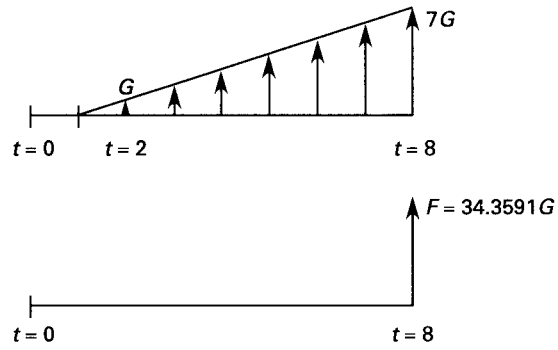
$$P = F(P/F, i\%, n) \qquad 85.5$$

Values of these *cash flow (discounting) factors* are tabulated in App. 85.B. There is often initial confusion about whether the (F/P) or (P/F) column should be used in a particular problem. There are several ways of remembering what the functional notations mean.

One method of remembering which factor should be used is to think of the factors as conditional probabilities. The conditional probability of event **A** given that event **B** has occurred is written as $p\{\mathbf{A}|\mathbf{B}\}$, where the given event comes after the vertical bar. In the standard notational form of discounting factors, the given amount is similarly placed after the slash. What you want comes before the slash. (F/P) would be a factor to find F given P.

Another method of remembering the notation is to interpret the factors algebraically. Thus, the (F/P) factor could be thought of as the fraction F/P. Algebraically, Eq. 85.4 would be

$$F = P(F/P) \qquad 85.6$$



This algebraic approach is actually more than an interpretation. The numerical values of the discounting factors are consistent with this algebraic manipulation. Thus, the (F/A) factor could be calculated as $(F/P) \times (P/A)$. This consistent relationship can be used to calculate other factors that might be occasionally needed, such as (F/G) or (G/P). For instance, the annual cash flow that would be equivalent to a uniform gradient may be found from

$$A = G(P/G, i\%, n)(A/P, i\%, n) \qquad 85.7$$

Formulas for the compounding and discounting factors are contained in Table 85.1. Normally, it will not be necessary to calculate factors from the formulas. Appendix 85.B is adequate for solving most problems.

Example 85.3

What factor will convert a gradient cash flow ending at $t = 8$ to a future value at $t = 8$? (That is, what is the $(F/G, i\%, 8)$ factor?) The effective annual interest rate is 10%.

Solution

method 1: From Table 85.1, the $(F/G, 10\%, 8)$ factor is

$$\begin{aligned}(F/G, 10\%, 8) &= \frac{(1+i)^n - 1}{i^2} - \frac{n}{i} \\ &= \frac{(1+0.10)^8 - 1}{(0.10)^2} - \frac{8}{0.10} \\ &= 34.3589\end{aligned}$$

method 2: The tabulated values of (P/G) and (F/P) in App. 85.B can be used to calculate the factor.

$$\begin{aligned}&(F/G, 10\%, 8) \\ &\quad = (P/G, 10\%, 8)(F/P, 10\%, 8) \\ &\quad = (16.0287)(2.1436) = 34.3591\end{aligned}$$

The (F/G) factor could also have been calculated as the product of the (A/G) and (F/A) factors.

Table 85.1 *Discount Factors for Discrete Compounding*

factor name	converts	symbol	formula
single payment compound amount	P to F	$(F/P, i\%, n)$	$(1+i)^n$
single payment present worth	F to P	$(P/F, i\%, n)$	$(1+i)^{-n}$
uniform series sinking fund	F to A	$(A/F, i\%, n)$	$\frac{i}{(1+i)^n - 1}$
capital recovery	P to A	$(A/P, i\%, n)$	$\frac{i(1+i)^n}{(1+i)^n - 1}$
uniform series compound amount	A to F	$(F/A, i\%, n)$	$\frac{(1+i)^n - 1}{i}$
uniform series present worth	A to P	$(P/A, i\%, n)$	$\frac{(1+i)^n - 1}{i(1+i)^n}$
uniform gradient present worth	G to P	$(P/G, i\%, n)$	$\frac{(1+i)^n - 1}{i^2(1+i)^n} - \frac{n}{i(1+i)^n}$
uniform gradient future worth	G to F	$(F/G, i\%, n)$	$\frac{(1+i)^n - 1}{i^2} - \frac{n}{i}$
uniform gradient uniform series	G to A	$(A/G, i\%, n)$	$\frac{1}{i} - \frac{n}{(1+i)^n - 1}$

13. CALCULATING UNIFORM SERIES EQUIVALENCE

A cash flow that repeats each year for n years without change in amount is known as an *annual amount* and is given the symbol A. As an example, a piece of equipment may require annual maintenance, and the maintenance cost will be an annual amount. Although the equivalent value for each of the n annual amounts could be calculated and then summed, it is more expedient to use one of the uniform series factors. For example, it is possible to convert from an annual amount to a future amount by use of the (F/A) factor.

$$F = A(F/A, i\%, n) \qquad 85.8$$

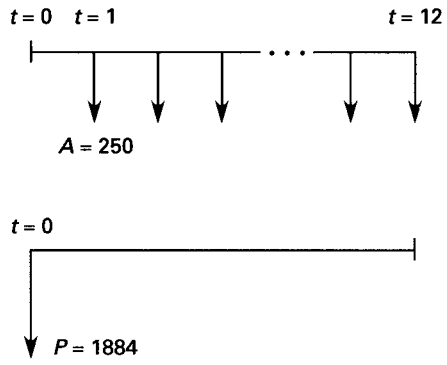
A *sinking fund* is a fund or account into which annual deposits of A are made in order to accumulate F at $t = n$ in the future. Since the annual deposit is calculated as $A = F(A/F, i\%, n)$, the (A/F) factor is known as the *sinking fund factor.* An *annuity* is a series of equal payments (A) made over a period of time.[10] Usually, it is necessary to "buy into" an investment (a bond, and insurance policy, etc.) in order to ensure the annuity. In the simplest case of an annuity that starts at the end of the first year and continues for n years, the purchase price (P) is

$$P = A(P/A, i\%, n) \qquad 85.9$$

The present worth of an *infinite (perpetual) series* of annual amounts is known as a *capitalized cost.* There is no $(P/A, i\%, \infty)$ factor in the tables, but the capitalized cost can be calculated simply as

$$P = \frac{A}{i} \qquad [i \text{ in decimal form}] \qquad 85.10$$

Alternatives with different lives will generally be compared by way of *equivalent uniform annual cost* (EUAC). An EUAC is the annual amount that is equivalent to all of the cash flows in the alternative. The EUAC differs in sign from all of the other cash flows. Costs and expenses expressed as EUACs, which would normally be considered negative, are actually positive. The term *cost* in the designation EUAC serves to make clear the meaning of a positive number.



[10] An annuity may also consist of a lump sum payment made at some future time. However, this interpretation is not considered in this chapter.

Example 85.4

Maintenance costs for a machine are \$250 each year. What is the present worth of these maintenance costs over a 12-year period if the interest rate is 8%?

Solution

$$P = A(P/A, 8\%, 12) = (-\$250)(7.5361)$$
$$= -\$1884$$

14. FINDING PAST VALUES

From time to time, it will be necessary to determine an amount in the past equivalent to some current (or future) amount. For example, you might have to calculate the original investment made 15 years ago given a current annuity payment.

Such problems are solved by placing the $t = 0$ point at the time of the original investment, and then calculating the past amount as a P value. For example, the original investment, P, can be extracted from the annuity, A, by using the standard cash flow factors.

$$P = A(P/A, i\%, n) \qquad 85.11$$

The choice of $t = 0$ is flexible. As a general rule, the $t = 0$ point should be selected for convenience in solving a problem.

Example 85.5

You are currently paying \$250 per month to lease your office phone equipment. You have three years (36 months) left on the five-year (60-month) lease. What would have been an equivalent purchase price two years ago? The effective interest rate per month is 1%.

Solution

The solution of this example is not affected by the fact that investigation is being performed in the middle of the horizon. This is a simple calculation of present worth.

$$P = A(P/A, 1\%, 60)$$
$$= (-\$250)(44.9550) = -\$11{,}239$$

15. TIMES TO DOUBLE AND TRIPLE AN INVESTMENT

If an investment doubles in value (in n compounding periods and with $i\%$ effective interest), the ratio of current value to past investment will be 2.

$$F/P = (1 + i)^n = 2 \qquad 85.12$$

Similarly, the ratio of current value to past investment will be 3 if an investment triples in value. This can be written as

$$F/P = (1 + i)^n = 3 \qquad 85.13$$

It is a simple matter to extract the number of periods, n, from Eqs. 85.12 and 85.13 to determine the *doubling time* and *tripling time*, respectively. For example, the doubling time is

$$n = \frac{\log 2}{\log (1 + i)} \qquad 85.14$$

When a quick estimate of the doubling time is needed, the *rule of 72* can be used. The doubling time is approximately $72/i$.

The tripling time is

$$n = \frac{\log 3}{\log (1 + i)} \qquad 85.15$$

Equations 85.14 and 85.15 form the basis of Table 85.2.

Table 85.2 *Doubling and Tripling Times for Various Interest Rates*

interest rate ($i\%$)	doubling time (periods)	tripling time (periods)
1	69.7	110.4
2	35.0	55.5
3	23.4	37.2
4	17.7	28.0
5	14.2	22.5

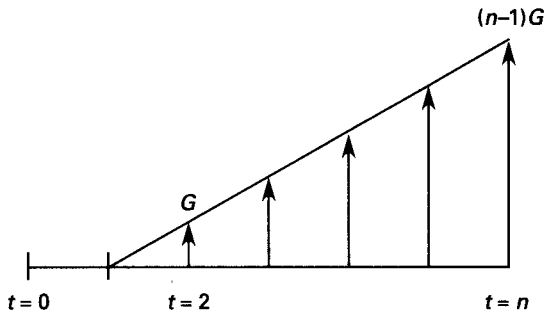
19	3.98	6.32
20	3.80	6.03

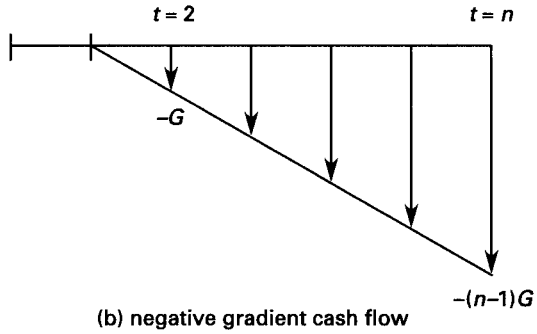
16. VARIED AND NONSTANDARD CASH FLOWS



Gradient Cash Flow

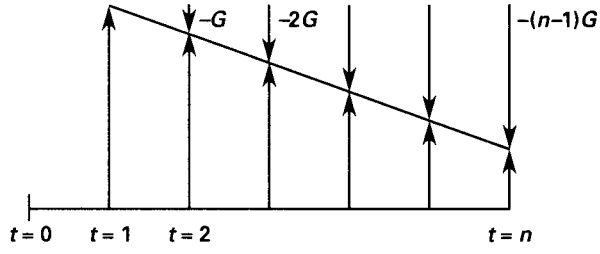
A common situation involves a uniformly increasing cash flow. If the cash flow has the proper form, its present worth can be determined by using the *uniform gradient factor*, $(P/G, i\%, n)$. The uniform gradient factor finds the present worth of a uniformly increasing cash flow that starts in year two (not in year one).

There are three common difficulties associated with the form of the uniform gradient. The first difficulty is that the initial cash flow occurs at $t = 2$. This convention recognizes that annual costs, if they increase uniformly, begin with some value at $t = 1$ (due to the year-end convention) but do not begin to increase until $t = 2$. The tabulated values of (P/G) have been calculated to find the present worth of only the increasing part of the annual expense. The present worth of the base expense incurred at $t = 1$ must be found separately with the (P/A) factor.



The second difficulty is that, even though the $(P/G, i\%, n)$ factor is used, there are only $n - 1$ actual cash flows. It is clear that n must be interpreted as the *period number* in which the last gradient cash flow occurs, not the number of gradient cash flows.

Finally, the sign convention used with gradient cash flows may seem confusing. If an expense increases each year (as in Ex. 85.6), the gradient will be negative, since it is an expense. If a revenue increases each year, the gradient will be positive. In most cases, the sign of the gradient depends on whether the cash flow is an expense or a revenue.[11]



(a) positive gradient cash flow

$P = G(P/G)$

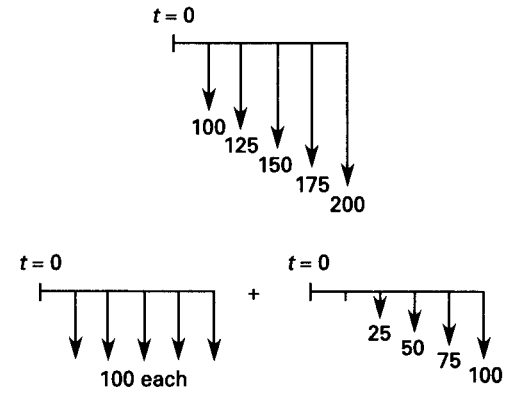
(b) negative gradient cash flow

$P = -G(P/G)$

(c) decreasing revenue incorporating a negative gradient

$P = S(P/A) - G(P/G)$

Figure 85.2 *Positive and Negative Gradient Cash Flows*



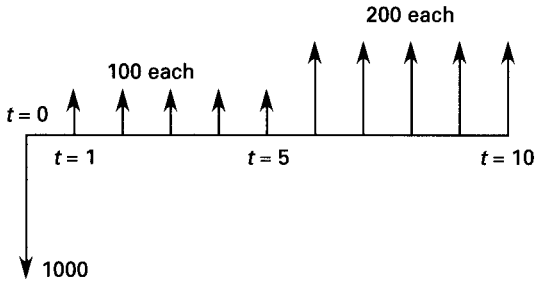
Example 85.6

Maintenance on an old machine is \$100 this year but is expected to increase by \$25 each year thereafter. What is the present worth of five years of the costs of maintenance? Use an interest rate of 10%.

Solution

In this problem, the cash flow must be broken down into parts. (Notice that the five-year gradient factor is used even though there are only four nonzero gradient cash flows.)

$$\begin{aligned} P &= A(P/A, 10\%, 5) + G(P/G, 10\%, 5) \\ &= (-\$100)(3.7908) - (\$25)(6.8618) \\ &= -\$551 \end{aligned}$$



[11] This is not a universal rule. It is possible to have a uniformly decreasing revenue as in Fig. 85.2(c). In this case, the gradient would be negative.

Stepped Cash Flows

Stepped cash flows are easily handled by the technique of *superposition of cash flows.* This technique is illustrated by Ex. 85.7.

Example 85.7

An investment costing \$1000 returns \$100 for the first five years and \$200 for the following five years. How would the present worth of this investment be calculated?

Solution

Using the principle of superposition, the revenue cash flow can be thought of as \$200 each year from $t = 1$ to $t = 10$, with a negative revenue of \$100 from $t = 1$ to $t = 5$. Superimposed, these two cash flows make up the actual performance cash flow.

$$P = -\$1000 + (\$200)(P/A, i\%, 10) - (\$100)(P/A, i\%, 5)$$

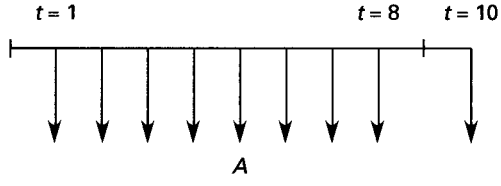
Missing and Extra Parts of Standard Cash Flows

A missing or extra part of a standard cash flow can also be handled by superposition. For example, suppose an annual expense is incurred each year for ten years, except in the ninth year. (The cash flow is illustrated in Figure 85.3.) The present worth could be calculated as a subtractive process.

$$P = A(P/A, i\%, 10) - A(P/F, i\%, 9) \qquad 85.16$$

Alternatively, the present worth could be calculated as an additive process.

$$P = A(P/A, i\%, 8) + A(P/F, i\%, 10) \qquad 85.17$$



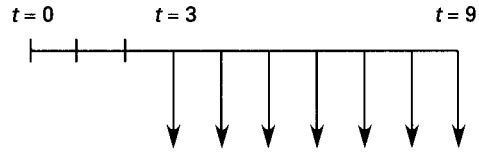


Figure 85.3 *Cash Flow with a Missing Part*

Delayed and Premature Cash Flows

There are cases when a cash flow matches a standard cash flow exactly, except that the cash flow is delayed or starts sooner than it should. Often, such cash flows can be handled with superposition. At other times, it may be more convenient to shift the time axis. This shift is known as the *projection method.* Example 85.8 illustrates the projection method.

Example 85.8

An expense of \$75 is incurred starting at $t = 3$ and continues until $t = 9$. There are no expenses or receipts until $t = 3$. Use the projection method to determine the present worth of this stream of expenses.

Solution

First, determine a cash flow at $t = 2$ that is equivalent to the entire expense stream. If $t = 0$ was where $t = 2$ actually is, the present worth of the expense stream would be

$$P' = (-\$75)(P/A, i\%, 7)$$

P' is a cash flow at $t = 2$. It is now simple to find the present worth (at $t = 0$) of this future amount.

$$P = P'(P/F, i\%, 2) = (-\$75)(P/A, i\%, 7)(P/F, i\%, 2)$$

Cash Flows at Beginnings of Years: The Christmas Club Problem

This type of problem is characterized by a stream of equal payments (or expenses) starting at $t = 0$ and ending at $t = n - 1$. It differs from the standard annual cash flow in the existence of a cash flow at $t = 0$ and the absence of a cash flow at $t = n$. This problem gets its name from the service provided by some savings institutions whereby money is automatically deposited each week or month (starting immediately, when the savings plan is opened) in order to accumulate money to purchase Christmas presents at the end of the year.

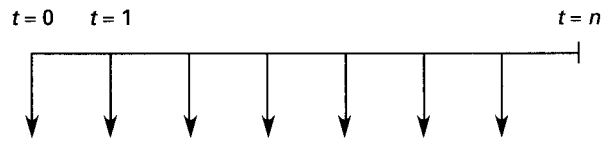

Figure 85.4 *Cash Flows at Beginnings of Years*

It may seem that the present worth of the savings stream can be determined by directly applying the (P/A) factor. However, this is not the case, since the Christmas

Club cash flow and the standard annual cash flow differ. The Christmas Club problem is easily handled by superposition, as illustrated by Ex. 85.9.

Example 85.9

How much can you expect to accumulate by $t = 10$ for a child's college education if you deposit \$300 at the beginning of each year for a total of ten payments?

Solution

Notice that the first payment is made at $t = 0$ and that there is no payment at $t = 10$. The future worth of the first payment is calculated with the (F/P) factor. The absence of the payment at $t = 10$ is handled by superposition. Notice that this "correction" is not multiplied by a factor.

$$\begin{aligned} F &= (\$300)(F/P, i\%, 10) + (\$300)(F/A, i\%, 10) - \$300 \\ &= (\$300)(F/A, i\%, 11) - \$300 \end{aligned}$$

17. THE MEANING OF PRESENT WORTH AND i

If \$100 is invested in a 5% bank account (using annual compounding), you can remove \$105 one year from now; if this investment is made, you will receive a *return on investment* (ROI) of \$5. The cash flow diagram and the present worth of the two transactions are

$$\begin{aligned} P &= -\$100 + (\$105)(P/F, 5\%, 1) \\ &= -\$100 + (\$105)(0.9524) = 0 \end{aligned}$$

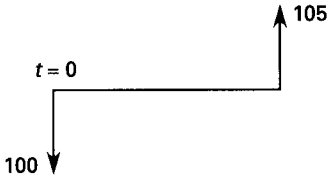

Figure 85.5 *Cash Flow Diagram*

Notice that the present worth is zero even though you will receive a \$5 return on your investment.

However, if you are offered \$120 for the use of \$100 over a one-year period, the cash flow diagram and present worth (at 5%) would be

$$\begin{aligned} P &= -\$100 + (\$120)(P/F, 5\%, 1) \\ &= -\$100 + (\$120)(0.9524) = \$14.29 \end{aligned}$$

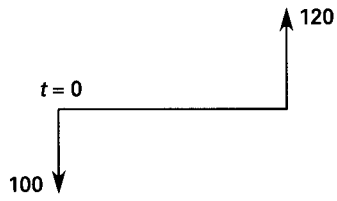

Figure 85.6 *Cash Flow Diagram*

Therefore, the present worth of an alternative is seen to be equal to the equivalent value at $t = 0$ of the increase in return above that which you would be able to earn in an investment offering $i\%$ per period. In the previous case, \$14.29 is the present worth of (\$20 − \$5), the difference in the two ROIs.

The present worth is also the amount that you would have to be given to dissuade you from making an investment, since placing the initial investment amount along with the present worth into a bank account earning $i\%$ will yield the same eventual return on investment. Relating this to the previous paragraphs, you could be dissuaded from investing \$100 in an alternative that would return \$120 in one year by a $t = 0$ payment of \$14.29. Clearly, (\$100 + \$14.29) invested at $t = 0$ will also yield \$120 in one year at 5%.

Income-producing alternatives with negative present worths are undesirable, and alternatives with positive present worths are desirable because they increase the average earning power of invested capital. (In some cases, such as municipal and public works projects, the present worths of all alternatives are negative, in which case, the least negative alternative is best.)

The selection of the interest rate is difficult in engineering economics problems. Usually, it is taken as the average rate of return that an individual or business organization has realized in past investments. Alternatively, the interest rate may be associated with a particular level of risk. Usually, i for individuals is the interest rate that can be earned in relatively *risk-free investments.*

18. SIMPLE AND COMPOUND INTEREST

If \$100 is invested at 5%, it will grow to \$105 in one year. During the second year, 5% interest continues to be accrued, but on \$105, not on \$100. This is the principle of *compound interest*: The interest accrues interest.[12]

If only the original principal accrues interest, the interest is said to be *simple interest.* Simple interest is rarely encountered in engineering economic analyses, but the concept may be incorporated into short-term transactions.

[12]This assumes, of course, that the interest remains in the account. If the interest is removed and spent, only the remaining funds accumulate interest.

19. EXTRACTING THE INTEREST RATE: RATE OF RETURN

An intuitive definition of the *rate of return* (ROR) is the effective annual interest rate at which an investment accrues income. That is, the rate of return of a project is the interest rate that would yield identical profits if all money were invested at that rate. Although this definition is correct, it does not provide a method of determining the rate of return.

It was previously seen that the present worth of a \$100 investment invested at 5% is zero when $i = 5\%$ is used to determine equivalence. Thus, a working definition of rate of return would be the effective annual interest rate that makes the present worth of the investment zero. Alternatively, rate of return could be defined as the effective annual interest rate that will discount all cash flows to a total present worth equal to the required initial investment.

It is tempting, but impractical, to determine a rate of return analytically. It is simply too difficult to extract the interest rate from the equivalence equation. For example, consider a \$100 investment that pays back \$75 at the end of each of the first two years. The present worth equivalence equation (set equal to zero in order to determine the rate of return) is

$$P = 0 = -\$100 + (\$75)(1+i)^{-1} + (\$75)(1+i)^{-2} \qquad 85.18$$

Solving Eq. 85.18 requires finding the roots of a quadratic equation. In general, for an investment or project spanning n years, the roots of an nth-order polynomial would have to be found. It should be obvious that an analytical solution would be essentially impossible for more complex cash flows. (The rate of return in this example is 31.87%.)

If the rate of return is needed, it can be found from a trial-and-error solution. To find the rate of return of an investment, proceed as follows.

step 1: Set up the problem as if to calculate the present worth.

step 2: Arbitrarily select a reasonable value for i. Calculate the present worth.

step 3: Choose another value of i (not too close to the original value), and again solve for the present worth.

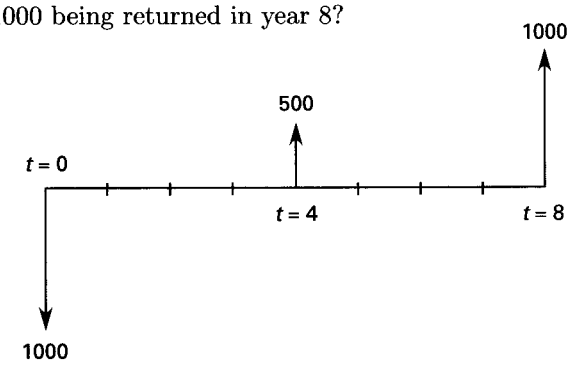
step 4: Interpolate or extrapolate the value of i that gives a zero present worth.

step 5: For increased accuracy, repeat steps 2 and 3 with two more values that straddle the value found in step 4.

A common, although incorrect, method of calculating the rate of return involves dividing the annual receipts or returns by the initial investment. (See Sec. 54.) However, this technique ignores such items as salvage, depreciation, taxes, and the time value of money. This technique also is inadequate when the annual returns vary.

It is possible that more than one interest rate will satisfy the zero present worth criteria. This confusing situation occurs whenever there is more than one change in sign in the investment's cash flow.[13] Table 85.3 indicates the numbers of possible interest rates as a function of the number of sign reversals in the investment's cash flow.

Table 85.3 *Multiplicity of Rates of Return*



number of sign reversals	number of distinct rates of return
0	0
1	0 or 1
2	0, 1, or 2
3	0, 1, 2, or 3
4	0, 1, 2, 3, or 4
m	$0, 1, 2, 3, \ldots m-1, m$

Difficulties associated with interpreting the meaning of multiple rates of return can be handled with the concepts of external investment and external rate of return. An *external investment* is an investment that is distinct from the investment being evaluated (which becomes known as the internal investment). The *external rate of return*, which is the rate of return earned by the external investment, does not need to be the same as the rate earned by the internal investment.

Generally, the multiple rates of return indicate that the analysis must proceed as though money will be invested outside of the project. The mechanics of how this is done are not covered here.

Example 85.10

What is the rate of return on invested capital if \$1000 is invested now with \$500 being returned in year 4 and \$1000 being returned in year 8?

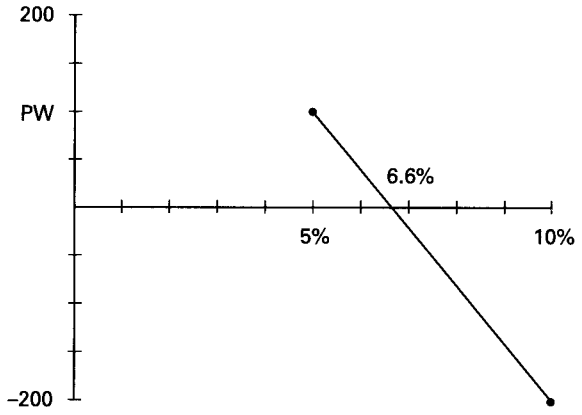
[13]There will always be at least one change of sign in the cash flow of a legitimate investment. (This excludes municipal and other tax-supported functions.) At $t = 0$, an investment is made (a negative cash flow). Hopefully, the investment will begin to return money (a positive cash flow) at $t = 1$ or shortly thereafter. Although it is possible to conceive of an investment in which all of the cash flows were negative, such an investment would probably be classified as a *hobby*.

Solution

First, set up the problem as a present worth calculation.

Try $i = 5\%$.

$$\begin{aligned} P &= -\$1000 + (\$500)(P/F, 5\%, 4) + (\$1000) \\ &\quad \times (P/F, 5\%, 8) \\ &= -\$1000 + (\$500)(0.8227) + (\$1000)(0.6768) \\ &= \$88 \end{aligned}$$



Next, try a larger value of i to reduce the present worth. If $i = 10\%$,

$$\begin{aligned} P &= -\$1000 + (\$500)(P/F, 10\%, 4) + (\$1000) \\ &\quad \times (P/F, 10\%, 8) \\ &= -\$1000 + (\$500)(0.6830) + (\$1000)(0.4665) \\ &= -\$192 \end{aligned}$$

Using simple interpolation, the rate of return is

$$\begin{aligned} \text{ROR} &= 5\% + \left(\frac{\$88}{\$88 + \$192}\right)(10\% - 5\%) \\ &= 6.6\% \end{aligned}$$

A second iteration between 6% and 7% yields 6.39%.

Example 85.11

An existing biomedical company is developing a new drug. A venture capital firm gives the company \$25 million initially and \$55 million more at the end of the first year. The drug patent will be sold at the end of year 5 to the highest bidder, and the biomedical company will receive \$80 million. (The venture capital firm will receive everything in excess of \$80 million.) The firm invests unused money in short-term commercial paper earning 10% effective interest per year through its bank. In the meantime, the biomedical company incurs development expenses of \$50 million annually for the first three years. The drug is to be evaluated by a government agency and there will be neither expenses nor revenues during the fourth year. What is the biomedical company's rate of return on this investment?

Solution

Normally, the rate of return is determined by setting up a present worth problem and varying the interest rate until the present worth is zero. Writing the cash flows, though, shows that there are two reversals of sign: one at $t = 2$ (positive to negative) and the other at $t = 5$ (negative to positive). Therefore, there could be two interest rates that produce a zero present worth. (In fact, there actually are two interest rates: 10.7% and 41.4%.)

time	cash flow (millions)
0	+25
1	+55 − 50 = +5
2	−50
3	−50
4	0
5	+80

However, this problem can be reduced to one with only one sign reversal in the cash flow series. The initial \$25 million is invested in commercial paper (an *external investment* having nothing to do with the drug development process) during the first year at 10%. The accumulation of interest and principal after one year is

$$(25)(1 + 0.10) = 27.5$$

This 27.5 is combined with the 5 (the money remaining after all expenses are paid at $t = 1$) and invested externally, again at 10%. The accumulation of interest and principal after one year (i.e., at $t = 2$) is

$$(27.5 + 5)(1 + 0.10) = 35.75$$

This 35.75 is combined with the development cost paid at $t = 2$.

The cash flow for the development project (the internal investment) is

time	cash flow (millions)
0	0
1	0
2	35.75 − 50 = −14.25
3	−50
4	0
5	+80

Now, there is only one sign reversal in the cash flow series. The *internal rate of return* on this development project is found by the traditional method to be 10.3%. Notice that this is different from the rate the company can earn from investing externally in commercial paper.

20. RATE OF RETURN VERSUS RETURN ON INVESTMENT

Rate of return (ROR) is an effective annual interest rate, typically stated in percent per year. *Return on investment* (ROI) is a dollar amount. Thus, *rate of return* and *return on investment* are not synonymous.

Return on investment can be calculated in two different ways. The accounting method is to subtract the total of all investment costs from the total of all net profits (i.e., revenues less expenses). The time value of money is not considered.

In engineering economic analysis, the return on investment is calculated from equivalent values. Specifically, the present worth (at $t = 0$) of all investment costs is subtracted from the future worth (at $t = n$) of all net profits.

When there are only two cash flows, a single investment amount and a single payback, the two definitions of return on investment yield the same numerical value. When there are more than two cash flows, the returns on investment will be different depending on which definition is used.

21. MINIMUM ATTRACTIVE RATE OF RETURN

A company may not know what effective interest rate, i, to use in engineering economic analysis. In such a case, the company can establish a minimum level of economic performance that it would like to realize on all investments. This criterion is known as the *minimum attractive rate of return* (MARR). Unlike the effective interest rate, i, the minimum attractive rate of return is not used in numerical calculations.[14] It is used only in comparisons with the rate of return.

Once a rate of return for an investment is known, it can be compared to the minimum attractive rate of return. To be a viable alternative, the rate of return must be greater than the minimum attractive rate of return.

The advantage of using comparisons to the minimum attractive rate of return is that an effective interest rate, i, never needs to be known. The minimum attractive rate of return becomes the correct interest rate for use in present worth and equivalent uniform annual cost calculations.

22. TYPICAL ALTERNATIVE-COMPARISON PROBLEM FORMATS

With the exception of some investment and rate of return problems, the typical problem involving engineering economics will have the following characteristics.

- An interest rate will be given.
- Two or more alternatives will be competing for funding.
- Each alternative will have its own cash flows.
- It is necessary to select the best alternative.

23. DURATIONS OF INVESTMENTS

Because they are handled differently, short-term investments and short-lived assets need to be distinguished from investments and assets that constitute an infinitely lived project. Short-term investments are easily identified: a drill press that is needed for three years or a temporary factory building that is being constructed to last five years.

Investments with perpetual cash flows are also (usually) easily identified: maintenance on a large flood control dam and revenues from a long-span toll bridge. Furthermore, some items with finite lives can expect renewal on a repeated basis.[15] For example, a major freeway with a pavement life of 20 years is unlikely to be abandoned; it will be resurfaced or replaced every 20 years.

Actually, if an investment's finite lifespan is long enough, it can be considered an infinite investment because money 50 or more years from now has little impact on current decisions. The $(P/F, 10\%, 50)$ factor, for example, is 0.0085. Thus, one dollar at $t = 50$ has an equivalent present worth of less than one penny. Since these far-future cash flows are eclipsed by present cash flows, long-term investments can be considered finite or infinite without significant impact on the calculations.

24. CHOICE OF ALTERNATIVES: COMPARING ONE ALTERNATIVE WITH ANOTHER ALTERNATIVE

Several methods exist for selecting a superior alternative from among a group of proposals. Each method has its own merits and applications.

Present Worth Method

When two or more alternatives are capable of performing the same functions, the superior alternative will have the largest present worth. The *present worth method* is restricted to evaluating alternatives that are mutually exclusive and that have the same lives. This method is suitable for ranking the desirability of alternatives.

Example 85.12

Investment A costs \$10,000 today and pays back \$11,500 two years from now. Investment B costs \$8000 today and pays back \$4500 each year for two years. If an interest rate of 5% is used, which alternative is superior?

[14] Not everyone adheres to this rule. Some people use "minimum attractive rate of return" and "effective interest rate" interchangeably.

[15] The term *renewal* can be interpreted to mean replacement or repair.

Solution

$$\begin{aligned} P(\text{A}) &= -\$10{,}000 + (\$11{,}500)(P/F, 5\%, 2) \\ &= -\$10{,}000 + (\$11{,}500)(0.9070) \\ &= \$431 \\ P(\text{B}) &= -\$8000 + (\$4500)(P/A, 5\%, 2) \\ &= -\$8000 + (\$4500)(1.8594) \\ &= \$367 \end{aligned}$$

Alternative A is superior and should be chosen.

Capitalized Cost Method

The present worth of a project with an infinite life is known as the *capitalized cost* or *life cycle cost.* Capitalized cost is the amount of money at $t = 0$ needed to perpetually support the project on the earned interest only. Capitalized cost is a positive number when expenses exceed income.

In comparing two alternatives, each of which is infinitely lived, the superior alternative will have the lowest capitalized cost.

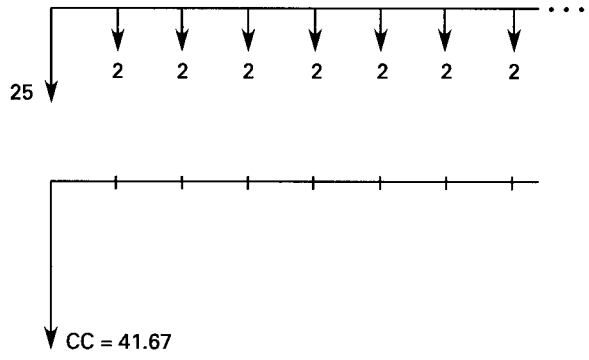
Normally, it would be difficult to work with an infinite stream of cash flows since most economics tables do not list factors for periods in excess of 100 years. However, the (A/P) discounting factor approaches the interest rate as n becomes large. Since the (P/A) and (A/P) factors are reciprocals of each other, it is possible to divide an infinite series of equal cash flows by the interest rate in order to calculate the present worth of the infinite series. This is the basis of Eq. 85.19.

$$\text{capitalized cost} = \text{initial cost} + \frac{\text{annual costs}}{i} \qquad 85.19$$

Equation 85.19 can be used when the annual costs are equal in every year. If the operating and maintenance costs occur irregularly instead of annually, or if the costs vary from year to year, it will be necessary to somehow determine a cash flow of equal annual amounts (EAA) that is equivalent to the stream of original costs.

The equal annual amount may be calculated in the usual manner by first finding the present worth of all the actual costs and then multiplying the present worth by the interest rate (the (A/P) factor for an infinite series). However, it is not even necessary to convert the present worth to an equal annual amount since Eq. 85.20 will convert the equal amount back to the present worth.

$$\begin{aligned} \text{capitalized cost} &= \text{initial cost} + \frac{\text{EAA}}{i} \\ &= \text{initial cost} + \frac{\text{present worth of all expenses}}{} \end{aligned} \qquad 85.20$$



Example 85.13

What is the capitalized cost of a public works project that will cost \$25,000,000 now and will require \$2,000,000 in maintenance annually? The effective annual interest rate is 12%.

Solution

Worked in millions of dollars, from Eq. 85.19, the capitalized cost is

$$\begin{aligned} \text{capitalized cost} &= 25 + (2)(P/A, 12\%, \infty) \\ &= 25 + \frac{2}{0.12} = 41.67 \end{aligned}$$

Annual Cost Method

Alternatives that accomplish the same purpose but that have unequal lives must be compared by the *annual cost method.*[16] The annual cost method assumes that each alternative will be replaced by an identical twin at the end of its useful life (infinite renewal). This method, which may also be used to rank alternatives according to their desirability, is also called the *annual return method* or *capital recovery method.*

Restrictions are that the alternatives must be mutually exclusive and repeatedly renewed up to the duration of the longest-lived alternative. The calculated annual cost is known as the *equivalent uniform annual cost* (EUAC) or just *equivalent annual cost.* Cost is a positive number when expenses exceed income.

Example 85.14

Which of the following alternatives is superior over a 30-year period if the interest rate is 7%?

	alternative A	alternative B
type	brick	wood
life	30 years	10 years
initial cost	\$1800	\$450
maintenance	\$5/year	\$20/year

[16]Of course, the annual cost method can be used to determine the superiority of assets with identical lives as well.

Solution

$$\begin{aligned}\text{EUAC(A)} &= (\$1800)(A/P, 7\%, 30) + \$5 \\ &= (\$1800)(0.0806) + \$5 \\ &= \$150 \\ \text{EUAC(B)} &= (\$450)(A/P, 7\%, 10) + \$20 \\ &= (\$450)(0.1424) + \$20 \\ &= \$84\end{aligned}$$

Alternative B is superior since its annual cost of operation is the lowest. It is assumed that three wood facilities, each with a life of 10 years and a cost of $450, will be built to span the 30-year period.

25. CHOICE OF ALTERNATIVES: COMPARING AN ALTERNATIVE WITH A STANDARD

With specific economic performance criteria, it is possible to qualify an investment as acceptable or unacceptable without having to compare it with another investment. Two such performance criteria are the benefit-cost ratio and the minimum attractive rate of return.

Benefit-Cost Ratio Method

The *benefit-cost ratio* method is often used in municipal project evaluations where benefits and costs accrue to different segments of the community. With this method, the present worth of all benefits (irrespective of the beneficiaries) is divided by the present worth of all costs. The project is considered acceptable if the ratio equals or exceeds 1.0, that is, if $B/C \geq 1.0$.

When the benefit-cost ratio method is used, disbursements by the initiators or sponsors are *costs*. Disbursements by the users of the project are known as *disbenefits*. It is often difficult to determine whether a cash flow is a cost or a disbenefit (whether to place it in the numerator or denominator of the benefit-cost ratio calculation).

Regardless of where the cash flow is placed, an acceptable project will always have a benefit-cost ratio greater than or equal to 1.0, although the actual numerical result will depend on the placement. For this reason, the benefit-cost ratio method should not be used to rank competing projects.

The benefit-cost ratio method of comparing alternatives is used extensively in transportation engineering where the ratio is often (but not necessarily) written in terms of annual benefits and annual costs instead of present worths. Another characteristic of highway benefit-cost ratios is that the route (road, highway, etc.) is usually already in place and that various alternative upgrades are being considered. There will be existing benefits and costs associated with the current route. Therefore, the *change* (usually an increase) in benefits and costs is used to calculate the benefit-cost ratio.[17]

$$B/C = \frac{\Delta^{\text{user}}_{\text{benefits}}}{\Delta^{\text{investment}}_{\text{cost}} + \Delta\text{maintenance} - \Delta^{\text{residual}}_{\text{value}}} \qquad 85.21$$

Notice that the change in *residual value (terminal value)* appears in the denominator as a negative item. An increase in the residual value would decrease the denominator.

Example 85.15

By building a bridge over a ravine, a state department of transportation can shorten the time it takes to drive through a mountainous area. Estimates of costs and benefits (due to decreased travel time, fewer accidents, reduced gas usage, etc.) have been prepared. Should the bridge be built? Use the benefit-cost ratio method of comparison.

	millions
initial cost	40
capitalized cost of perpetual annual maintenance	12
capitalized value of annual user benefits	49
residual value	0

Solution

If Eq. 85.21 is used, the benefit-cost ratio is

$$B/C = \frac{49}{40 + 12 + 0} = 0.942$$

Since the benefit-cost ratio is less than 1.00, the bridge should not be built.

If the maintenance costs are placed in the numerator (per Ftn. 17), the benefit-cost ratio value will be different but the conclusion will not change.

$$B/C_{\text{alternate method}} = \frac{49 - 12}{40} = 0.925$$

Rate of Return Method

The minimum attractive rate of return (MARR) has already been introduced as a standard of performance against which an investment's actual *rate of return*

[17]This discussion of highway benefit-cost ratios is not meant to imply that everyone agrees with Eq. 85.21. In *Economic Analysis for Highways* (International Textbook Company, Scranton, PA, 1969), author Robley Winfrey takes a strong stand on one aspect of the benefits versus disbenefits issue: highway maintenance. According to Winfrey, regular highway maintenance costs should be placed in the numerator as a subtraction from the user benefits. Some have called this mandate the *Winfrey method*.

(ROR) is compared. If the rate of return is equal to or exceeds the minimum attractive rate of return, the investment is qualified. This is the basis for the *rate of return method* of alternative selection.

Finding the rate of return can be a long, iterative process. Usually, the actual numerical value of rate of return is not needed; it is sufficient to know whether or not the rate of return exceeds the minimum attractive rate of return. This *comparative analysis* can be accomplished without calculating the rate of return simply by finding the present worth of the investment using the minimum attractive rate of return as the effective interest rate (i.e., $i = \text{MARR}$). If the present worth is zero or positive, the investment is qualified. If the present worth is negative, the rate of return is less than the minimum attractive rate of return.

26. RANKING MUTUALLY EXCLUSIVE MULTIPLE PROJECTS

Ranking of multiple investment alternatives is required when there is sufficient funding for more than one investment. Since the best investments should be selected first, it is necessary to be able to place all investments into an ordered list.

Ranking is relatively easy if the present worths, future worths, capitalized costs, or equivalent uniform annual costs have been calculated for all the investments. The highest ranked investment will be the one with the largest present or future worth, or the smallest capitalized or annual cost. Present worth, future worth, capitalized cost, and equivalent uniform annual cost can all be used to rank multiple investment alternatives.

However, neither rates of return nor benefit-cost ratios should be used to rank multiple investment alternatives. Specifically, if two alternatives both have rates of return exceeding the minimum acceptable rate of return, it is not sufficient to select the alternative with the highest rate of return.

An *incremental analysis*, also known as a *rate of return on added investment study*, should be performed if rate of return is used to select between investments. An incremental analysis starts by ranking the alternatives in order of increasing initial investment. Then, the cash flows for the investment with the lower initial cost are subtracted from the cash flows for the higher-priced alternative on a year-by-year basis. This produces, in effect, a third alternative representing the costs and benefits of the added investment. The added expense of the higher priced investment is not warranted unless the rate of return of this third alternative exceeds the minimum attractive rate of return as well. The choice criterion is to select the alternative with the higher initial investment if the incremental rate of return exceeds the minimum attractive rate of return.

An incremental analysis is also required if ranking is to be done by the benefit-cost ratio method. The incremental analysis is accomplished by calculating the ratio of differences in benefits to differences in costs for each possible pair of alternatives. If the ratio exceeds 1.0, alternative 2 is superior to alternative 1. Otherwise, alternative 1 is superior.[18]

$$\frac{B_2 - B_1}{C_2 - C_1} \geq 1 \quad \text{[alternative 2 superior]} \qquad 85.22$$

27. ALTERNATIVES WITH DIFFERENT LIVES

Comparison of two alternatives is relatively simple when both alternatives have the same life. For example, a problem might be stated: "Which would you rather have: car A with a life of three years, or car B with a life of five years?"

However, care must be taken to understand what is going on when the two alternatives have different lives. If car A has a life of three years and car B has a life of five years, what happens at $t = 3$ if the five-year car is chosen? If a car is needed for five years, what happens at $t = 3$ if the three-year car is chosen?

In this type of situation, it is necessary to distinguish between the length of the need (the *analysis horizon*) and the lives of the alternatives or assets intended to meet that need. The lives do not have to be the same as the horizon.

Finite Horizon with Incomplete Asset Lives

If an asset with a five-year life is chosen for a three-year need, the disposition of the asset at $t = 3$ must be known in order to evaluate the alternative. If the asset is sold at $t = 3$, the salvage value is entered into the analysis (at $t = 3$) and the alternative is evaluated as a three-year investment. The fact that the asset is sold when it has some useful life remaining does not affect the analysis horizon.

Similarly, if a three-year asset is chosen for a five-year need, something about how the need is satisfied during the last two years must be known. Perhaps a rental asset will be used. Or, perhaps the function will be "farmed out" to an outside firm. In any case, the costs of satisfying the need during the last two years enter the analysis, and the alternative is evaluated as a five-year investment.

If both alternatives are "converted" to the same life, any of the alternative selection criteria (present worth method, annual cost method, etc.) can be used to determine which alternative is superior.

[18] It goes without saying that the benefit-cost ratios for all investment alternatives by themselves must also be equal to or greater than 1.0.

Finite Horizon with Integer Multiple Asset Lives

It is common to have a long-term horizon (need) that must be met with short-lived assets. In special instances, the horizon will be an integer number of asset lives. For example, a company may be making a 12-year transportation plan and may be evaluating two cars: one with a three-year life, and another with a four-year life.

In this example, four of the first car or three of the second car are needed to reach the end of the 12-year horizon.

If the horizon is an integer number of asset lives, any of the alternative selection criteria can be used to determine which is superior. If the present worth method is used, all alternatives must be evaluated over the entire horizon. (In this example, the present worth of 12 years of car purchases and use must be determined for both alternatives.)

If the equivalent uniform annual cost method is used, it may be possible to base the calculation of annual cost on one lifespan of each alternative only. It may not be necessary to incorporate all of the cash flows into the analysis. (In the running example, the annual cost over three years would be determined for the first car; the annual cost over four years would be determined for the second car.) This simplification is justified if the subsequent asset replacements (renewals) have the same cost and cash flow structure as the original asset. This assumption is typically made implicitly when the annual cost method of comparison is used.

Infinite Horizon

If the need horizon is infinite, it is not necessary to impose the restriction that asset lives of alternatives be integer multiples of the horizon. The superior alternative will be replaced (renewed) whenever it is necessary to do so, forever.

Infinite horizon problems are almost always solved with either the annual cost or capitalized cost method. It is common to (implicitly) assume that the cost and cash flow structure of the asset replacements (renewals) are the same as the original asset.

28. OPPORTUNITY COSTS

An *opportunity cost* is an imaginary cost representing what will not be received if a particular strategy is rejected. It is what you will lose if you do or do not do something. As an example, consider a growing company with an existing operational computer system. If the company trades in its existing computer as part of an upgrade plan, it will receive a *trade-in allowance.* (In other problems, a *salvage value* may be involved.)

If one of the alternatives being evaluated is not to upgrade the computer system at all, the trade-in allowance (or, salvage value in other problems) will not be realized. The amount of the trade-in allowance is an opportunity cost that must be included in the problem analysis.

Similarly, if one of the alternatives being evaluated is to wait one year before upgrading the computer, the *difference in trade-in allowances* is an opportunity cost that must be included in the problem analysis.

29. REPLACEMENT STUDIES

An investigation into the retirement of an existing process or piece of equipment is known as a *replacement study.* Replacement studies are similar in most respects to other alternative comparison problems: An interest rate is given, two alternatives exist, and one of the previously mentioned methods of comparing alternatives is used to choose the superior alternative. Usually, the annual cost method is used on a year-by-year basis.

In replacement studies, the existing process or piece of equipment is known as the *defender.* The new process or piece of equipment being considered for purchase is known as the *challenger.*

30. TREATMENT OF SALVAGE VALUE IN REPLACEMENT STUDIES

Since most defenders still have some market value when they are retired, the problem of what to do with the salvage arises. It seems logical to use the salvage value of the defender to reduce the initial purchase cost of the challenger. This is consistent with what would actually happen if the defender were to be retired.

By convention, however, the defender's salvage value is subtracted from the defender's present value. This does not seem logical, but it is done to keep all costs and benefits related to the defender with the defender. In this case, the salvage value is treated as an opportunity cost that would be incurred if the defender is not retired.

If the defender and the challenger have the same lives and a present worth study is used to choose the superior alternative, the placement of the salvage value will have no effect on the net difference between present worths for the challenger and defender. Although the values of the two present worths will be different depending on the placement, the difference in present worths will be the same.

If the defender and the challenger have different lives, an annual cost comparison must be made. Since the salvage value would be "spread over" a different number of years depending on its placement, it is important to abide by the conventions listed in this section.

There are a number of ways to handle salvage value in retirement studies. The best way is to calculate the cost of keeping the defender one more year. In addition to the usual operating and maintenance costs, that cost includes an opportunity interest cost incurred by not selling the defender, and also a drop in the salvage value if the defender is kept for one additional year. Specifically,

$$\begin{aligned}\text{EUAC (defender)} = {} & \text{next year's maintenance costs} \\ & + i\,(\text{current salvage value}) \\ & + \text{current salvage} \\ & - \text{next year's salvage} \end{aligned} \quad \textit{85.23}$$

It is important in retirement studies not to double count the salvage value. That is, it would be incorrect to add the salvage value to the defender and at the same time subtract it from the challenger.

Equation 85.23 contains the difference in salvage value between two consecutive years. This calculation shows that the defender/challenger decision must be made on a year-by-year basis. One application of Eq. 85.23 will not usually answer the question of whether the defender should remain in service indefinitely. The calculation must be repeatedly made as long as there is a drop in salvage value from one year to the next.

31. ECONOMIC LIFE: RETIREMENT AT MINIMUM COST

As an asset grows older, its operating and maintenance costs typically increase. Eventually, the cost to keep the asset in operation becomes prohibitive, and the asset is retired or replaced. However, it is not always obvious when an asset should be retired or replaced.

As the asset's maintenance cost is increasing each year, the amortized cost of its initial purchase is decreasing. It is the sum of these two costs that should be evaluated to determine the point at which the asset should be retired or replaced. Since an asset's initial purchase price is likely to be high, the amortized cost will be the controlling factor in those years when the maintenance costs are low. Therefore, the EUAC of the asset will decrease in the initial part of its life.

However, as the asset grows older, the change in its amortized cost decreases while maintenance cost increases. Eventually, the sum of the two costs reaches a minimum and then starts to increase. The age of the asset at the minimum cost point is known as the *economic life* of the asset. The economic life generally is less than the length of need and the technological lifetime of the asset.

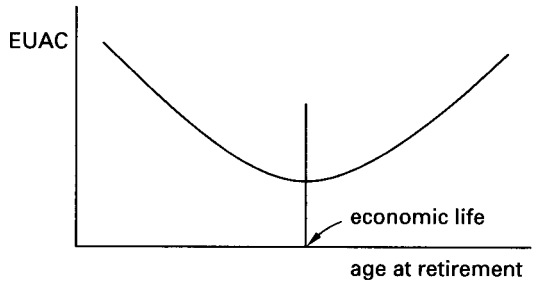


Figure 85.7 *EUAC versus Age at Retirement*

The determination of an asset's economic life is illustrated by Ex. 85.16.

Example 85.16

Buses in a municipal transit system have the characteristics listed. When should the city replace its buses if money can be borrowed at 8%?

initial cost of bus: $120,000

year	maintenance cost	salvage value
1	35,000	60,000
2	38,000	55,000
3	43,000	45,000
4	50,000	25,000
5	65,000	15,000

Solution

The annual maintenance is different each year. Each maintenance cost must be spread over the life of the bus. This is done by first finding the present worth and then amortizing the maintenance costs. If a bus is kept for one year and then sold, the annual cost will be

$$\begin{aligned}\text{EUAC}(1) &= (\$120{,}000)(A/P, 8\%, 1) \\ &\quad + (\$35{,}000)(A/F, 8\%, 1) \\ &\quad - (\$60{,}000)(A/F, 8\%, 1) \\ &= (\$120{,}000)(1.0800) + (\$35{,}000)(1.000) \\ &\quad - (\$60{,}000)(1.000) \\ &= \$104{,}600\end{aligned}$$

If a bus is kept for two years and then sold, the annual cost will be

$$\begin{aligned}\text{EUAC}(2) &= [\$120{,}000 + (\$35{,}000)(P/F, 8\%, 1)] \\ &\quad \times (A/P, 8\%, 2) \\ &\quad + (\$38{,}000 - \$55{,}000)(A/F, 8\%, 2) \\ &= [\$120{,}000 + (\$35{,}000)(0.9259)](0.5608) \\ &\quad + (\$38{,}000 - \$55{,}000)(0.4808) \\ &= \$77{,}296\end{aligned}$$

If a bus is kept for three years and then sold, the annual cost will be

$$\begin{aligned}\text{EUAC}(3) &= [\$120{,}000 + (35{,}000)(P/F, 8\%, 1) \\ &\quad + (\$38{,}000)(P/F, 8\%, 2)](A/P, 8\%, 3) \\ &\quad + (\$43{,}000 - \$45{,}000)(A/F, 8\%, 3) \\ &= [\$120{,}000 + (\$35{,}000)(0.9259) \\ &\quad + (\$38{,}000)(0.8573)](0.3880) \\ &\quad - (\$2000)(0.3080) \\ &= \$71{,}158\end{aligned}$$

This process is continued until the annual cost begins to increase. In this example, EUAC(4) is $71,700. Therefore, the buses should be retired after three years.

32. LIFE-CYCLE COST

The *life-cycle cost* of an alternative is the equivalent value (at $t = 0$) of the alternative's cash flow over the alternative's lifespan. Since the present worth is evaluated using an effective interest rate of i (which would be the interest rate used for all engineering economic analyses), the life-cycle cost is the same as the alternative's present worth. If the alternative has an infinite horizon, the life-cycle cost and capitalized cost will be identical.

33. CAPITALIZED ASSETS VERSUS EXPENSES

High expenses reduce profit, which in turn reduces income tax. It seems logical to label each and every expenditure, even an asset purchase, as an expense. As an alternative to this *expensing the asset*, it may be decided to capitalize the asset. *Capitalizing the asset* means that the cost of the asset is divided into equal or unequal parts, and only one of these parts is taken as an expense each year. Expensing is clearly the more desirable alternative, since the after-tax profit is increased early in the asset's life.

There are long-standing accounting conventions as to what can be expensed and what must be capitalized.[19] Some companies capitalize everything—regardless of cost—with expected lifetimes greater than one year. Most companies, however, expense items whose purchase costs are below a cut-off value. A cut-off value in the range of $250 to $500, depending on the size of the company, is chosen as the maximum purchase cost of an expensed asset. Assets costing more than this are capitalized.

It is not necessary for a large corporation to keep track of every lamp, desk, and chair for which the purchase price is greater than the cut-off value. Such assets, all of which have the same lives and have been purchased in the same year, can be placed into groups or *asset classes*. A group cost, equal to the sum total of the purchase costs of all items in the group, is capitalized as though the group was an identifiable and distinct asset itself.

[19]For example, purchased vehicles must be capitalized; payments for leased vehicles can be expensed. Repainting a building with paint that will last five years is an expense, but the replacement cost of a leaking roof must be capitalized.

34. PURPOSE OF DEPRECIATION

Depreciation is an *artificial expense* that spreads the purchase price of an asset or other property over a number of years.[20] Depreciating an asset is an example of capitalization, as previously defined. The inclusion of depreciation in engineering economic analysis problems will increase the after-tax present worth (profitability) of an asset. The larger the depreciation, the greater will be the profitability. Therefore, individuals and companies eligible to utilize depreciation want to maximize and accelerate the depreciation available to them.

Although the entire property purchase price is eventually recognized as an expense, the net recovery from the expense stream never equals the original cost of the asset. That is, depreciation cannot realistically be thought of as a fund (an annuity or sinking fund) that accumulates capital to purchase a replacement at the end of the asset's life. The primary reason for this is that the depreciation expense is reduced significantly by the impact of income taxes, as will be seen in later sections.

35. DEPRECIATION BASIS OF AN ASSET

The *depreciation basis* of an asset is the part of the asset's purchase price that is spread over the *depreciation period*, also known as the *service life*.[21] Usually, the depreciation basis and the purchase price are not the same.

A common depreciation basis is the difference between the purchase price and the expected salvage value at the end of the depreciation period. That is,

$$\text{depreciation basis} = C - S_n \qquad 85.24$$

There are several methods of calculating the year-by-year depreciation of an asset. Equation 85.24 is not universally compatible with all depreciation methods.

[20]The IRS tax regulations allow depreciation on almost all forms of *business property* except land. The following types of property are distinguished: *real* (e.g., buildings used for business), *residential* (e.g., buildings used as rental property), and *personal* (e.g., equipment used for business). Personal property does *not* include items for personal use (such as a personal residence), despite its name. *Tangible personal property* is distinguished from *intangible property* (goodwill, copyrights, patents, trademarks, franchises, agreements not to compete, etc.).

[21]The *depreciation period* is selected to be as short as possible within recognized limits. This depreciation will not normally coincide with the *economic life* or *useful life* of an asset. For example, a car may be capitalized over a depreciation period of three years. It may become uneconomical to maintain and use at the end of an economic life of nine years. However, the car may be capable of operation over a useful life of 25 years.

Some methods do not consider the salvage value. This is known as an *unadjusted basis.* When the depreciation method is known, the depreciation basis can be rigorously defined.[22]

36. DEPRECIATION METHODS

Generally, tax regulations do not allow the cost of an asset to be treated as a deductible expense in the year of purchase. Rather, portions of the depreciation basis must be allocated to each of the n years of the asset's depreciation period. The amount that is allocated each year is called the *depreciation.*

Various methods exist for calculating an asset's depreciation each year.[23] Although the depreciation calculations may be considered independently (for the purpose of determining book value or as an academic exercise), it is important to recognize that depreciation has no effect on engineering economic analyses unless income taxes are also considered.

Straight Line Method

With the *straight line method,* depreciation is the same each year. The depreciation basis $(C - S_n)$ is allocated uniformly to all of the n years in the depreciation period. Each year, the depreciation will be

$$D = \frac{C - S_n}{n} \qquad 85.25$$

Constant Percentage Method

The *constant percentage method*[24] is similar to the straight line method in that the depreciation is the same each year. If the fraction of the basis used as depreciation is $1/n$, there is no difference between the constant percentage and straight line methods. The two methods differ only in what information is available. (With the straight line method, the life is known. With the constant percentage method, the depreciation fraction is known.)

Each year, the depreciation will be

$$\begin{aligned} D &= (\text{depreciation fraction})(\text{depreciation basis}) \\ &= (\text{depreciation fraction})(C - S_n) \end{aligned} \qquad 85.26$$

Sum-of-the-Years' Digits Method

In *sum-of-the-years' digits* (SOYD) depreciation, the digits from 1 to n inclusive are summed. The total, T, can also be calculated from

$$T = \tfrac{1}{2}n(n+1) \qquad 85.27$$

The depreciation in year j can be found from Eq. 85.28. Notice that the depreciation in year j, D_j, decreases by a constant amount each year.

$$D_j = \frac{(C - S_n)(n - j + 1)}{T} \qquad 85.28$$

Double Declining Balance Method[25]

Double declining balance[26] (DDB) depreciation is independent of salvage value. Furthermore, the book value never stops decreasing, although the depreciation decreases in magnitude. Usually, any book value in excess of the salvage value is written off in the last year of the asset's depreciation period. Unlike any of the other depreciation methods, double declining balance depends on accumulated depreciation.

$$D_{\text{first year}} = \frac{2C}{n} \qquad 85.29$$

$$D_j = \frac{2\left(C - \sum_{m=1}^{j-1} D_m\right)}{n} \qquad 85.30$$

Calculating the depreciation in the middle of an asset's life appears particularly difficult with double declining balance, since all previous years' depreciation amounts seem to be required. It appears that the depreciation in the sixth year, for example, cannot be calculated unless the values of depreciation for the first five years are calculated. However, this is not true.

Depreciation in the middle of an asset's life can be found from the following equations. (d is known as the *depreciation rate.*)

$$d = \frac{2}{n} \qquad 85.31$$

$$D_j = dC(1 - d)^{j-1} \qquad 85.32$$

Statutory Depreciation Systems

In the United States, property placed into service in 1981 and thereafter must use the *Accelerated Cost Recovery System* (ACRS), and after 1986, the *Modified*

[22]For example, with the Accelerated Cost Recovery System (ACRS) the *depreciation basis* is the total purchase cost, regardless of the expected salvage value. With declining balance methods, the depreciation basis is the purchase cost less any previously taken depreciation.

[23]This discussion gives the impression that any form of depreciation may be chosen regardless of the nature and circumstances of the purchase. In reality, the IRS tax regulations place restrictions on the higher-rate (accelerated) methods, such as declining balance and sum-of-the-years' digits methods. Furthermore, the *Economic Recovery Act of 1981* and the *Tax Reform Act of 1986* substantially changed the laws relating to personal and corporate income taxes.

[24]The *constant percentage method* should not be confused with the declining balance method, which used to be known as the *fixed percentage on diminishing balance method.*

[25]In the past, the *declining balance method* has also been known as the *fixed percentage of book value* and *fixed percentage on diminishing balance method.*

[26]Double declining balance depreciation is a particular form of *declining balance depreciation,* as defined by the IRS tax regulations. Declining balance depreciation includes 125% declining balance and 150% declining balance depreciations that can be calculated by substituting 1.25 and 1.50, respectively, for the 2 in Eq. 85.29.

Accelerated Cost Recovery System (MACRS) or other statutory method. Other methods (straight line, declining balance, etc.) cannot be used except in special cases.

Property placed into service in 1980 or before must continue to be depreciated according to the method originally chosen (e.g., straight line, declining balance, or sum-of-the-years' digits). ACRS and MACRS cannot be used.

Under ACRS and MACRS, the cost recovery amount in the jth year of an asset's cost recovery period is calculated by multiplying the initial cost by a factor.

$$D_j = C \times \text{factor} \qquad 85.33$$

The initial cost used is not reduced by the asset's salvage value for ACRS and MACRS calculations. The factor used depends on the asset's cost recovery period. Such factors are subject to continuing legislation changes. Current tax publications should be consulted before using this method.

Table 85.4 *Representative ACRS and MACRS Depreciation Factors*[a]

	recovery period (n)		
year j	3 years	5 years	10 years
	ACRS/MACRS	ACRS/MACRS	ACRS/MACRS
1	0.25/0.3333	0.15/0.2000	0.08/0.100
2	0.38/0.4445	0.22/0.3200	0.14/0.180
3	0.37/0.1481	0.21/0.1920	0.12/0.1440
4	0/0.0741	0.21/0.1152	0.10/0.1152
5		0.21/0.1152	0.10/0.0922
6		0/0.0576	0.10/0.0737
7			0.09/0.0655
8			0.09/0.0655
9			0.09/0.0656
10			0.09/0.0655
11			0/0.0328

[a]MACRS values are for the "half-year" convention. This table gives typical values only. Since these factors are subject to continuing revision, they should not be used without consulting an accounting professional.

Production or Service Output Method

If an asset has been purchased for a specific task and that task is associated with a specific lifetime amount of output or production, the depreciation may be calculated by the fraction of total production produced during the year. The depreciation is not expected to be the same each year.

$$D_j = (C - S_n)\left(\frac{\text{actual output in year } j}{\text{estimated lifetime output}}\right) \qquad 85.34$$

Sinking Fund Method

The *sinking fund method* is seldom used in industry because the initial depreciation is low. The formula for sinking fund depreciation (which increases each year) is

$$D_j = (C - S_n)(A/F, i\%, n)(F/P, i\%, j - 1) \qquad 85.35$$

Disfavored Methods

Three other depreciation methods are mentioned here, not because they are currently accepted or in widespread use, but because they are still occasionally encountered in the literature.[27]

The *sinking fund plus interest on first cost* depreciation method, like the following two methods, is an attempt to include the *opportunity interest cost* on the purchase price with the depreciation. That is, the purchasing company not only incurs an annual expense due to the drop in book value, but it also loses the interest on the purchase price. The formula for this method is

$$D = (C - S_n)(A/F, i\%, n) + Ci \qquad 85.36$$

The *straight line plus interest on first cost* method is similar. Its formula is

$$D = \left(\frac{1}{n}\right)(C - S_n) + Ci \qquad 85.37$$

The *straight line plus average interest method* assumes that the opportunity interest cost should be based on the book value only, not on the full purchase price. Since the book value changes each year, an average value is used. The depreciation formula is

$$D = \left(\frac{C - S_n}{n}\right)\left(1 + \frac{i(n+1)}{2}\right) + iS_n \qquad 85.38$$

Example 85.17

An asset is purchased for \$9000. Its estimated economic life is ten years, after which it will be sold for \$200. Find the depreciation in the first three years using straight line, double declining balance, and sum-of-the-years' digits depreciation methods.

[27]These three depreciation methods should not be used in the usual manner (e.g., in conjunction with the income tax rate). These methods are attempts to calculate a more accurate annual cost of an alternative. Sometimes they give misleading answers. Their use cannot be recommended. They are included in this chapter only for the sake of completeness.

Solution

SL: $D = \dfrac{\$9000 - \$200}{10} = \$880$ each year

DDB: $D_1 = \dfrac{(2)(\$9000)}{10} = \$1800$ in year 1

$D_2 = \dfrac{(2)(\$9000 - \$1800)}{10} = \$1440$ in year 2

$D_3 = \dfrac{(2)(\$9000 - \$3240)}{10} = \$1152$ in year 3

SOYD: $T = \left(\frac{1}{2}\right)(10)(11) = 55$

$D_1 = \left(\frac{10}{55}\right)(\$9000 - \$200) = \$1600$ in year 1

$D_2 = \left(\frac{9}{55}\right)(\$8800) = \$1440$ in year 2

$D_3 = \left(\frac{8}{55}\right)(\$8800) = \$1280$ in year 3

37. ACCELERATED DEPRECIATION METHODS

An *accelerated depreciation method* is one that calculates a depreciation amount greater than a straight line amount. Double declining balance and sum-of-the-years' digits methods are accelerated methods. The ACRS and MACRS methods are explicitly accelerated methods. Straight line and sinking fund methods are not accelerated methods.

Use of an accelerated depreciation method may result in unexpected tax consequences when the depreciated asset or property is disposed of. Professional tax advice should be obtained in this area.

38. BOOK VALUE

The difference between original purchase price and accumulated depreciation is known as *book value.*[28] At the end of each year, the book value (which is initially equal to the purchase price) is reduced by the depreciation in that year.

It is important to properly synchronize depreciation calculations. It is difficult to answer the question, "What is the book value in the fifth year?" unless the timing of the book value change is mutually agreed upon. It is better to be specific about an inquiry by identifying when the book value change occurs. For example, the following question is unambiguous: "What is the book value at the end of year 5, after subtracting depreciation in the fifth year?" or "What is the book value after five years?"

Unfortunately, this type of care is seldom taken in book value inquiries, and it is up to the respondent to exercise reasonable care in distinguishing between beginning-of-year book value and end-of-year book value. To be consistent, the book value equations in this chapter have been written in such a way that the year subscript (j) has the same meaning in book value and depreciation calculations. That is, BV_5 means the book value at the end of the fifth year, after five years of depreciation, including D_5, has been subtracted from the original purchase price.

There can be a great difference between the book value of an asset and the *market value* of that asset. There is no legal requirement for the two values to coincide, and no intent for book value to be a reasonable measure of market value.[29] Therefore, it is apparent that book value is merely an accounting convention with little practical use. Even when a depreciated asset is disposed of, the book value is used to determine the consequences of disposal, not the price the asset should bring at sale.

The calculation of book value is relatively easy, even for the case of the declining balance depreciation method.

For the straight line depreciation method, the book value at the end of the jth year, after the jth depreciation deduction has been made, is

$$\text{BV}_j = C - \frac{j(C - S_n)}{n} = C - jD \qquad 85.39$$

For the sum-of-the-years' digits method, the book value is

$$\text{BV}_j = (C - S_n)\left[1 - \frac{j(2n + 1 - j)}{n(n + 1)}\right] + S_n \qquad 85.40$$

For the declining balance method, the book value is

$$\text{BV}_j = C(1 - d)^j \qquad 85.41$$

For the sinking fund method, the book value is calculated directly as

$$\text{BV}_j = C - (C - S_n)(A/F, i\%, n)(F/A, i\%, j) \qquad 85.42$$

[28]The balance sheet of a corporation usually has two asset accounts: the *equipment account* and the *accumulated depreciation account.* There is no book value account on this financial statement, other than the implicit value obtained from subtracting the accumulated depreciation account from the equipment account. The book values of various assets, as well as their original purchase cost, date of purchase, salvage value, and so on, and accumulated depreciation appear on detail sheets or other peripheral records for each asset.

[29]Common examples of assets with great divergences of book and market values are buildings (rental houses, apartment complexes, factories, etc.) and company luxury automobiles (Porsches, Mercedes, etc.) during periods of inflation. Book values decrease, but actual values increase.

Of course, the book value at the end of year j can always be calculated for any method by successive subtractions (i.e., subtraction of the accumulated depreciation), as Eq. 85.43 illustrates.

$$\mathrm{BV}_j = C - \sum_{m=1}^{j} D_m \qquad 85.43$$

Figure 85.8 illustrates the book value of a hypothetical asset depreciated using several depreciation methods. Notice that the double declining balance method initially produces the fastest write-off, while the sinking fund method produces the slowest write-off. Note also that the book value does not automatically equal the salvage value at the end of an asset's depreciation period with the double declining balance method.[30]

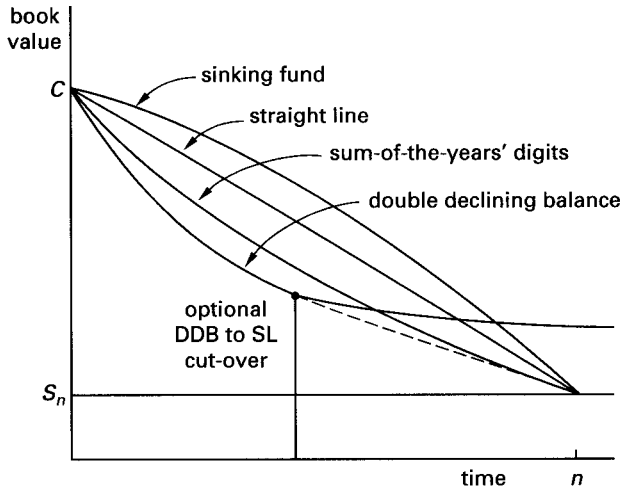

Figure 85.8 *Book Value with Different Depreciation Methods*

Example 85.18

For the asset described in Ex. 85.17, calculate the book value at the end of the first three years if sum-of-the-years' digits depreciation is used. The book value at the beginning of year 1 is \$9000.

Solution

From Eq. 85.43,

$$\mathrm{BV}_1 = \$9000 - \$1600 = \$7400$$
$$\mathrm{BV}_2 = \$7400 - \$1440 = \$5960$$
$$\mathrm{BV}_3 = \$5960 - \$1280 = \$4680$$

[30]This means that the straight line method of depreciation may result in a lower book value at some point in the depreciation period than if double declining balance is used. A *cut-over* from double declining balance to straight line may be permitted in certain cases. Finding the *cut-over point*, however, is usually done by comparing book values determined by both methods. The analytical method is complicated.

39. AMORTIZATION

Amortization and depreciation are similar in that they both divide up the cost basis or value of an asset. In fact, in certain cases, the term "amortization" may be used in place of the term "depreciation." However, depreciation is a specific form of amortization.

Amortization spreads the cost basis or value of an asset over some base. The base can be time, units of production, number of customers, and so on. The asset can be tangible (e.g., a delivery truck or building) or intangible (e.g., goodwill or a patent).

If the asset is tangible, if the base is time, and if the length of time is consistent with accounting standards and taxation guidelines, then the term "depreciation" is appropriate. However, if the asset is intangible, if the base is some other variable, or if some length of time other than the customary period is used, then the term "amortization" is more appropriate.[31]

Example 85.19

A company purchases complete and exclusive patent rights to an invention for \$1,200,000. It is estimated that once commercially produced, the invention will have a specific but limited market of 1200 units. For the purpose of allocating the patent right cost to production cost, what is the amortization rate in dollars per unit?

Solution

The patent should be amortized at the rate of

$$\frac{\$1{,}200{,}000}{1200 \text{ units}} = \$1000 \text{ per unit}$$

40. DEPLETION

Depletion is another artificial deductible operating expense, designed to compensate mining organizations for decreasing mineral reserves. Since original and remaining quantities of minerals are seldom known accurately, the *depletion allowance* is calculated as a fixed percentage of the organization's gross income. These percentages are usually in the 10 to 20% range and apply to such mineral deposits as oil, natural gas, coal, uranium, and most metal ores.

41. BASIC INCOME TAX CONSIDERATIONS

The issue of income taxes is often overlooked in academic engineering economic analysis exercises. Such a position is justifiable when an organization (e.g., a nonprofit school, a church, or the government) pays no

[31]From time to time, the U.S. Congress has allowed certain types of facilities (e.g., emergency, grain storage, and pollution control) to be written off more rapidly than would otherwise be permitted in order to encourage investment in such facilities. The term "amortization" has been used with such write-off periods.

income taxes. However, if an individual or organization is subject to income taxes, the income taxes must be included in an economic analysis of investment alternatives.

Assume that an organization pays a fraction f of its profits to the federal government as income taxes. If the organization also pays a fraction s of its profits as state income taxes and if state taxes paid are recognized by the federal government as tax-deductible expenses, then the composite tax rate is

$$t = s + f - sf \qquad 85.44$$

The basic principles used to incorporate taxation into engineering economic analyses are the following.

- Initial purchase expenditures are unaffected by income taxes.
- Salvage revenues are unaffected by income taxes.
- Deductible expenses, such as operating costs, maintenance costs, and interest payments, are reduced by the fraction t (e.g., multiplied by the quantity $1 - t$).
- Revenues are reduced by the fraction t (e.g., multiplied by the quantity $1 - t$).
- Since tax regulations allow the depreciation in any year to be handled as if it were an actual operating expense, and since operating expenses are deductible from the income base prior to taxation, the after-tax profits will be increased. If D is the depreciation, the net result to the after-tax cash flow will be the addition of tD. Depreciation is multiplied by t and added to the appropriate year's cash flow, increasing that year's present worth.

For simplicity, most engineering economics practice problems involving income taxes specify a single income tax rate. In practice, however, federal and most state tax rates depend on the income level. Each range of incomes and its associated tax rate are known as *income bracket* and *tax bracket*, respectively. For example, the state income tax rate might be 4% for incomes up to and including \$30,000, and 5% for incomes above \$30,000. The income tax for a taxpaying entity with an income of \$50,000 would have to be calculated in two parts.

$$\begin{aligned}\text{tax} &= (0.04)(\$30{,}000) + (0.05)(\$50{,}000 - \$30{,}000) \\ &= \$2200\end{aligned}$$

Income taxes and depreciation have no bearing on municipal or governmental projects since municipalities, states, and the U.S. government pay no taxes.

Example 85.20

A corporation that pays 53% of its profit in income taxes invests \$10,000 in an asset that will produce a \$3000 annual revenue for eight years. If the annual expenses are \$700, salvage after eight years is \$500, and 9% interest is used, what is the after-tax present worth? Disregard depreciation.

Solution

$$\begin{aligned}P &= -\$10{,}000 + (\$3000)(P/A, 9\%, 8)(1 - 0.53) \\ &\quad - (\$700)(P/A, 9\%, 8)(1 - 0.53) \\ &\quad + (\$500)(P/F, 9\%, 8) \\ &= -\$10{,}000 + (\$3000)(5.5348)(0.47) \\ &\quad - (\$700)(5.5348)(0.47) + (\$500)(0.5019) \\ &= -\$3766\end{aligned}$$

42. TAXATION AT THE TIMES OF ASSET PURCHASE AND SALE

There are numerous rules and conventions that governmental tax codes and the accounting profession impose on organizations. Engineers are not normally expected to be aware of most of the rules and conventions, but occasionally it may be necessary to incorporate their effects into an engineering economic analysis.

Tax Credit

A *tax credit* (also known as an *investment tax credit* or *investment credit*) is a one-time credit against income taxes.[32] Therefore, it is added to the after-tax present worth as a last step in an engineering economic analysis. Such tax credits may be allowed by the government from time to time for equipment purchases, employment of various classes of workers, rehabilitation of historic landmarks, and so on.

A tax credit is usually calculated as a fraction of the initial purchase price or cost of an asset or activity.

$$\text{TC} = \text{fraction} \times \text{initial cost} \qquad 85.45$$

When the tax credit is applicable, the fraction used is subject to legislation. A professional tax expert or accountant should be consulted prior to applying the tax credit concept to engineering economic analysis problems.

Since the investment tax credit reduces the buyer's tax liability, a tax credit should be included only in after-tax engineering economic analyses. The credit is assumed to be received at the end of the year.

Gain or Loss on the Sale of a Depreciated Asset

If an asset that has been depreciated over a number of prior years is sold for more than its current book value, the difference between the book value and selling price is taxable income in the year of the sale. Alternatively, if the asset is sold for less than its current book value, the difference between the selling price and book value is an expense in the year of the sale.

[32]Strictly, *tax credit* is the more general term, and applies to a credit for doing anything creditable. An *investment tax credit* requires an investment in something (usually real property or equipment).

Example 85.21

One year, a company makes a $5000 investment in a historic building. The investment is not depreciable, but it does qualify for a one-time 20% tax credit. In that same year, revenue is $45,000 and expenses (exclusive of the $5000 investment) are $25,000. The company pays a total of 53% in income taxes. What is the after-tax present worth of this year's activities if the company's interest rate for investment is 10%?

Solution

The tax credit is

$$\text{TC} = (0.20)(\$5000) = \$1000$$

This tax credit is assumed to be received at the end of the year. The after-tax present worth is

$$\begin{aligned} P &= -\$5000 + (\$45{,}000 - \$25{,}000)(1 - 0.53) \\ &\quad \times (P/F, 10\%, 1) + (\$1000)(P/F, 10\%, 1) \\ &= -\$5000 + (\$20{,}000)(0.47)(0.9091) \\ &\quad + (\$1000)(0.9091) \\ &= \$4455 \end{aligned}$$

43. DEPRECIATION RECOVERY

The economic effect of depreciation is to reduce the income tax in year j by tD_j. The present worth of the asset is also affected: The present worth is increased by $tD_j(P/F, i\%, j)$. The after-tax present worth of all depreciation effects over the depreciation period of the asset is called the *depreciation recovery* (DR).[33]

$$\text{DR} = t\sum_{j=1}^{n} D_j(P/F, i\%, j) \qquad 85.46$$

Straight line depreciation recovery from an asset is easily calculated, since the depreciation is the same each year. Assuming the asset has a constant depreciation of D and depreciation period of n years, the depreciation recovery is

$$\text{DR} = tD(P/A, i\%, n) \qquad 85.47$$

$$D = \frac{C - S_n}{n} \qquad 85.48$$

Sum-of-the-years' digits depreciation recovery is also relatively easily calculated, since the depreciation decreases uniformly each year.

$$\text{DR} = \left(\frac{t(C - S_n)}{T}\right)\left(n(P/A, i\%, n) - (P/G, i\%, n)\right) \qquad 85.49$$

[33]Since the depreciation benefit is reduced by taxation, depreciation cannot be thought of as an annuity to fund a replacement asset.

Finding *declining balance depreciation recovery* is more involved. There are three difficulties. The first (the apparent need to calculate all previous depreciations in order to determine the subsequent depreciation) has already been addressed by Eq. 85.32.

The second difficulty is that there is no way to ensure (that is, to force) the book value to be S_n at $t = n$. Therefore, it is common to write off the remaining book value (down to S_n) at $t = n$ in one lump sum. This assumes $\text{BV}_n \geq S_n$.

The third difficulty is that of finding the present worth of an *exponentially decreasing cash flow.* Although the proof is omitted here, such exponential cash flows can be handled with the *exponential gradient factor*, (P/EG).[34]

$$(P/EG, z - 1, n) = \frac{z^n - 1}{z^n(z - 1)} \qquad 85.50$$

$$z = \frac{1 + i}{1 - d} \qquad 85.51$$

Then, as long as $\text{BV}_n > S_n$, the declining balance depreciation recovery is

$$\text{DR} = tC\left(\frac{d}{1 - d}\right)(P/EG, z - 1, n) \qquad 85.52$$

Example 85.22

For the asset described in Ex. 85.17, calculate the after-tax depreciation recovery with straight line and sum-of-the-years' digits depreciation methods. Use 6% interest with 48% income taxes.

Solution

SL:
$$\begin{aligned} \text{DR} &= (0.48)(\$880)(P/A, 6\%, 10) \\ &= (0.48)(\$880)(7.3601) \\ &= \$3109 \end{aligned}$$

SOYD: The depreciation series can be thought of as a constant $1600 term with a negative $160 gradient.

$$\begin{aligned} \text{DR} &= (0.48)(\$1600)(P/A, 6\%, 10) \\ &\quad - (0.48)(\$160)(P/G, 6\%, 10) \\ &= (0.48)(\$1600)(7.3601) \\ &\quad - (0.48)(\$160)(29.6023) \\ &= \$3379 \end{aligned}$$

[34]The (P/A) columns in App. 85.B can be used for (P/EG) as long as the interest rate is assumed to be $z - 1$.

Table 85.5 *Depreciation Calculation Summary*

method	depreciation basis	depreciation in year j (D_j)	book value after jth depreciation (BV_j)	after-tax depreciation recovery (DR)	supplementary formulas
straight line (SL)	$C - S_n$	$\frac{C - S_n}{n}$ (constant)	$C - jD$	$tD(P/A, i\%, n)$	
constant percentage	$C - S_n$	fraction $\times$ $(C - S_n)$ (constant)	$C - jD$	$tD(P/A, i\%, n)$	
sum-of-the-years' digits (SOYD)	$C - S_n$	$\frac{(C - S_n)}{T} \times (n - j + 1)$	$(C - S_n) \times \left(1 - \frac{j(2n + 1 - j)}{n(n+1)}\right) + S_n$	$\frac{t(C - S_n)}{T} \times (n(P/A, i\%, n) - (P/G, i\%, n))$	$T = \frac{1}{2}n(n+1)$
double declining balance (DDB)	C	$dC(1 - d)^{j-1}$	$C(1 - d)^j$	$tC\left(\frac{d}{1-d}\right) \times (P/EG, z - 1, n)$	$d = \frac{2}{n}$; $z = \frac{1+i}{1-d}$ $(P/EG, z - 1, n) = \frac{z^n - 1}{z^n(z-1)}$
sinking fund (SF)	$C - S_n$	$(C - S_n) \times (A/F, i\%, n) \times (F/P, i\%, j - 1)$	$C - (C - S_n) \times (A/F, i\%, n) \times (F/A, i\%, j)$	$\frac{t(C - S_n)(A/F, i\%, n)}{1 + i}$	
accelerated cost recovery system (ACRS/ MACRS)	C	$C \times$ factor	$C - \sum_{m=1}^{j} D_m$	$t \sum_{j=1}^{n} D_j(P/F, i\%, j)$	
production or service output	$C - S_n$	$(C - S_n) \times \left(\frac{\text{actual output in year } j}{\text{lifetime output}}\right)$	$C - \sum_{m=1}^{j} D_m$	$t \sum_{j=1}^{n} D_j(P/F, i\%, j)$	

Notice that the ten-year (P/G) factor is used even though there are only nine years in which the gradient reduces the initial \$1600 amount.

Example 85.23

What is the after-tax present worth of the asset described in Ex. 85.20 if straight line, sum-of-the-years' digits, and double declining balance depreciation methods are used?

Solution

Using SL, the depreciation recovery is

$$\begin{aligned}
\text{DR} &= (0.53)\left(\frac{\$10{,}000 - \$500}{8}\right)(P/A, 9\%, 8) \\
&= (0.53)\left(\frac{\$9500}{8}\right)(5.5348) \\
&= \$3483
\end{aligned}$$

Using SOYD, the depreciation recovery is calculated as follows.

$$\begin{aligned}
T &= \left(\tfrac{1}{2}\right)(8)(9) = 36 \\
\text{depreciation base} &= \$10{,}000 - \$500 = \$9500 \\
D_1 &= \left(\tfrac{8}{36}\right)(\$9500) = \$2111 \\
G &= \text{gradient} = \left(\tfrac{1}{36}\right)(\$9500) \\
&= \$264 \\
\text{DR} &= (0.53)[(\$2111)(P/A, 9\%, 8) \\
&\quad - (\$264)(P/G, 9\%, 8)] \\
&= (0.53)[(\$2111)(5.5348) \\
&\quad - (\$264)(16.8877)] \\
&= \$3830
\end{aligned}$$

Using DDB, the depreciation recovery is calculated as follows.[35]

$$d = \frac{2}{8} = 0.25$$

$$z = \frac{1 + 0.09}{1 - 0.25} = 1.4533$$

$$(P/EG, z-1, n) = \frac{(1.4533)^8 - 1}{(1.4533)^8(0.4533)} = 2.095$$

From Eq. 85.52,

$$\begin{aligned} \text{DR} &= (0.53)\left(\frac{(0.25)(\$10{,}000)}{0.75}\right)(2.095) \\ &= \$3701 \end{aligned}$$

The after-tax present worth, neglecting depreciation, was previously found to be −$3766.

The after-tax present worths, including depreciation recovery, are

$$\begin{aligned} &\text{SL:} && P = -\$3766 + \$3483 = -\$283 \\ &\text{SOYD:} && P = -\$3766 + \$3830 = \$64 \\ &\text{DDB:} && P = -\$3766 + \$3701 = -\$65 \end{aligned}$$

44. OTHER INTEREST RATES

The *effective interest rate per period*, i (also called *yield* by banks), is the only interest rate that should be used in equivalence equations. The interest rates at the top of the factor tables in App. 85.B are implicitly all effective interest rates. Usually, the period will be one year, hence the name *effective annual interest rate*. However, there are other interest rates in use as well.

The term *nominal interest rate*, r (*rate per annum*), is encountered when compounding is more than once per year. The nominal rate does not include the effect of compounding and is not the same as the effective rate. And, since the effective interest rate can be calculated from the nominal rate only if the number of compounding periods per year is known, nominal rates cannot be compared unless the method of compounding is specified. The only practical use for a nominal rate per year is for calculating the effective rate per period.

45. RATE AND PERIOD CHANGES

If there are k compounding periods during the year (two for semiannual compounding, four for quarterly compounding, twelve for monthly compounding, etc.) and the nominal rate is r, the *effective rate per compounding period* is

$$\phi = \frac{r}{k} \qquad 85.53$$

[35]This method should start by checking that the book value at the end of the depreciation period is greater than the salvage value. In this example, such is the case. However, the step is not shown.

The effective annual rate, i, can be calculated from the effective rate per period, ϕ, by using Eq. 85.54.

$$\begin{aligned} i &= (1+\phi)^k - 1 \\ &= \left(1 + \frac{r}{k}\right)^k - 1 \end{aligned} \qquad 85.54$$

Sometimes, only the effective rate per period (e.g., per month) is known. However, that will be a simple problem since compounding for n periods at an effective rate per period is not affected by the definition or length of the period.

The following rules may be used to determine which interest rate is given in a problem.

- Unless specifically qualified in the problem, the interest rate given is an annual rate.
- If the compounding is annual, the rate given is the effective rate. If compounding is other than annual, the rate given is the nominal rate.

The effective annual interest rate determined on a *daily compounding basis* will not be significantly different than if *continuous compounding* is assumed.[36] In the case of continuous (or daily) compounding, the discounting factors can be calculated directly from the nominal interest rate and number of years, without having to find the effective interest rate per period. Table 85.6 can be used to determine the discount factors for continuous compounding.

Table 85.6 *Discount Factors for Continuous Compounding (n is the number of years)*

symbol	formula
$(F/P, r\%, n)$	e^{rn}
$(P/F, r\%, n)$	e^{-rn}
$(A/F, r\%, n)$	$\dfrac{e^r - 1}{e^{rn} - 1}$
$(F/A, r\%, n)$	$\dfrac{e^{rn} - 1}{e^r - 1}$
$(A/P, r\%, n)$	$\dfrac{e^r - 1}{1 - e^{-rn}}$
$(P/A, r\%, n)$	$\dfrac{1 - e^{-rn}}{e^r - 1}$

[36]The number of *banking days in a year* (250, 360, etc.) must be specifically known.

Example 85.24

A savings and loan offers a nominal rate of 5¼% compounded daily over 365 days in a year. What is the effective annual rate?

Solution

method 1: Use Eq. 85.54.

$$r = 0.0525,\ k = 365$$

$$i = \left(1 + \frac{0.0525}{365}\right)^{365} - 1 = 0.0539$$

method 2: Assume daily compounding is the same as continuous compounding.

$$i = (F/P, r\%, 1) - 1$$
$$= e^{0.0525} - 1 = 0.0539$$

Example 85.25

A real estate investment trust pays $7,000,000 for a 100-unit apartment complex. The trust expects to sell the complex in ten years for $15,000,000. In the meantime, it expects to receive an average rent of $900 per month from each apartment. Operating expenses are expected to be $200 per month per occupied apartment. A 95% occupancy rate is predicted. In similar investments, the trust has realized a 15% effective annual return on its investment. Compare the expected present worth of this investment when calculated assuming (a) annual compounding (i.e., the year-end convention), and (b) monthly compounding. Disregard taxes, depreciation, and all other factors.

Solution

(a) The net annual income will be

$$(0.95)(100 \text{ units})\left(\$900\ \frac{\$}{\text{unit-month}} - \$200\ \frac{\$}{\text{unit-month}}\right)\left(12\ \frac{\text{months}}{\text{year}}\right)$$
$$= \$798{,}000/\text{year}$$

The present worth of ten years of operation is

$$P = -\$7{,}000{,}000 + (\$798{,}000)(P/A, 15\%, 10) + (\$15{,}000{,}000)(P/F, 15\%, 10)$$
$$= -\$7{,}000{,}000 + (\$798{,}000)(5.0188) + (\$15{,}000{,}000)(0.2472)$$
$$= \$713{,}000$$

(b) The net monthly income is

$$(0.95)(100 \text{ units})\left(\$900\ \frac{\$}{\text{unit-month}} - \$200\ \frac{\$}{\text{unit-month}}\right) = \$66{,}500/\text{month}$$

Equation 85.54 is used to calculate the effective monthly rate, ϕ, from the effective annual rate, $i = 15\%$, and the number of compounding periods per year, $k = 12$.

$$\phi = (1+i)^{\frac{1}{k}} - 1$$
$$= (1+0.15)^{\frac{1}{12}} - 1 = 0.011715\ \ (1.1715\%)$$

The number of compounding periods in ten years is

$$n = (10 \text{ years})\left(12\ \frac{\text{months}}{\text{year}}\right) = 120 \text{ months}$$

The present worth of 120 months of operation is

$$P = -\$7{,}000{,}000 + (\$66{,}500)(P/A, 1.1715\%, 120) + (\$15{,}000{,}000)(P/F, 1.1715\%, 120)$$

Since table values for 1.1715% discounting factors are not available, the factors are calculated from Table 85.1.

$$(P/A, 1.1715\%, 120) = (1+i)^n - \frac{1}{i(1+i)^n}$$
$$= \frac{(1+0.011715)^{120} - 1}{(0.011715)(1+0.011715)^{120}}$$
$$= 64.261$$
$$(P/F, 1.1715\%, 120) = (1+i)^{-n} = (1+0.011715)^{-120}$$
$$= 0.2472$$

The present worth over 120 monthly compounding periods is

$$P = -\$7{,}000{,}000 + (\$66{,}500)(64.261) + (\$15{,}000{,}000)(0.2472)$$
$$= \$981{,}357$$

46. BONDS

A *bond* is a method of long-term financing commonly used by governments, states, municipalities, and very large corporations.[37] The bond represents a contract to pay the bondholder specific amounts of money at specific times. The holder purchases the bond in exchange for specific payments of interest and principal. Typical municipal bonds call for quarterly or semiannual interest payments and a payment of the *face value of the bond* on the *date of maturity* (end of the bond period).[38] Due to the practice of discounting in the bond market, a bond's face value and its purchase price generally will not coincide.

[37] In the past, 30-year bonds were typical. Shorter term 10-year, 15-year, 20-year, and 25-year bonds are also commonly issued.

[38] A *fully amortized bond* pays back interest and principal throughout the life of the bond. There is no balloon payment.

In the past, a bondholder had to submit a coupon or ticket in order to receive an interim interest payment. This has given rise to the term *coupon rate*, which is the nominal annual interest rate on which the interest payments are made. Coupon books are seldom used with modern bonds, but the term survives. The coupon rate determines the magnitude of the semiannual (or otherwise) interest payments during the life of the bond. The bondholder's own effective interest rate should be used for economic decisions about the bond.

Actual *bond yield* is the bondholder's actual rate of return of the bond, considering the purchase price, interest payments, and face value payment (or, value realized if the bond is sold before it matures). By convention, bond yield is calculated as a nominal rate (rate per annum), not an effective rate per year. The bond yield should be determined by finding the effective rate of return per payment period (e.g., per semiannual interest payment) as a conventional rate of return problem. Then, the nominal rate can be found by multiplying the effective rate per period by the number of payments per year, as in Eq. 85.54.

Example 85.26

What is the maximum amount an investor should pay for a 25-year bond with a $20,000 face value and 8% coupon rate (interest only paid semiannually)? The bond will be kept to maturity. The investor's effective annual interest rate for economic decisions is 10%.

Solution

For this problem, take the compounding period to be six months. Then, there are 50 compounding periods. Since 8% is a nominal rate, the effective bond rate per period is calculated from Eq. 85.53 as

$$\phi_{\text{bond}} = \frac{r}{k} = \frac{8\%}{2} = 4\%$$

The bond payment received semiannually is

$$(0.04)(\$20{,}000) = \$800$$

10% is the investor's effective rate per year, so Eq. 85.54 is again used to calculate the effective analysis rate per period.

$$0.10 = (1+\phi)^2 - 1$$
$$\phi = 0.04881 \quad (4.88\%)$$

The maximum amount that the investor should be willing to pay is the present worth of the investment.

$$P = (\$800)(P/A, 4.88\%, 50) + (\$20{,}000)(P/F, 4.88\%, 50)$$

Table 85.1 can be used to calculate the following factors.

$$(P/A, 4.88\%, 50) = \frac{(1+0.0488)^{50} - 1}{(0.0488)(1.0488)^{50}} = 18.600$$

$$(P/F, 4.88\%, 50) = \frac{1}{(1+0.0488)^{50}} = 0.09233$$

Then, the present worth is

$$P = (\$800)(18.600) + (\$20{,}000)(0.09233)$$
$$= \$16{,}727$$

47. PROBABILISTIC PROBLEMS

If an alternative's cash flows are specified by an implicit or explicit probability distribution rather than being known exactly, the problem is *probabilistic.*

Probabilistic problems typically possess the following characteristics.

- There is a chance of loss that must be minimized (or, rarely, a chance of gain that must be maximized) by selection of one of the alternatives.
- There are multiple alternatives. Each alternative offers a different degree of protection from the loss. Usually, the alternatives with the greatest protection will be the most expensive.
- The magnitude of loss or gain is independent of the alternative selected.

Probabilistic problems are typically solved using annual costs and expected values. An *expected value* is similar to an *average value* since it is calculated as the mean of the given probability distribution. If cost 1 has a probability of occurrence, p_1, cost 2 has a probability of occurrence, p_2, and so on, the expected value is

$$\mathcal{E}\{\text{cost}\} = p_1(\text{cost } 1) + p_2(\text{cost } 2) + \cdots \qquad 85.55$$

Example 85.27

Flood damage in any year is given according to the following table. What is the present worth of flood damage for a ten-year period? Use 6% as the effective annual interest rate.

damage	probability
0	0.75
$10,000	0.20
$20,000	0.04
$30,000	0.01

Solution

The expected value of flood damage in any given year is

$$\mathcal{E}\{\text{damage}\} = (0)(0.75) + (\$10{,}000)(0.20) + (\$20{,}000)(0.04) + (\$30{,}000)(0.01)$$
$$= \$3100$$

The present worth of ten years of expected flood damage is

$$\begin{aligned}\text{present worth} &= (\$3100)(P/A, 6\%, 10)\\ &= (\$3100)(7.3601)\\ &= \$22{,}816\end{aligned}$$

Example 85.28

A dam is being considered on a river that periodically overflows and causes $600,000 damage. (The damage is essentially the same each time the river causes flooding.) The project horizon is 40 years. A 10% interest rate is being used.

Three different designs are available, each with different costs and storage capacities.

design alternative	cost	maximum capacity
A	$500,000	1 unit
B	$625,000	1.5 units
C	$900,000	2.0 units

The national weather service has provided a statistical analysis of annual rainfall runoff from the watershed draining into the river.

units annual rainfall	probability
0	0.10
0.1 to 0.5	0.60
0.6 to 1.0	0.15
1.1 to 1.5	0.10
1.6 to 2.0	0.04
2.1 or more	0.01

Which design alternative would you choose assuming the dam is essentially empty at the start of each rainfall season?

Solution

The sum of the construction cost and the expected damage should be minimized. If alternative A is chosen, it will have a capacity of 1 unit. Its capacity will be exceeded (causing $600,000 damage) when the annual rainfall exceeds 1 unit. Therefore, the expected value of the annual cost of alternative A is

$$\begin{aligned}&\mathcal{E}\{\text{EUAC(A)}\}\\ &\quad= (\$500{,}000)(A/P, 10\%, 40)\\ &\qquad+ (\$600{,}000)(0.10 + 0.04 + 0.01)\\ &\quad= (\$500{,}000)(0.1023) + (\$600{,}000)(0.15)\\ &\quad= \$141{,}150\end{aligned}$$

Similarly,

$$\begin{aligned}\mathcal{E}\{\text{EUAC(B)}\} &= (\$625{,}000)(A/P, 10\%, 40)\\ &\quad+ (\$600{,}000)(0.04 + 0.01)\\ &= (\$625{,}000)(0.1023) + (\$600{,}000)(0.05)\\ &= \$93{,}938\end{aligned}$$

$$\begin{aligned}\mathcal{E}\{\text{EUAC(C)}\} &= (\$900{,}000)(A/P, 10\%, 40)\\ &\quad+ (\$600{,}000)(0.01)\\ &= (\$900{,}000)(0.1023) + (\$600{,}000)(0.01)\\ &= \$98{,}070\end{aligned}$$

Alternative B should be chosen.

48. FIXED AND VARIABLE COSTS

The distinction between fixed and variable costs depends on how these costs vary when an independent variable changes. For example, factory or machine production is frequently the independent variable. However, it could just as easily be vehicle miles driven, hours of operation, or quantity (mass, volume, etc.).

If a cost is a function of the independent variable, the cost is said to be a *variable cost.* The change in cost per unit variable change (i.e., what is usually called the *slope*) is known as the *incremental cost.* Material and labor costs are examples of variable costs. They increase in proportion to the number of product units manufactured.

If a cost is not a function of the independent variable, the cost is said to be a *fixed cost.* Rent and lease payments are typical fixed costs. These costs will be incurred regardless of production levels.

Some costs have both fixed and variable components, as Fig. 85.9 illustrates. The fixed portion can be determined by calculating the cost at zero production.

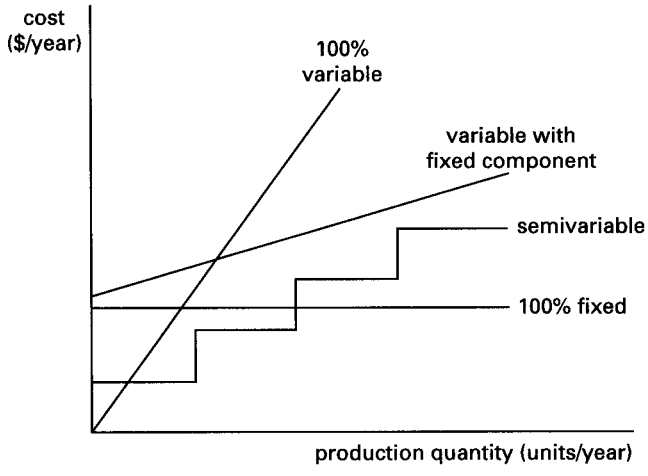

Figure 85.9 *Fixed and Variable Costs*

An additional category of cost is the *semivariable cost.* This type of cost increases step-wise. Semivariable cost structures are typical of situations where *excess capacity* exists. For example, supervisory cost is a step-wise function of the number of production shifts. Also, labor cost for truck drivers is a step-wise function of weight (volume) transported. As long as a truck has room left (i.e., excess capacity), no additional driver is needed. As soon as the truck is filled, labor cost will increase.

Table 85.7 *Summary of Fixed and Variable Costs*

fixed costs
- rent
- property taxes
- interest on loans
- insurance
- janitorial service expense
- tooling expense
- setup, cleanup, and tear-down expenses
- depreciation expense
- marketing and selling costs
- cost of utilities
- general burden and overhead expense

variable costs
- direct material costs
- direct labor costs
- cost of miscellaneous supplies
- payroll benefit costs
- income taxes
- supervision costs

49. ACCOUNTING COSTS AND EXPENSE TERMS

The accounting profession has developed special terms for certain groups of costs. When annual costs are incurred due to the functioning of a piece of equipment, they are known as *operating and maintenance* (O&M) *costs.* The annual costs associated with operating a business (other than the costs directly attributable to production) are known as *general, selling, and administrative* (GS&A) *expenses.*

Direct labor costs are costs incurred in the factory, such as assembly, machining, and painting labor costs. *Direct material costs* are the costs of all materials that go into production.[39] Typically, both direct labor and direct material costs are given on a per-unit or per-item basis. The sum of the direct labor and direct material costs is known as the *prime cost.*

There are certain additional expenses incurred in the factory, such as the costs of factory supervision, stock-picking, quality control, factory utilities, and miscellaneous supplies (cleaning fluids, assembly lubricants, routing tags, etc.) that are not incorporated into the final product. Such costs are known as *indirect manufacturing expenses* (IME) or *indirect material and labor costs.*[40] The sum of the per-unit indirect manufacturing expense and prime cost is known as the *factory cost.*

Research and development (R&D) *costs* and *administrative expenses* are added to the factory cost to give the *manufacturing cost* of the product.

Additional costs are incurred in marketing the product. Such costs are known as *selling expenses* or *marketing expenses.* The sum of the selling expenses and manufacturing cost is the *total cost* of the product.

Figure 85.10 illustrates these terms.[41]

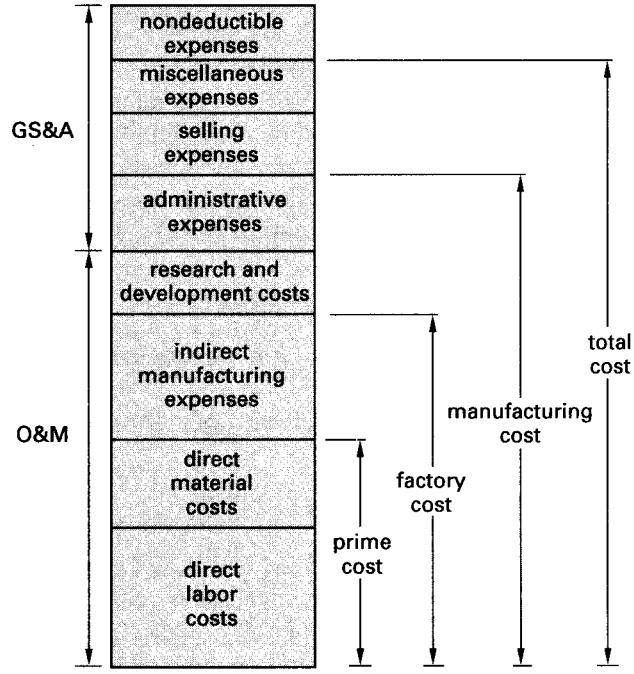

Figure 85.10 *Costs and Expenses Combined*

The distinctions among the various forms of cost (particularly with overhead costs) are not standardized. Each company must develop a classification system to deal with the various cost factors in a consistent manner. There are also other terms in use (e.g., *raw materials, operating supplies, general plant overhead*), but these terms must be interpreted within the framework of each company's classification system. Table 85.8 is typical of such classification systems.

[39]There may be problems with pricing the material when it is purchased from an outside vendor and the stock on hand derives from several shipments purchased at different prices.

[40]The *indirect material* and *labor costs* usually exclude costs incurred in the office area.

[41]Notice that *total cost* does not include income taxes.

Table 85.8 *Typical Classification of Expenses*

direct material expenses
- items purchased from other vendors
- manufactured assemblies

direct labor expenses
- machining and forming
- assembly
- finishing
- inspection
- testing

factory overhead expenses
- supervision
- benefits
  - pension
  - medical insurance
  - vacations
- wages overhead
  - unemployment compensation taxes
  - social security taxes
  - disability taxes
- stock-picking
- quality control and inspection
- expediting
- rework
- maintenance
- miscellaneous supplies
  - routing tags
  - assembly lubricants
  - cleaning fluids
  - wiping cloths
  - janitorial supplies
- packaging (materials and labor)
- factory utilities
- laboratory
- depreciation on factory equipment

research and development expenses
- engineering (labor)
- patents
- testing
- prototypes (material and labor)
- drafting
- O&M of R&D facility

administrative expenses
- corporate officers
- accounting
- secretarial/clerical/reception
- security (protection)
- medical (nurse)
- employment (personnel)
- reproduction
- data processing
- production control
- depreciation on nonfactory equipment
- office supplies
- office utilities
- O&M of offices

selling expenses
- marketing (labor)
- advertising
- transportation (if not paid by customer)
- outside sales force (labor and expenses)
- demonstration units
- commissions
- technical service and support
- order processing
- branch office expenses

miscellaneous expenses
- insurance
- property taxes
- interest on loans

nondeductible expenses
- federal income taxes
- fines and penalties

50. ACCOUNTING PRINCIPLES

Basic Bookkeeping

An accounting or *bookkeeping system* is used to record historical financial transactions. The resultant records are used for product costing, satisfaction of statutory requirements, reporting of profit for income tax purposes, and general company management.

Bookkeeping consists of two main steps: recording the transactions, followed by categorization of the transactions.[42] The transactions (receipts and disbursements) are recorded in a *journal (book of original entry)* to complete the first step. Such a journal is organized in a simple chronological and sequential manner.[43] The transactions are then categorized (into interest income, advertising expense, etc.) and posted (i.e., entered or written) into the appropriate *ledger account.*

The ledger accounts together constitute the *general ledger* or *ledger.* All ledger accounts can be classified into one of three types: *asset accounts, liability accounts,* and *owners' equity accounts.* Strictly speaking, income and expense accounts, kept in a separate journal, are included within the classification of owners' equity accounts.

Together, the journal and ledger are known simply as "the books" of the company.

Balancing the Books

In a business environment, *balancing the books* means more than reconciling the checkbook and bank statements. All accounting entries must be posted in such a way as to maintain the equality of the *basic accounting equation,*

$$\text{assets} = \text{liability} + \text{owners' equity} \qquad 85.56$$

In a *double-entry bookkeeping system,* the equality is maintained within the ledger system by entering each transaction into two balancing ledger accounts. For example, paying a utility bill would decrease the cash account (an asset account) and decrease the utility expense account (a liability account) by the same amount.

Transactions are either *debits* or *credits,* depending on their sign. Increases in asset accounts are debits; decreases are credits. For liability and equity accounts, the opposite is true: Increases are credits, and decreases are debits.[44]

[42]These two steps are not to be confused with the *double-entry bookkeeping method.*

[43]The two-step process is more typical of a *manual bookkeeping system* than a computerized *general ledger system.* However, even most computerized systems produce reports in journal entry order, as well as account summaries.

[44]There is a difference in sign between asset and liability accounts. Thus, an increase in an expense account is actually a decrease. The accounting profession, apparently, is comfortable with the common confusion that exists between debits and credits.

Cash and Accrual Systems[45]

The simplest form of bookkeeping is based on the *cash system.* The only transactions that are entered into the journal are those that represent cash receipts and disbursements. In effect, a checkbook register or bank deposit book could serve as the journal.

During a given period (e.g., month or quarter), expense liabilities may be incurred even though the payments for those expenses have not been made. For example, an invoice (bill) may have been received but not paid. Under the *accrual system*, the obligation is posted into the appropriate expense account before it is paid.[46] Analogous to expenses, under the accrual system, income will be claimed before payment is received. Specifically, a sales transaction can be recorded as income when the customer's order is received, when the outgoing invoice is generated, or when the merchandise is shipped.

Financial Statements

Each period, two types of corporate financial statements are typically generated: the *balance sheet* and *profit and loss* (P&L) *statements.*[47] The profit and loss statement, also known as a *statement of income and retained earnings*, is a summary of sources of *income* or *revenue* (interest, sales, fees charged, etc.) and *expenses* (utilities, advertising, repairs, etc.) for the period. The expenses are subtracted from the revenues to give a *net income* (generally, before taxes).[48] Figure 85.11 illustrates a simple profit and loss statement.

The *balance sheet* presents the *basic accounting equation* in tabular form. The balance sheet lists the major categories of assets and outstanding liabilities. The difference between asset values and liabilities is the *equity*, as defined in Eq. 85.56. This equity represents what would be left over after satisfying all debts by liquidating the company.

[45]There is also a distinction made between cash flows that are known and those that are expected. It is a *standard accounting principle* to record losses in full, at the time they are recognized, even before their occurrence. In the construction industry, for example, losses are recognized in full and projected to the end of a project as soon as they are foreseeable. Profits, on the other hand, are recognized only as they are realized (typically, as a percentage of project completion). The difference between cash and accrual systems is a matter of *bookkeeping.* The difference between loss and profit recognition is a matter of *accounting convention.* Engineers seldom need to be concerned with the accounting tradition.

[46]The expense for an item or service might be accrued even *before* the invoice is received. It might be recorded when the purchase order for the item or service is generated, or when the item or service is received.

[47]Other types of financial statements (*statements of changes in financial position, cost of sales statements*, inventory and asset reports, etc.) also will be generated, depending on the needs of the company.

[48]Financial statements also can be prepared with percentages (of total assets and net revenue) instead of dollars, in which case they are known as *common size financial statements.*

revenue				
interest	2000			
sales	237,000			
returns	(23,000)			
net revenue		216,000		
expenses				
salaries	149,000			
utilities	6000			
advertising	28,000			
insurance	4000			
supplies	1000			
net expenses		188,000		
period net income			28,000	
beginning retained earnings			63,000	
net year-to-date earnings				91,000

Figure 85.11 *Simplified Profit and Loss Statement*

There are several terms that appear regularly on balance sheets.

- *current assets:* cash and other assets that can be converted quickly into cash, such as accounts receivable, notes receivable, and merchandise (inventory). Also known as *liquid assets.*
- *fixed assets:* relatively permanent assets used in the operation of the business and relatively difficult to convert into cash. Examples are land, buildings, and equipment. Also known as *nonliquid assets.*
- *current liabilities:* liabilities due within a short period of time (e.g., within one year) and typically paid out of current assets. Examples are accounts payable, notes payable, and other accrued liabilities.
- *long-term liabilities:* obligations that are not totally payable within a short period of time (e.g., within one year).

Figure 85.12 is a simplified balance sheet.

Analysis of Financial Statements

Financial statements are evaluated by management, lenders, stockholders, potential investors, and many other groups for the purpose of determining the *health of the company.* The health can be measured in terms of *liquidity* (ability to convert assets to cash quickly), *solvency* (ability to meet debts as they become due), and *relative risk* (of which one measure is *leverage*—the portion of total capital contributed by owners).

The analysis of financial statements involves several common ratios, usually expressed as percentages. The following are some frequently encountered ratios.

- *current ratio:* an index of short-term paying ability.

$$\text{current ratio} = \frac{\text{current assets}}{\text{current liabilities}}$$

ASSETS			
current assets			
cash	14,000		
accounts receivable	36,000		
notes receivable	20,000		
inventory	89,000		
prepaid expenses	3000		
total current assets		162,000	
plant, property, and equipment			
land and buildings	217,000		
motor vehicles	31,000		
equipment	94,000		
accumulated depreciation	(52,000)		
total fixed assets		290,000	
total assets			452,000
LIABILITIES AND OWNERS' EQUITY			
current liabilities			
accounts payable	66,000		
accrued income taxes	17,000		
accrued expenses	8000		
total current liabilities		91,000	
long-term debt			
notes payable	117,000		
mortgage	23,000		
total long-term debt		140,000	
owners' and stockholders' equity			
stock	130,000		
retained earnings	91,000		
total owners' equity		221,000	
total liabilities and owners' equity			452,000

Figure 85.12 *Simplified Balance Sheet*

- *quick* (or *acid-test) ratio:* a more stringent measure of short-term debt-paying ability. The *quick assets* are defined to be current assets minus inventories and prepaid expenses.

$$\text{quick ratio} = \frac{\text{quick assets}}{\text{current liabilities}}$$

- *receivable turnover:* a measure of the average speed with which accounts receivable are collected.

$$\text{receivable turnover} = \frac{\text{net credit sales}}{\text{average net receivables}}$$

- *average age of receivables:* number of days, on the average, in which receivables are collected.

$$\text{average age of receivables} = \frac{365}{\text{receivable turnover}}$$

- *inventory turnover:* a measure of the speed with which inventory is sold, on the average.

$$\text{inventory turnover} = \frac{\text{cost of goods sold}}{\text{average cost of inventory on hand}}$$

- *days supply of inventory on hand:* number of days, on the average, that the current inventory would last.

$$\text{days supply of inventory on hand} = \frac{365}{\text{inventory turnover}}$$

- *book value per share of common stock:* number of dollars represented by the balance sheet owners' equity for each share of common stock outstanding.

$$\text{book value per share of common stock} = \frac{\text{common shareholders' equity}}{\text{number of outstanding shares}}$$

- *gross margin:* gross profit as a percentage of sales. (Gross profit is sales less cost of goods sold.)

$$\text{gross margin} = \frac{\text{gross profit}}{\text{net sales}}$$

- *profit margin ratio:* percentage of each dollar of sales that is net income.

$$\text{profit margin} = \frac{\text{net income before taxes}}{\text{net sales}}$$

- *return on investment ratio:* shows the percent return on owners' investment.

$$\text{return on investment} = \frac{\text{net income}}{\text{owners' equity}}$$

- *price-earnings ratio:* indication of relationship between earnings and market price per share of common stock, useful in comparisons between alternative investments.

$$\text{price-earnings} = \frac{\text{market price per share}}{\text{earnings per share}}$$

51. COST ACCOUNTING

Cost accounting is the system that determines the cost of manufactured products. Cost accounting is called *job cost accounting* if costs are accumulated by part number or contract. It is called *process cost accounting* if costs are accumulated by departments or manufacturing processes.

Cost accounting is dependent on historical and recorded data. The unit product cost is determined from actual expenses and numbers of units produced. Allowances (i.e., budgets) for future costs are based on these historical figures. Any deviation from historical figures is called a *variance*. Where adequate records are available, variances can be divided into *labor variance* and *material variance*.

When determining a unit product cost, the direct material and direct labor costs are generally clear-cut and easily determined. Furthermore, these costs are 100% variable costs. However, the indirect cost per unit of product is not as easily determined. Indirect costs (*burden*, *overhead*, etc.) can be fixed or semivariable costs. The amount of indirect cost allocated to a unit will depend on the unknown future overhead expense as well as the unknown future production (*vehicle size*).

A typical method of allocating indirect costs to a product is as follows.

step 1: Estimate the total expected indirect (and overhead) costs for the upcoming year.

step 2: Determine the most appropriate vehicle (basis) for allocating the overhead to production. Usually, this vehicle is either the number of units expected to be produced or the number of direct hours expected to be worked in the upcoming year.

step 3: Estimate the quantity or size of the overhead vehicle.

step 4: Divide expected overhead costs by the expected overhead vehicle to obtain the unit overhead.

step 5: Regardless of the true size of the overhead vehicle during the upcoming year, one unit of overhead cost is allocated per unit of overhead vehicle.

Once the prime cost has been determined and the indirect cost calculated based on projections, the two are combined into a *standard factory cost* or *standard cost*, which remains in effect until the next budgeting period (usually a year).

During the subsequent manufacturing year, the standard cost of a product is not generally changed merely because it is found that an error in projected indirect costs or production quantity (vehicle size) has been made. The allocation of indirect costs to a product is assumed to be independent of errors in forecasts. Rather, the difference between the expected and actual expenses, known as the *burden (overhead) variance*, experienced during the year is posted to one or more *variance accounts*.

Burden (overhead) variance is caused by errors in forecasting both the actual indirect expense for the upcoming year and the overhead vehicle size. In the former case, the variance is called *burden budget variance*; in the latter, it is called *burden capacity variance*.

Example 85.29

A company expects to produce 8000 items in the coming year. The current material cost is \$4.54 each. Sixteen minutes of direct labor are required per unit. Workers are paid \$7.50 per hour. 2133 direct labor hours are forecasted for the product. Miscellaneous overhead costs are estimated at \$45,000.

Find (a) the expected direct material cost, (b) the direct labor cost, (c) the prime cost, (d) the burden as a function of production and direct labor, and (e) the total cost.

Solution

(a) The direct material cost was given as \$4.54.

(b) The direct labor cost is

$$\left(\frac{16\ \text{min}}{60\ \frac{\text{min}}{\text{hr}}}\right)(\$7.50) = \$2.00$$

(c) The prime cost is

$$\$4.54 + \$2.00 = \$6.54$$

(d) If the burden vehicle is production, the burden rate is \$45,000/8000 = \$5.63 per item, making the total cost

$$\$4.54 + \$2.00 + \$5.63 = \$12.17$$

(e) If the burden vehicle is direct labor hours, the burden rate is \$45,000/2133 = \$21.10 per hour, making the total cost

$$\$4.54 + \$2.00 + \left(\frac{16\ \text{min}}{60\ \frac{\text{min}}{\text{hr}}}\right)(\$21.10) = \$12.17$$

Example 85.30

The actual performance of the company in Ex. 85.29 is given by the following figures.

actual production: 7560
actual overhead costs: \$47,000

What are the burden budget variance and the burden capacity variance?

Solution

The burden capacity variance is

$$\$45{,}000 - (7560)(\$5.63) = \$2437$$

The burden budget variance is

$$\$47{,}000 - \$45{,}000 = \$2000$$

The overall burden variance is

$$\$47{,}000 - (7560)(\$5.63) = \$4437$$

The sum of the burden capacity and burden budget variances should equal the overall burden variance.

$$\$2437 + \$2000 = \$4437$$

52. COST OF GOODS SOLD

Cost of goods sold (COGS) is an accounting term that represents an inventory account adjustment.[49] Cost of goods sold is the difference between the starting and ending inventory valuations. That is,

$$\begin{aligned}\text{COGS} &= \text{starting inventory valuation} \\ &\quad - \text{ending inventory valuation}\end{aligned} \qquad 85.57$$

Cost of goods sold is subtracted from *gross profit* to determine the *net profit* of a company. Despite the fact that cost of goods sold can be a significant element in the profit equation, the inventory adjustment may not be made each accounting period (e.g., each month) due to the difficulty in obtaining an accurate inventory valuation.

With a *perpetual inventory system*, a company automatically maintains up-to-date inventory records, either through an efficient stocking and stock-releasing system or through a *point of sale* (POS) *system* integrated with the inventory records. If a company only counts its inventory (i.e., takes a *physical inventory*) at regular intervals (e.g., once a year), it is said to be operating on a *periodic inventory system*.

Inventory accounting is a source of many difficulties. The inventory value is calculated by multiplying the quantity on hand by the standard cost. In the case of completed items actually assembled or manufactured at the company, this standard cost usually is the manufacturing cost, although factory cost also can be used. In the case of purchased items, the standard cost will be the cost per item charged by the supplying vendor. In some cases, delivery and transportation costs will be included in this standard cost.

It is not unusual for the elements in an item's inventory to come from more than one vendor, or from one vendor in more than one order. Inventory valuation is more difficult if the price paid is different for these different purchases. There are four methods of determining the cost of elements in inventory. Any of these methods can be used (if applicable), but the method must be used consistently from year to year. The four methods are as follows.

- *specific identification method:* Each element can be uniquely associated with a cost. Inventory elements with serial numbers fit into this costing scheme. Stock, production, and sales records must include the serial number.
- *average cost method:* The standard cost of an item is the average of (recent or all) purchase costs for that item.
- *first-in, first-out* (FIFO) *method:* This method keeps track of how many of each item were purchased each time and the number remaining out of each purchase, as well as the price paid at each purchase. The inventory system assumes that the oldest elements are issued first.[50] Inventory value is a weighted average dependent on the number of elements from each purchase remaining. Items issued no longer contribute to the inventory value.
- *last-in, first-out* (LIFO) *method:* This method keeps track of how many of each item were purchased each time and the number remaining out of each purchase, as well as the price paid at each purchase.[51] The inventory value is a weighted average dependent on the number of elements from each purchase remaining. Items issued no longer contribute to the inventory value.

53. BREAK-EVEN ANALYSIS

Special Nomenclature

f	fixed cost that does not vary with production
a	*incremental cost* to produce one additional item (also called *marginal cost* or *differential cost*)
Q	quantity sold
p	*incremental value* (price)
R	total revenue
C	total cost

Break-even analysis is a method of determining when the value of one alternative becomes equal to the value of another. A common application is that of determining when costs exactly equal revenue. If the manufactured quantity is less than the break-even quantity, a loss is incurred. If the manufactured quantity is greater than the break-even quantity, a profit is made.

Assuming no change in the inventory, the *break-even point* can be found by setting costs equal to revenue ($C = R$).

$$C = f + aQ \qquad 85.58$$

$$R = pQ \qquad 85.59$$

$$Q^* = \frac{f}{p - a} \qquad 85.60$$

[49]The cost of goods sold inventory adjustment is posted to the *COGS expense account*.

[50]If all elements in an item's inventory are identical, and if all shipments of that item are agglomerated, there will be no way to guarantee that the oldest element in inventory is issued first. But, unless *spoilage* is a problem, it really does not matter.

[51]See Ftn. 50.

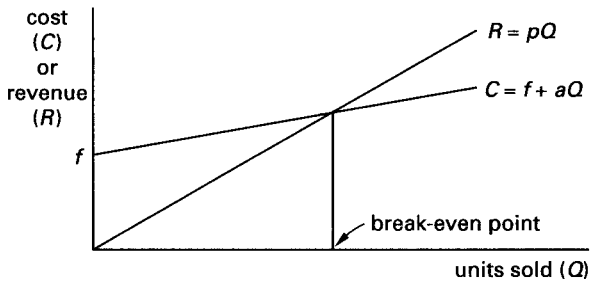

Figure 85.13 *Break-Even Quantity*

An alternative form of the break-even problem is to find the number of units per period for which two alternatives have the same total costs. Fixed costs are to be spread over a period longer than one year using the equivalent uniform annual cost (EUAC) concept. One of the alternatives will have a lower cost if production is less than the break-even point. The other will have a lower cost for production greater than the break-even point.

Example 85.31

Two plans are available for a company to obtain automobiles for its salesmen. How many miles must the cars be driven each year for the two plans to have the same costs? Use an interest rate of 10%. (Use the year-end convention for all costs.)

plan A: Lease the cars and pay \$0.15 per mile.

plan B: Purchase the cars for \$5000. Each car has an economic life of three years, after which it can be sold for \$1200. Gas and oil cost \$0.04 per mile. Insurance is \$500 per year.

Solution

Let x be the number of miles driven per year. Then, the EUAC for both alternatives is

$$\begin{aligned}
\text{EUAC(A)} &= 0.15x \\
\text{EUAC(B)} &= 0.04x + \$500 + (\$5000)(A/P, 10\%, 3) \\
&\quad - (\$1200)(A/F, 10\%, 3) \\
&= 0.04x + \$500 + (\$5000)(0.4021) \\
&\quad - (\$1200)(0.3021) \\
&= 0.04x + 2148
\end{aligned}$$

Setting EUAC(A) and EUAC(B) equal and solving for x yields 19,527 miles per year as the break-even point.

54. PAY-BACK PERIOD

The *pay-back period* is defined as the length of time, usually in years, for the cumulative net annual profit to equal the initial investment. It is tempting to introduce equivalence into pay-back period calculations, but by convention, this is generally not done.[52]

$$\text{pay-back period} = \frac{\text{initial investment}}{\text{net annual profit}} \qquad 85.61$$

Example 85.32

A ski resort installs two new ski lifts at a total cost of \$1,800,000. The resort expects the annual gross revenue to increase by \$500,000 while it incurs an annual expense of \$50,000 for lift operation and maintenance. What is the pay-back period?

Solution

From Eq. 85.61,

$$\text{pay-back period} = \frac{\$1{,}800{,}000}{\$500{,}000 - \$50{,}000} = 4\,\text{years}$$

55. MANAGEMENT GOALS

Depending on many factors (market position, age of the company, age of the industry, perceived marketing and sales windows, etc.), a company may select one of many production and marketing strategic goals. Three such strategic goals are

- maximization of product demand
- minimization of cost
- maximization of profit

Such goals require knowledge of how the dependent variable (e.g., demand quantity or quantity sold) varies as a function of the independent variable (e.g., price). Unfortunately, these three goals are not usually satisfied simultaneously. For example, minimization of product cost may require a large production run to realize economies of scale, while the actual demand is too small to take advantage of such economies of scale.

If sufficient data are available to plot the independent and dependent variables, it may be possible to optimize the dependent variable graphically. Of course, if the relationship between independent and dependent variables is known algebraically, the dependent variable can be optimized by taking derivatives or by use of other numerical methods.

[52]Equivalence (i.e., interest and compounding) generally is not considered when calculating the "pay-back period." However, if it is desirable to include equivalence, then the term *pay-back period* should not be used. Other terms, such as *cost recovery period* or *life of an equivalent investment*, should be used. Unfortunately, this convention is not always followed in practice.

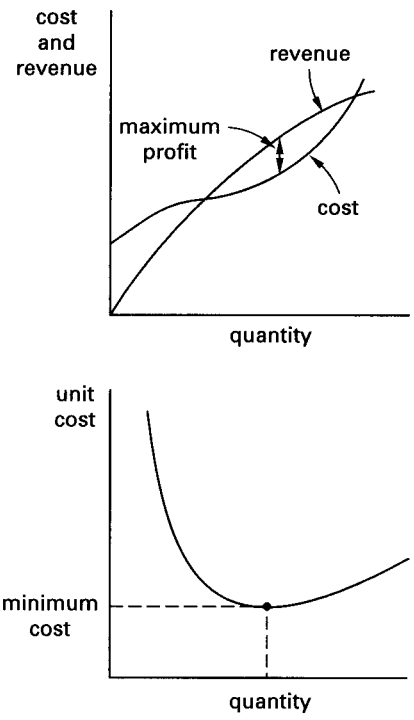

Figure 85.14 *Graphs of Management Goal Functions*

56. INFLATION

It is important to perform economic studies in terms of *constant value dollars.* One method of converting all cash flows to constant value dollars is to divide the flows by some annual *economic indicator* or price index.

If indicators are not available, cash flows can be adjusted by assuming that inflation is constant at a decimal rate (e) per year. Then, all cash flows can be converted to $t = 0$ dollars by dividing by $(1 + e)^n$, where n is the year of the cash flow.

An alternative is to replace the effective annual interest rate (i) with a value corrected for inflation. This corrected value (i') is

$$i' = i + e + ie \qquad 85.62$$

This method has the advantage of simplifying the calculations. However, precalculated factors are not available for the non-integer values of i'. Therefore, Table 85.1 must be used to calculate the factors.

Example 85.33

What is the uninflated present worth of a \$2000 future value in two years if the average inflation rate is 6% and i is 10%?

Solution

$$P = \frac{\$2000}{(1 + 0.10)^2(1 + 0.06)^2} = \$1471$$

Example 85.34

Repeat Ex. 85.33 using i'.

Solution

$$i' = 0.10 + 0.06 + (0.10)(0.06) = 0.166$$

$$P = \frac{\$2000}{(1 + 0.166)^2} = \$1471$$

57. CONSUMER LOANS

Special Nomenclature

BAL_j	balance after the jth payment
LV	principal total value loaned (cost minus down payment)
j	payment or period number
N	total number of payments to pay off the loan
PI_j	jth interest payment
PP_j	jth principal payment
PT_j	jth total payment
ϕ	effective rate per period (r/k)

Many different arrangements can be made between a borrower and a lender. With the advent of creative financing concepts, it often seems that there are as many variations of loans as there are loans made. Nevertheless, there are several traditional types of transactions. Real estate or investment texts, or a financial consultant, should be consulted for more complex problems.

Simple Interest

Interest due does not compound with a *simple interest loan.* The interest due is merely proportional to the length of time that the principal is outstanding. Because of this, simple interest loans are seldom made for long periods (e.g., more than one year). (For loans less than one year, it is commonly assumed that a year consists of 12 months of 30 days each.)

Example 85.35

A \$12,000 simple interest loan is taken out at 16% per annum interest rate. The loan matures in two years with no intermediate payments. How much will be due at the end of the second year?

Solution

The interest each year is

$$\text{PI} = (0.16)(\$12{,}000) = \$1920$$

The total amount due in two years is

$$\text{PT} = \$12{,}000 + (2)(\$1920) = \$15{,}840$$

Example 85.36

$4000 is borrowed for 75 days at 16% per annum simple interest. How much will be due at the end of 75 days?

Solution

$$\text{amount due} = \$4000 + (0.16)\left(\frac{75 \text{ days}}{360 \dfrac{\text{days}}{\text{bank yr}}}\right)(\$4000)$$

$$= \$4133$$

Loans with Constant Amount Paid Toward Principal

With this loan type, the payment is not the same each period. The amount paid toward the principal is constant, but the interest varies from period to period. The equations that govern this type of loan are

$$\text{BAL}_j = \text{LV} - (j)(\text{PP}) \quad 85.63$$

$$\text{PI}_j = \phi(\text{BAL})_{j-1} \quad 85.64$$

$$\text{PT}_j = \text{PP} + \text{PI}_j \quad 85.65$$

$$\text{PP} = \frac{\text{LV}}{N} \quad 85.66$$

$$N = \frac{\text{LV}}{\text{PP}} \quad 85.67$$

$$\text{LV} = (\text{PP} + \text{PI}_1)(P/A, \phi, N) - \text{PI}_N(P/G, \phi, N) \quad 85.68$$

$$1 = \left(\frac{1}{N} + \phi\right)(P/A, \phi, N) - \left(\frac{\phi}{N}\right)(P/G, \phi, N) \quad 85.69$$

Figure 85.15 *Loan with Constant Amount Paid Toward Principal*

Example 85.37

A $12,000 six-year loan is taken from a bank that charges 15% effective annual interest. Payments toward the principal are uniform, and repayments are made at the end of each year. Tabulate the interest, total payments, and the balance remaining after each payment is made.

Solution

The amount of each principal payment is

$$\text{PP} = \frac{\$12{,}000}{6} = \$2000$$

At the end of the first year (before the first payment is made), the principal balance is $12,000 (i.e., BAL_0 = $12,000). From Eq. 85.64, the interest payment is

$$\text{PI}_1 = (0.15)(\$12{,}000) = \$1800$$

The total first payment is

$$\text{PT}_1 = \text{PP} + \text{PI} = \$2000 + \$1800 = \$3800$$

The following table is similarly constructed.

	BAL_j	PP_j	PI_j	PT_j
j		(in dollars)		
0	12,000	–	–	–
1	10,000	2000	1800	3800
2	8000	2000	1500	3500
3	6000	2000	1200	3200
4	4000	2000	900	2900
5	2000	2000	600	2600
6	0	2000	300	2300

Direct Reduction Loans

This is the typical "interest paid on unpaid balance" loan. The amount of the periodic payment is constant, but the amounts paid toward the principal and interest both vary.

$$\text{BAL}_{j-1} = \text{PT}\left(\frac{1 - (1+\phi)^{j-1-N}}{\phi}\right) \quad 85.70$$

$$\text{PI}_j = \phi(\text{BAL})_{j-1} \quad 85.71$$

$$\text{PP}_j = \text{PT} - \text{PI}_j \quad 85.72$$

$$\text{BAL}_j = \text{BAL}_{j-1} - \text{PP}_j \quad 85.73$$

$$N = \frac{-\ln\left(1 - \dfrac{\phi(\text{LV})}{\text{PT}}\right)}{\ln(1+\phi)} \quad 85.74$$

Equation 85.74 calculates the number of payments necessary to pay off a loan. This equation can be solved with effort for the total periodic payment (PT) or the

initial value of the loan (LV). It is easier, however, to use the $(A/P, i\%, n)$ factor to find the payment and loan value.

$$\text{PT} = \text{LV}(A/P, \phi\%, N) \qquad 85.75$$

If the loan is repaid in yearly installments, then i is the effective annual rate. If the loan is paid off monthly, then i should be replaced by the effective rate per month (ϕ from Eq. 85.54). For monthly payments, N is the number of months in the loan period.

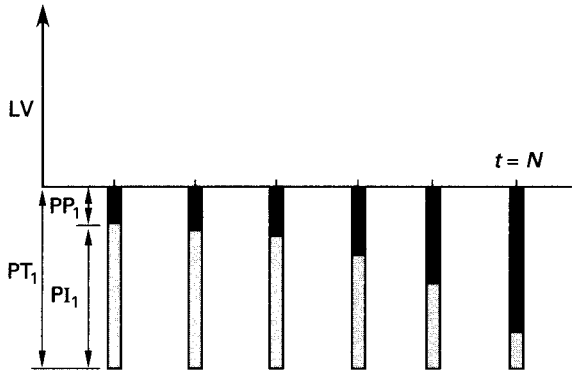

Figure 85.16 *Direct Reduction Loan*

Example 85.38

A $45,000 loan is financed at 9.25% per annum. The monthly payment is $385. What are the amounts paid toward interest and principal in the 14th period? What is the remaining principal balance after the 14th payment has been made?

Solution

The effective rate per month is

$$\phi = \frac{r}{k} = \frac{0.0925}{12}$$
$$= 0.0077083\ldots \quad \text{[say 0.007708]}$$

$$N = \frac{-\ln\left(1 - \frac{(0.007708)(45{,}000)}{385}\right)}{\ln(1 + 0.007708)} = 301$$

$$\text{BAL}_{13} = (\$385)\left(\frac{1 - (1 + 0.007708)^{14-1-301}}{0.007708}\right)$$
$$= \$44{,}476.39$$

$$\text{PI}_{14} = (0.007708)(\$44{,}476.39) = \$342.82$$

$$\text{PP}_{14} = \$385 - \$342.82 = \$42.18$$

$$\text{BAL}_{14} = \$44{,}476.39 - \$42.18 = \$44{,}434.21$$

Direct Reduction Loans with Balloon Payments

This type of loan has a constant periodic payment, but the duration of the loan is insufficient to completely pay back the principal (i.e, the loan is not fully amortized). Therefore, all remaining unpaid principal must be paid back in a lump sum when the loan matures. This large payment is known as a *balloon payment.*[53]

Equations 85.71 through 85.75 also can be used with this type of loan. The remaining balance after the last payment is the balloon payment. This balloon payment must be repaid along with the last regular payment calculated.

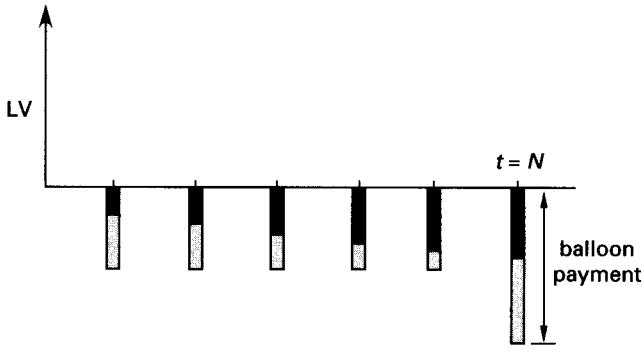

Figure 85.17 *Direct Reduction Loan with Balloon Payment*

58. FORECASTING

There are many types of forecasting models, although most are variations of the basic types.[54] All models produce a *forecast* (F_{t+1}) of some quantity (*demand* is used in this section) in the next period based on actual measurements (D_j) in current and prior periods. All of the models also try to provide *smoothing* (or *damping*) of extreme data points.

Forecasts by Moving Averages

The method of *moving average forecasting* weights all previous demand data points equally and provides some smoothing of extreme data points. The amount of smoothing increases as the number of data points, n, increases.

$$F_{t+1} = \frac{1}{n}\sum_{m=t+1-n}^{t} D_m \qquad 85.76$$

Forecasts by Exponentially Weighted Averages

With *exponentially weighted forecasts*, the more current (most recent) data points receive more weight. This method uses a *weighting factor* (α), also known as a *smoothing coefficient*, which typically varies between

[53]The term *balloon payment* may include the final interest payment as well. Generally, the problem statement will indicate whether the balloon payment is inclusive or exclusive of the regular payment made at the end of the loan period.

[54]For example, forecasting models that take into consideration steady (linear), cyclical, annual, and seasonal trends are typically variations of the exponentially weighted model. A truly different forecasting tool, however, is *Monte Carlo simulation.*

0.01 and 0.30. An initial forecast is needed to start the method. Forecasts immediately following are sensitive to the accuracy of this first forecast. It is common to choose $F_0 = D_1$ to get started.

$$F_{t+1} = \alpha D_t + (1 - \alpha)F_t \qquad 85.77$$

59. LEARNING CURVES

Special Nomenclature

R	decimal learning curve rate (2^{-b})
T_1	time or cost for the first item
T_n	time or cost for the nth item
n	total number of items produced
b	learning curve constant

The more products that are made, the more efficient the operation becomes due to experience gained. Therefore, direct labor costs decrease.[55] Usually, a *learning curve* is specified by the decrease in cost each time the cumulative quantity produced doubles. If there is a 20% decrease per doubling, the curve is said to be an 80% learning curve (i.e., the *learning curve rate*, R, is 80%).

Then, the time to produce the nth item is

$$T_n = T_1 n^{-b} \qquad 85.78$$

The total time to produce units from quantity n_1 to n_2 inclusive is approximately given by Eq. 85.79. T_1 is a constant, the time for item 1, and does not correspond to n unless $n_1 = 1$.

$$\int_{n_1}^{n_2} T_n \, dn \approx \left(\frac{T_1}{1-b}\right)\left(\left(n_2 + \tfrac{1}{2}\right)^{1-b} - \left(n_1 - \tfrac{1}{2}\right)^{1-b}\right) \qquad 85.79$$

The *average time per unit* over the production from n_1 to n_2 is the above total time from Eq. 85.79 divided by the quantity produced, $(n_2 - n_1 + 1)$.

$$T_{\text{ave}} = \frac{\int_{n_1}^{n_2} T_n dn}{n_2 - n_1 + 1} \qquad 85.80$$

Table 85.9 lists representative values of the *learning curve constant* (b). For learning curve rates not listed in the table, Eq. 85.81 can be used to find b.

$$b = \frac{-\log_{10} R}{\log_{10}(2)} = \frac{-\log_{10} R}{0.301} \qquad 85.81$$

[55]Remember that learning curve reductions apply only to direct labor costs. They are not applied to indirect labor or direct material costs.

Table 85.9 *Learning Curve Constants*

learning curve rate (R)	b
0.70 (70%)	0.515
0.75 (75%)	0.415
0.80 (80%)	0.322
0.85 (85%)	0.234
0.90 (90%)	0.152
0.95 (95%)	0.074

Example 85.39

A 70% learning curve is used with an item whose first production time is 1.47 hr. (a) How long will it take to produce the 11th item? (b) How long will it take to produce the 11th through 27th items?

Solution

(a) From Eq. 85.78,

$$T_{11} = (1.47 \text{ hr})(11)^{-0.515} = 0.428 \text{ hr}$$

(b) The time to produce the 11th item through 27th item is given by Eq. 85.79.

$$T \approx \left(\frac{1.47 \text{ hr}}{1 - 0.515}\right)\left((27.5)^{1-0.515} - (10.5)^{1-0.515}\right)$$
$$= 5.643 \text{ hr}$$

60. ECONOMIC ORDER QUANTITY

Special Nomenclature

a	constant depletion rate (items/unit time)
h	inventory storage cost ($/item-unit time)
H	total inventory storage cost between orders ($)
K	fixed cost of placing an order ($)
Q	order quantity (original quantity on hand)

The *economic order quantity* (EOQ) is the order quantity that minimizes the inventory costs per unit time. Although there are many different EOQ models, the simplest is based on the following assumptions.

- Reordering is instantaneous. The time between order placement and receipt is zero.
- Shortages are not allowed.
- Demand for the inventory item is deterministic (i.e., is not a random variable).
- Demand is constant with respect to time.
- An order is placed when the inventory is zero.

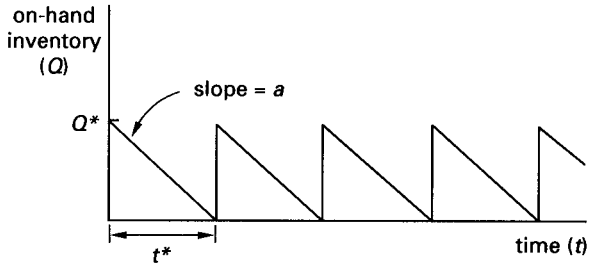

Figure 85.18 *Inventory with Instantaneous Reorder*

If the original quantity on hand is Q, the stock will be depleted at

$$t^* = \frac{Q}{a} \qquad 85.82$$

The total inventory storage cost between t_0 and t^* is

$$H = \tfrac{1}{2}Qht^* = \frac{Q^2h}{2a} \qquad 85.83$$

The total inventory and ordering cost per unit time is

$$C_t = \frac{aK}{Q} + \frac{hQ}{2} \qquad 85.84$$

C_t can be minimized with respect to Q. The economic order quantity and time between orders are

$$Q^* = \sqrt{\frac{2aK}{h}} \qquad 85.85$$

$$t^* = \frac{Q^*}{a} \qquad 85.86$$

61. SENSITIVITY ANALYSIS

Data analysis and forecasts in economic studies require estimates of costs that will occur in the future. There are always uncertainties about these costs. However, these uncertainties are insufficient reason not to make the best possible estimates of the costs. Nevertheless, a decision between alternatives often can be made more confidently if it is known whether or not the conclusion is sensitive to moderate changes in data forecasts. Sensitivity analysis provides this extra dimension to an economic analysis.

The sensitivity of a decision is determined by inserting a range of estimates for critical cash flows and other parameters. If radical changes can be made to a cash flow without changing the decision, the decision is said to be *insensitive* to uncertainties regarding that cash flow. However, if a small change in the estimate of a cash flow will alter the decision, that decision is said to be very *sensitive* to changes in the estimate. If the decision is sensitive only for a limited range of cash flow values, the term *variable sensitivity* is used. Figure 85.19 illustrates these terms.

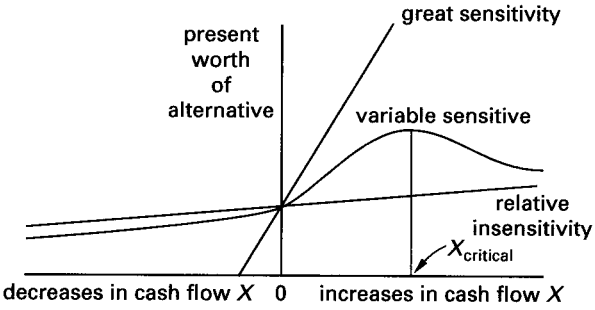

Figure 85.19 *Types of Sensitivity*

An established semantic tradition distinguishes between risk analysis and uncertainty analysis. *Risk analysis* addresses variables that have a known or estimated probability distribution. In this regard, statistics and probability theory can be used to determine the probability of a cash flow varying between given limits. On the other hand, *uncertainty analysis* is concerned with situations in which there is not enough information to determine the probability or frequency distribution for the variables involved.

As a first step, sensitivity analysis should be applied one at a time to the dominant factors. Dominant cost factors are those that have the most significant impact on the present value of the alternative.[56] If warranted, additional investigation can be used to determine the sensitivity to several cash flows varying simultaneously. Significant judgment is needed, however, to successfully determine the proper combinations of cash flows to vary. It is common to plot the dependency of the present value on the cash flow being varied in a two-dimensional graph. Simple linear interpolation is used (within reason) to determine the critical value of the cash flow being varied.

62. VALUE ENGINEERING

The *value* of an investment is defined as the ratio of its return (performance or utility) to its cost (effort or investment). The basic object of *value engineering* (VE, also referred to as *value analysis*) is to obtain the maximum per-unit value.[57]

Value engineering concepts often are used to reduce the cost of mass-produced manufactured products. This is done by eliminating unnecessary, redundant, or superfluous features, by redesigning the product for a less expensive manufacturing method, and by including features for easier assembly without sacrificing utility and

[56] In particular, engineering economic analysis problems are sensitive to the choice of effective interest rate (i) and to accuracy in cash flows at or near the beginning of the horizon. The problems will be less sensitive to accuracy in far-future cash flows, such as salvage value and subsequent generation replacement costs.

[57] Value analysis, the methodology that has become today's value engineering, was developed in the early 1950s by Lawrence D. Miles, an analyst at General Electric.

function.[58] However, the concepts are equally applicable to one-time investments, such as buildings, chemical processing plants, and space vehicles. In particular, value engineering has become an important element in all federally funded work.[59]

Typical examples of large-scale value engineering work are using stock-sized bearings and motors (instead of custom manufactured units), replacing rectangular concrete columns with round columns (which are easier to form), and substituting custom buildings with prefabricated structures.

Value engineering is usually a team effort. And, while the original designers may be on the team, usually outside consultants are utilized. The cost of value engineering is usually returned many times over by reduced construction and life-cycle costs.

PRACTICE PROBLEMS

1. At 6% effective annual interest, how much will be accumulated if $1000 is invested for ten years?

Answer: $1790.85 ($1790.80)

2. At 6% effective annual interest, what is the present worth of $2000 that becomes available in four years?

Answer: $1584.19 ($1584.20)

3. At 6% effective annual interest, how much should be invested to accumulate $2000 in 20 years?

Answer: $623.61 ($623.60)

4. At 6% effective annual interest, what year-end annual amount deposited over seven years is equivalent to $500 invested now?

Answer: $89.57

5. At 6% effective annual interest, what will be the accumulated amount at the end of ten years if $50 is invested at the end of each year for ten years?

Answer: $659.04 ($659.05)

6. At 6% effective annual interest, how much should be deposited at the start of each year for ten years (a total of ten deposits) in order to empty the fund by drawing out $200 at the end of each year for ten years (a total of ten withdrawals)?

Answer: $188.72 ($188.68)

7. At 6% effective annual interest, how much should be deposited at the start of each year for five years to accumulate $2000 on the date of the last deposit?

Answer: $354.79

8. At 6% effective annual interest, how much will be accumulated in ten years if three payments of $100 are deposited every other year for four years, with the first payment occurring at $t = 0$?

Answer: $480.31

9. $500 is compounded monthly at a 6% effective annual interest rate. How much will have accumulated in five years?

Answer: $674.50

10. What is the effective annual rate of return on an $80 investment that pays back $120 in seven years?

Answer: 6%

11. A new machine will cost $17,000 and will have a resale value of $14,000 after five years. Special tooling will cost $5000. The tooling will have a resale value of $2500 after five years. Maintenance will be $2000 per year. The effective annual interest rate is 6%. What will be the average annual cost of ownership during the next five years?

Answer: $4295.70

12. An old covered wooden bridge can be strengthened at a cost of $9000, or it can be replaced for $40,000. The present salvage value of the old bridge is $13,000. It is estimated that the reinforced bridge will last for 20 years, will have an annual cost of $500, and will have a salvage value of $10,000 at the end of 20 years. The estimated salvage value of the new bridge after 25 years is $15,000. Maintenance for the new bridge would cost $100 annually. The effective annual interest rate is 8%. Which is the best alternative?

Answer: Strengthen the old bridge.

13. A firm expects to receive $32,000 each year for 15 years from sales of a product. An initial investment of $150,000 will be required to manufacture the product. Expenses will run $7530 per year. Salvage value is zero, and straight-line depreciation is used. The income tax rate is 48%. What is the after-tax rate of return?

Answer: 8%

14. A public works project has initial costs of $1,000,000, benefits of $1,500,000, and disbenefits of $300,000. (a) What is the benefit/cost ratio? (b) What is the excess of benefits over costs?

Answers: (a) B/C = 1.2; (b) $200,000

[58] Some people say that value engineering is "the act of going over the plans and taking out everything that is interesting."

[59] U.S. Government Office of Management and Budget Circular A-131 outlines value engineering for federally funded construction projects.

15. A speculator in land pays $14,000 for property that he expects to hold for ten years. $1000 is spent in renovation, and a monthly rent of $75 is collected from the tenants. (Use the year-end convention.) Taxes are $150 per year, and maintenance costs are $250 per year. What must be the sale price in ten years to realize a 10% rate of return?

Answer: $30,937

16. What is the effective annual interest rate for a payment plan of 30 equal payments of $89.30 per month when a lump sum payment of $2000 would have been an outright purchase?

Answer: 26.82%

17. A depreciable item is purchased for $500,000. The salvage value at the end of 25 years is estimated at $100,000. What is the depreciation in each of the first three years using the (a) straight line, (b) sum-of-the-years' digits, and (c) double-declining balance methods?

Answers: (a) $16,000; (b) $30,769, $29,538, $28,308; (c) $40,000, $36,800, $33,856

18. Equipment that is purchased for $12,000 now is expected to be sold after ten years for $2000. The estimated maintenance is $1000 for the first year, but it is expected to increase $200 each year thereafter. The effective annual interest rate is 10%. What are the (a) present worth and (b) annual cost?

Answers: (a) $21,952; (b) $3572.70

19. A new grain combine with a twenty year life can remove seven pounds of rocks from its harvest per hour. Any rocks left in its output hopper will cause $25,000 damage in subsequent processes. Several investments are available to increase the rock-removal capacity, as listed in the table. The effective annual interest rate is 10%. What should be done?

rock removal rate	probability of exceeding rock removal rate	required investment to achieve removal rate
7	0.15	0
8	0.10	$15,000
9	0.07	$20,000
10	0.03	$30,000

Answer: Do nothing.

20. (*Time limit: one hour*) A mechanism that costs $10,000 has operating costs and salvage values as given. An effective annual interest rate of 20% is to be used.

year	operating cost	salvage value
1	$2000	$8000
2	$3000	$7000
3	$4000	$6000
4	$5000	$5000
5	$6000	$4000

(a) What is the economic life of the mechanism? (b) Assuming that the mechanism has been owned and operated for four years already, what is the cost of owning and operating the mechanism for one more year?

Answers: (a) 2 yr; (b) $8000

21. (*Time limit: one hour*) A salesperson intends to purchase a car for $50,000 for personal use, driving 15,000 miles per year. Insurance for personal use costs $2000 per year, and maintenance costs $1500 per year. The car gets 15 miles per gallon, and gasoline costs $1.50 per gallon. The resale value after five years will be $10,000. The salesperson's employer has asked that the car be used for business driving of 50,000 miles per year and has offered a reimbursement of $0.30 per mile. Using the car for business would increase the insurance cost to $3000 per year and maintenance to $2000 per year. The salvage value after five years would be reduced to $5000. If the employer purchased a car for the salesperson to use, the initial cost would be the same, but insurance, maintenance, and salvage would be $2500, $2000, and $8000, respectively. The salesperson's effective annual interest rate is 10%. (a) Is the reimbursement offer adequate? (b) With a reimbursement of $0.30 per mile, how many miles must the car be driven per year to justify the employer buying the car for the salesperson to use?

Answers: (a) $0.14638/mi; (b) 81,898 mi

22. (*Time limit: one hour*) Alternatives A and B are being evaluated. The effective annual interest rate is 10%. What alternative is economically superior?

	alternative A	alternative B
first cost	$80,000	$35,000
life	20 years	10 years
salvage value	$7000	0
annual costs		
years 1–5	$1000	$3000
years 6–10	$1500	$4000
years 11–20	$2000	0
additional cost		
year 10	$5000	0

Answer: Alternative B is economically superior.

23. (*Time limit: one hour*) A car is needed for three years. Plans A and B for acquiring the car are being evaluated. An effective annual interest rate of 10% is to be used. Which plan is economically superior?

plan A: lease the car for \$0.25/mile (all inclusive)

plan B: purchase the car for \$30,000
keep the car for three years
sell the car after three years for \$7200
pay \$0.14 per mile for oil and gas
pay other costs of \$500 per year

Answer: Plan A is economically superior until that mileage is exceeded.

24. (*Time limit: one hour*) Two methods are being considered to meet strict air pollution control requirements over the next ten years. Method A uses equipment with a life of ten years. Method B uses equipment with a life of five years that will be replaced with new equipment with an additional life of five years. Capacities of the two methods are different, but operating costs do not depend on the throughput. Operation is 24 hours per day, 365 days per year. The effective annual interest rate for this evaluation is 7%.

	method A	method B	
	years 1–10	years 1–5	years 6–10
installation cost	\$13,000	\$6000	\$7000
equipment cost	\$10,000	\$2000	\$2200
operating cost per hour	\$10.50	\$8.00	\$8.00
salvage value	\$5000	\$2000	\$2000
capacity (tons/yr)	50	20	20
life	10 years	5 years	5 years

(a) What is the uniform annual cost per ton for each method? (b) Over what range of throughput (in tons/yr) does each method have the minimum cost?

Answers: (a) A: \$1897.86 per ton-yr, B: \$3590.27 per ton-yr; (b) 0 to 20 tons, B; above 20 tons/yr, A

25. (*Time limit: one hour*) A transit district has asked for your assistance in determining the proper fare for its bus system. An effective annual interest rate of 7% is to be used. The following additional information was compiled for your study.

cost per bus	\$60,000
bus life	20 years
salvage value	\$10,000
miles driven per year	37,440
number of passengers per year	80,000
operating cost	\$1.00 per mile in the first year, increasing \$0.10 per mile each year thereafter

(a) If the fare is to remain constant for the next 20 years, what is the break-even fare per passenger? (b) If the transit district decides to set the per-passenger fare at \$0.35 for the first year, by what amount should the per-passenger fare go up each year thereafter such that the district can break even in 20 years? (c) If the transit district decides to set the per-passenger fare at \$0.35 for the first year and the per-passenger fare goes up \$0.05 each year thereafter, what additional governmental subsidy (per passenger) is needed for the district to break even in 20 years?

Answers: (a) \$0.878/passenger; (b) \$0.072 increase; (c) \$0.162

26. Make a recommendation to your client to accept one of the following alternatives. Use the present worth comparison method. (Initial costs are the same.)

A: a 25 year annuity paying \$4800 at the end of each year, where the interest rate is a nominal 12% per annum

B: a 25 year annuity paying \$1200 every quarter at 12% nominal annual interest

Answer: Alternative B is superior.

27. A firm has two alternatives for improvement of its existing production line. The data are as follows.

	alternative A	alternative B
initial installment cost	\$1500	\$2500
annual operating cost	\$800	\$650
service life	5 years	8 years
salvage value	0	0

Determine the best alternative using an interest rate of 15%.

Answer: Alternative B is superior.

28. Two mutually exclusive alternatives requiring different investments are being considered. The life of both alternatives is estimated at 20 years with no salvage values. The minimum rate of return that is considered acceptable is 4%. Which alternative is best?

	alternative A	alternative B
investment required	\$70,000	\$40,000
net income per year	\$5620	\$4075
rate of return on total investment	5%	8%

Answer: Alternative B is superior.

29. Compare the costs of two plant renovation schemes, A and B. Assume equal lives of 25 years, no salvage values, and interest at 25%. Make the comparison on the basis of (a) present worth, (b) capitalized cost, and (c) annual cost.

	alternative A	alternative B
first cost	$20,000	$25,000
annual expenditure	$3000	$2500

Answers: (a) A; (b) A; (c) A

30. With interest at 8%, obtain the solutions to the following to the nearest dollar. (a) A machine costs $18,000 and has a salvage value of $2000. It has a useful life of eight years. What is its book value at the end of five years using straight line depreciation? (b) Using data from part (a), find the depreciation in the first three years using the sinking fund method. (c) Repeat part (a) using double declining balance depreciation to find the first five years' depreciation.

Answers: (a) $8000; (b) $1504, $1624, $1754; (c) $4500, $3375, $2531, $1898, $1424, $4272 (book value)

31. A chemical pump motor unit is purchased for $14,000. The estimated life is eight years, after which it will be sold for $1800. Find the depreciation in the first two years by the sum-of-the-years' digits method. Calculate the after-tax depreciation recovery using 15% interest with 52% income tax.

Answer: $4125.74

32. A soda ash plant has the water effluent from processing equipment treated in a large settling basin. The settling basin eventually discharges into a river that runs alongside the basin. Recently enacted environmental regulations require all rainfall on the plant to be diverted and treated in the settling basin. A heavy rainfall will cause the entire basin to overflow. An uncontrolled overflow will cause environmental damage and heavy fines. The construction of additional height on the existing basic walls is under consideration.

Data on the costs of construction and expected costs for environmental cleanup and fines are shown. Data on 50 typical winters have been collected. The soda ash plant management considers 12% to be their minimum rate of return, and it is felt that after 15 years the plant will be closed. The company wants to select the alternative that minimizes its total expected costs.

additional basin height (ft)	number of winters with basin overflow	expense for environmental clean up per year	construction cost
0	24		0
5	14	$600,000	$600,000
10	8	$650,000	$710,000
15	3	$700,000	$900,000
20	1	$800,000	$1,000,000
	50		

Answer: 20 ft

33. A wood processing plant installed a waste gas scrubber at a cost of $30,000 to remove pollutants from the exhaust discharged into the atmosphere. The scrubber has no salvage value and will cost $18,700 to operate next year, with operating costs expected to increase at the rate of $1200 per year thereafter. When should the company consider replacing the scrubber? Money can be borrowed at 12%.

Answer: Replace after 8 yr.

34. Two alternative piping schemes are being considered by a water treatment facility. On the basis of a ten year life and an interest rate of 12%, determine the number of hours of operation for which the two installations will break even.

	alternative A	alternative B
pipe diameter	4 in	6 in
head loss for required flow	48 ft	26 ft
size motor required	20 hp	7 hp
energy cost per hour of operation	$ 0.30	$ 0.10
cost of motor installed	$3600	$2800
cost of pipes and fittings	$3050	$5010
salvage value at end of 10 years	$200	$280

Answer: 1003.8 hr

35. An 88% learning curve is used with an item whose first production time was six weeks. How long will it take to produce the fourth item? How long will it take to produce the 6th through 14th items?

Answers: (a) 4.65 wk; (b) 35.6 wk

36. *(Time limit: one hour)* A company is considering two alternatives, only one of which can be selected.

alternative	initial investment	salvage value	annual net profit	life
A	$120,000	$15,000	$57,000	5 yr
B	$170,000	$20,000	$67,000	5 yr

The net profit is after operating and maintenance costs, but before taxes. The company pays 45% of its year-end profit as income taxes. Use straight line depreciation. Do not use investment tax credit. Find the best alternative if the company's minimum attractive rate of return is 15%.

Answer: Alternative A is superior.

37. *(Time limit: one hour)* A company is considering the purchase of equipment to expand its capacity. The equipment cost is $300,000. The equipment is needed for five years, after which it will be sold for $50,000. The company's before-tax cash flow will be improved $90,000 annually by the purchase of the asset.

The corporate tax rate is 48%, and straight line depreciation will be used. The company will take an investment tax credit of 6.67%. What is the after-tax rate of return associated with this equipment purchase?

Answer: $12\% < i < 12\frac{1}{4}\%$

38. *(Time limit: one hour)* A 120-room hotel is purchased for $2,500,000. A 25 year loan is available for 12%. A study was conducted to determine the various occupancy rates.

occupancy	probability
65% full	0.40
70%	0.30
75%	0.20
80%	0.10

The operating costs of the hotel are as follows.

taxes and insurance	$20,000 annually
maintenance	$50,000 annually
operating	$200,000 annually

The life of the hotel is figured to be 25 years when operating 365 days per year. The salvage value after 25 years is $500,000.

Neglect tax credit and income taxes. Determine the average rate that should be charged per room per night to return 15% of the initial cost each year.

Answer: $31.36

39. *(Time limit: one hour)* A company is insured for $3,500,000 against fire. The insurance rate is $0.69/1000. The insurance company will decrease the rate to $0.47/1000 if fire sprinklers are installed. The initial cost of the sprinklers is $7500. Annual costs are $200; additional taxes are $100 annually. The system life is 25 years. What is the rate of return on this investment?

Answer: 3.75%

40. *(Time limit: one hour)* Heat losses through the walls in an existing building cost a company $1,300,000 per year. This amount is considered excessive, and two alternatives are being evaluated. Neither of the alternatives will increase the life of the existing building beyond the current expected life of six years, and neither of the alternatives will produce a salvage value.

Alternative A: Do nothing. Continue with current losses.

Alternative B: Spend $2,000,000 immediately to upgrade the building and reduce the loss by 80%. This alternative will require annual maintenance of $150,000.

Alternative C: Spend $1,200,000 immediately. Repeat the $1,200,000 expenditure three years from now. Heat loss the first year will be reduced 80%. Due to deterioration, the reduction will be 55% and 20% in the second and third years. (The pattern is repeated starting after the second expenditure.) There are no maintenance costs.

All energy and maintenance costs are considered expenses for tax purposes. The company's tax rate is 48%, and straight line depreciation is used. 15% is regarded as the effective annual interest rate. Evaluate each alternative on an after-tax basis, and recommend the best alternative.

Answer: Alternative B is superior.

41. *(Time limit: one hour)* You have been asked to determine if a seven year old machine should be replaced. Give a full explanation for your recommendation. Base your decision on a before-tax interest rate of 15%.

The existing machine is presumed to have a ten year life. It has been depreciated on a straight line basis from its original value of $1,250,000 to a current book value of $620,000. Its ultimate salvage value was assumed to be $350,000 for purposes of depreciation. Its present salvage value is estimated at $400,000, and this is not expected to change over the next three years. The current operating costs are not expected to change from $200,000 per year.

A new machine costs $800,000, with operating costs of $40,000 the first year, and increasing by $30,000 each year thereafter. The new machine has an expected life of ten years. The salvage value depends on the year the new machine is retired.

year retired	salvage
1	$600,000
2	$500,000
3	$450,000
4	$400,000
5	$350,000
6	$300,000
7	$250,000
8	$200,000
9	$150,000
10	$100,000

Answer: Keep the defender.

1. FORMS OF COMPANY OWNERSHIP

There are three basic forms of company ownership in the United States: (a) sole proprietorship, (b) partnership, and (c) corporation.[2] Each of these forms of ownership has advantages and disadvantages.

2. SOLE PROPRIETORSHIPS

A *sole proprietorship (single proprietorship)* is the easiest form of ownership to establish. Other than the necessary licenses (which apply to all forms of ownership), no legal formalities are required to start business operations. A sole proprietor (the owner) has virtually total control of the business and makes all supervisory and management decisions.

Legally, there is no distinction between the sole proprietor and the sole proprietorship (the business). This is the greatest disadvantage of this form of business. The owner is solely responsible for the operation of the business, even if the owner hires others for assistance. The owner assumes personal, legal, and financial liability for all acts and debts of the company. If the company debts remain unpaid, or in the event there is a legal judgment against the company, the owner's personal assets (home, car, savings, etc.) can be seized or attached.

Another disadvantage of the sole proprietorship is the lack of significant organizational structure. In times of business crisis or trouble, there may be no one to share the responsibility or to help make decisions. When the owner is sick or dies, there may be no way to continue the business.

There is also no distinction between the incomes of the business and the owner. Therefore, the business income is taxed at the owner's income tax rate. Depending on the owner's financial position, the success of the business, and the tax structure, this can be an advantage or a disadvantage.[3]

3. PARTNERSHIPS

A *partnership* (also known as a *general partnership*) is ownership by two or more persons known as *general partners*. Legally, this form is very similar to a sole proprietorship, and the two forms of business have many of the same advantages and disadvantages. For example, with the exception of an optional *partnership agreement*, there are a minimum of formalities to setting up business. The partners make all business and management decisions themselves according to an agreed-upon process. The business income is split among the partners and taxed at the partners' individual tax rates.[4] Continuity of the business is still a problem since most partnerships are automatically dissolved upon the withdrawal or death of one of the partners.[5]

One advantage of a partnership over a sole proprietorship is the increase in available funding. Not only do more partners bring in more start-up capital, but the resource pool may make business credit easier to obtain. Also, the partners bring a diversity of skills and talents.

[1]The author is not giving legal advice in this chapter, nor is this chapter intended to be a substitute for professional advice. Law is not always black and white. For every rule there are exceptions. For every legal principle, there are variations. For every type of injury, there are numerous legal precedents. This chapter covers the superficial basics of a small subset of U.S. law affecting engineers.

[2]The discussion of forms of company ownership in Sections 2, 3, and 4 applies equally to service-oriented companies (e.g., consulting engineering firms) and product-oriented companies.

[3]To use a simplistic example, if the corporate tax rates are higher than the individual tax rates, it would be *financially* better to be a sole proprietor because the company income would be taxed at a lower rate.

[4]The percentage split is specified in the partnership agreement.

[5]Some or all of the remaining partners may want to form a new partnership, but this is not always possible.

Unless the partnership agreement states otherwise, each partner can individually obligate (i.e., *bind*) the partnership without the consent of the other partners. Similarly, each partner has personal responsibility and liability for the acts and debts of the partnership company, just as sole proprietors do. In fact, each partner assumes the *sole* responsibility, not just a proportionate share. If one or more partners are unable to pay, the remaining partners shoulder the entire debt. The possibility of one partner having to pay for the actions of another partner must be considered when choosing this form of business ownership.

A *limited partnership* differs from a general partnership in that one or more of the partners is silent. The *limited partners* make a financial contribution to the business and receive a share of the profit but do not participate in the management and cannot bind the partnership. While *general partners* have unlimited personal liabilities, limited partners are generally liable only to the extent of their investment.[6] A written partnership agreement is required, and the agreement must be filed with the proper authorities.

4. CORPORATIONS

A corporation is a legal entity (i.e., a legal person) distinct from the founders and owners. The separation of ownership and management makes the corporation a fundamentally different kind of business form than a sole proprietorship or partnership, with very different advantages and disadvantages.

A corporation becomes legally distinct from its founders upon formation and proper registration. Ownership of the corporation is through shares of stock, which are distributed to the founders and investors according to some agreed-upon investment and distribution rule. Thus, the founders and investors become the stockholders (i.e., owners) of the corporation. A *closely held* (*private*) *corporation* is one in which all stock is owned by a family or small group of coinvestors. A *public corporation* is one whose stock is available for the public-at-large to purchase.

There is no mandatory connection between ownership and management functions. The decision-making power is vested in the executive officers and a *board of directors* that governs by majority vote. The stockholders elect the board of directors which, in turn, hires the executive officers, management, and other employees. Employees of the corporation may or may not be stockholders.

Disadvantages (at least for a person or persons who could form a partnership or sole proprietorship instead) include the higher corporate tax rate, difficulty in forming (some states require a minimum number of persons on the board of directors), and additional legal and accounting paperwork.

However, since a corporation is distinctly separate from its founders and investors, those individuals are not liable for the acts and debts of the corporation. Debts are paid from the corporate assets. Income to the corporation is not taxable income to the owners. (Only the salaries, if any, paid to the employees by the corporation are taxable to the employees.) Even if the corporation were to go bankrupt, the assets of the owners would not ordinarily be subject to seizure or attachment.

A corporation offers the best guarantee of continuity of operation in the event of the death, incapacity, or retirement of the founders since, as a legal entity, it is distinct from the founders and owners.

5. AGENCY

In some contracts, decision-making authority and right of action are transferred from one party (the owner, or *principal*) who would normally have that authority to another person (the *agent*). For example, in construction contracts, the engineer is ordinarily the agent of the owner. Agents are limited in what they can do by the scope of the agency agreement. Within that scope, however, an agent acts on behalf of the principal, and the principal is liable for the acts of the agent and is bound by contracts made in the principal's name by the agent.

Agents are required to execute their work with care, skill, and diligence. Specifically, agents have *fiduciary responsibility* toward their principal, meaning that agent must be honest and loyal. Agents will be liable for damages resulting from a lack of diligence, loyalty, and/or honesty. If the agents misrepresented their skills when obtaining the agency, they can be liable for breach of contract or fraud.

6. GENERAL CONTRACTS

A *contract* is a legally binding agreement or promise to exchange goods or services.[7] A written contract is merely a documentation of the agreement. Some agreements must be in writing, but most agreements for engineering services can be verbal, particularly if the parties to the agreement know each other well.[8] Written contract documents do not need to contain intimidating legal language, but all agreements must satisfy three basic requirements to be enforceable (binding).

[6] That is, if the partnership fails or is liquidated to pay debts, the limited partners lose no more than their initial investments.

[7] Not all agreements are legally binding (i.e., enforceable). Two parties may agree on something, but unless the agreement meets all of the requirements and conditions of a contract, the parties cannot hold each other to the agreement.

[8] All states have a *statute of frauds* that, among other things, specifies what types of contracts must be in writing to be enforceable. These include contracts for the sale of land, contracts requiring more than one year for performance, contracts for the sale of goods over $500 in value, contracts to satisfy the debts of another, and marriage contracts. Contracts to provide engineering services do not fall under the statute of frauds.

- There must be a clear, specific, and definite *offer* with no room for ambiguity or misunderstanding.
- There must be some form of conditional future *consideration* (i.e., payment).[9]
- There must be an *acceptance* of the offer.

There are other conditions that the agreement must meet to be enforceable. These conditions are not normally part of the explicit agreement but represent the conditions under which the agreement was made.

- The agreement must be *voluntary* for all parties.
- All parties must have *legal capacity* (i.e., be mentally competent, of legal age, and uninfluenced by drugs).
- The purpose of the agreement must be *legal.*

For small projects, a simple *letter of agreement* on one party's stationery may suffice. For larger, complex projects, a more formal document may be required. Some clients prefer to use a *purchase order*, which can function as a contract if all basic requirements are met.

Regardless of the format of the written document—letter of agreement, purchase order, or standard form—a contract should include the following features.[10]

- introduction, preamble, or preface indicating the purpose of the contract
- name, address, and business forms of both contracting parties
- signature date of the agreement
- effective date of the agreement (if different from the signature date)
- duties and obligations of both parties
- deadlines and required service dates
- fee amount
- fee schedule and payment terms
- agreement expiration date
- standard boilerplate clauses
- signatures of parties or their agents
- declaration of authority of the signatories to bind the contracting parties
- supporting documents

[9]Actions taken or payments made prior to the agreement are irrelevant. Also, it does not matter to the courts whether the exchange is based on equal value or not.

[10]*Construction contracts* are unique unto themselves. Items that might also be included as part of the *contract documents* are the agreement form, the general conditions, drawings, specifications, and addenda.

7. STANDARD BOILERPLATE CLAUSES

It is common for full-length contract documents to include important *boilerplate clauses.* These clauses have specific wordings that should not normally be changed, hence the name "boilerplate." Some of the most common boilerplate clauses are paraphrased here.

- Delays and inadequate performance due to war, strikes, and acts of God and nature are forgiven (*force majeure*).
- The contract document is the complete agreement, superseding all previous verbal and written agreements.
- The contract can be modified or canceled only in writing.
- Parts of the contract that are determined to be void or unenforceable shall not affect the enforceability of the remainder of the contract (*severability*). Alternatively, parts of the contract that are determined to be void or unenforceable shall be rewritten to accomplish their intended purpose without affecting the remainder of the contract.
- None (or one, or both) of the parties can (or cannot) assign its (or their) rights and responsibilities under the contract (*assignment*).
- All notices provided for in the agreement must be in writing and sent to the address in the agreement.
- Time is of the essence.[11]
- The subject headings of the agreement paragraphs are for convenience only and do not control the meaning of the paragraphs.
- The laws of the state in which the contract is signed must be used to interpret and govern the contract.
- Disagreements shall be arbitrated according to the rules of the American Arbitration Association.
- Any lawsuits related to the contract must be filed in the county and state in which the contract is signed.
- Obligations under the agreement are unique, and in the event of a breach, the defaulting party waives the defense that the loss can be adequately compensated by monetary damages (*specific performance*).
- In the event of a lawsuit, the prevailing party is entitled to an award of reasonable attorneys' and court fees.[12]
- Consequential damages are not recoverable in a lawsuit.

[11]Without this clause in writing, damages for delay cannot be claimed.

[12]Without this clause in writing, attorneys' fees and court costs are rarely recoverable.

8. SUBCONTRACTS

When a party to a contract engages a third party to perform the work in the original contract, the contract with the third party is known as a *subcontract.* Whether or not responsibilities can be subcontracted under the original contract depends on the content of the *assignment clause* in the original contract.

9. PARTIES TO A CONSTRUCTION CONTRACT

A specific set of terms has developed for referring to parties in consulting and construction contracts. The *owner* of a construction project is the person, partnership, or corporation that actually owns the land, assumes the financial risk, and ends up with the completed project. The *developer* contracts with the architect and/or engineer for the design and with the contractors for the construction of the project. In some cases, the owner and developer are the same, in which case the term *owner-developer* can be used.

The *architect* designs the project according to established codes and guidelines but leaves most stress and capacity calculations to the *engineer.*[13] Depending on the construction contract, the engineer may work for the architect, or vice versa, or both may work for the developer.

Once there are approved plans, the developer hires *contractors* to do the construction. Usually, the entire construction project is awarded to a *general contractor.* Due to the nature of the construction industry, separate *subcontracts* are used for different tasks (electrical, plumbing, mechanical, framing, fire sprinkler installation, finishing, etc.). The general contractor who hires all of these different *subcontractors* is known as the *prime contractor* (or *prime*). (The subcontractors can also work directly for the owner-developer, although this is less common.) The prime contractor is responsible for all of the acts of the subcontractors and is liable for any damage suffered by the owner-developer due to those acts.

Construction is managed by an agent of the owner-developer known as the *construction manager*, who may be the engineer, the architect, or someone else.

10. STANDARD CONTRACTS FOR DESIGN PROFESSIONALS

Several of the design engineering societies have produced standard agreement forms and other standard documents for design professionals.[14] Among other standard forms, notices, and agreements, the following standard contracts are available.[15]

- standard contract between engineer and client
- standard contract between engineer and architect
- standard contract between engineer and contractor
- standard contract between owner and construction manager

The major advantage of the standard contracts is that the meanings of the clauses are well established, not only among the design professionals and their clients but also in the courts. The clauses in these contracts have already been litigated many times. Where a clause has been found to be unclear or ambiguous, it has been rewritten to accomplish its intended purpose.

11. CONSULTING FEE STRUCTURE

Compensation for consulting engineering services can incorporate one or more of the following concepts.

- *lump-sum fee*: This is a predetermined fee agreed upon by client and engineer. This payment can be used for small projects where the scope of work is clearly defined.
- *cost plus fixed fee*: All costs (labor, material, travel, etc.) incurred by the engineer are paid by the client. The client also pays a predetermined fee as profit. This method has an advantage when the scope of services cannot be determined accurately in advance. Detailed records must be kept by the engineer in order to allocate costs among different clients.
- *per diem fee*: The engineer is paid a specific sum for each day spent on the job. Usually, certain direct expenses (e.g., travel and reproduction) are billed in addition to the per diem rate.
- *salary plus*: The client pays for the employees on an engineer's payroll (the salary) plus an additional percentage to cover indirect overhead and profit plus certain direct expenses.
- *retainer*: This is a minimum amount paid by the client, usually in total and in advance, for a normal amount of work expected during an agreed-upon period. None of the retainer is returned, regardless of how little work the engineer performs. The engineer can be paid for additional work

[13] On simple small projects, such as wood-framed residential units, the design may be developed by a *building designer.* The legal capacities of building designers vary from state to state.

[14] There are two main sources of standard forms. The American Consulting Engineers' Council (ACEC), National Society of Professional Engineers (NSPE), and American Society of Civil Engineers (ASCE) have produced one set. Working independently, the American Institute of Architects (AIA) and the Associated General Contractors of America (AGC) have produced another.

[15] The Construction Specifications Institute (CSI) has produced standard specifications for materials.

beyond what is normal, however. Some direct costs, such as travel and reproduction expenses, may be billed directly to the client.

- *percentage of construction cost*: This method, which is widely used in construction design contracts, pays the architect and/or the engineer a percentage of the final total cost of the project. Cost of land, financing, and legal fees are generally not included in the construction cost, and other costs (plan revisions, project management labor, value engineering, etc.) are billed separately.

12. DISCHARGE OF A CONTRACT

A contract is normally discharged when all parties have satisfied their obligations. However, a contract can also be terminated for the following reasons.

- mutual agreement of all parties to the contract
- impossibility of performance (e.g., death of a party to the contract)
- illegality of the contract
- material breach by one or more parties to the contract
- fraud on the part of one or more parties
- failure (i.e., loss or destruction) of consideration (e.g., the burning of a building one party expected to own or occupy upon satisfaction of the obligations)

Some contracts may be dissolved by actions of the court (e.g., bankruptcy), passage of new laws and public acts, or a declaration of war.

Extreme difficulty (including economic hardship) in satisfying the contract does not discharge it, even if it becomes more costly or less profitable than originally anticipated.

13. TORTS

A *tort* is a civil wrong committed by one person causing damage to another person or person's property, emotional well-being, or reputation.[16] It is a breach of the rights of an individual to be secure in person or property. In order to correct the wrong, a civil lawsuit (*tort action* or *civil complaint*) is brought by the alleged injured party (the *plaintiff*) against the *defendant*. To be a valid *tort action* (i.e., lawsuit), there must have been injury (i.e., damage). Generally, there will be no contract between the two parties, so the tort action cannot claim a breach of contract.[17]

Tort law is concerned with compensation for the injury, not punishment. Therefore, tort awards usually consist of general, compensatory, and special damages and rarely include punitive and exemplary damages. (See Sec. 17 for definitions of these damages.)

14. BREACH OF CONTRACT, NEGLIGENCE, MISREPRESENTATION, AND FRAUD

A *breach of contract* occurs when one of the parties fails to satisfy all of its obligations under a contract. The breach can be *willful* (as in a contractor walking off a construction job) or *unintentional* (as in providing less than adequate quality work or materials). A *material breach* is defined as nonperformance that results in the injured party receiving something substantially less than or different from what the contract intended.

Normally, the only redress that an *injured party* has through the courts in the event of a breach of contract is to force the breaching party to provide *specific performance*—that is, to satisfy all remaining contract provisions and to pay for any damage caused. Normally, *punitive damages* (to punish the breaching party) are unavailable.

Negligence is an action, willful or unwillful, taken without proper care or consideration for safety, resulting in damages to property or injury to persons. "Proper care" is a subjective term, but in general it is the diligence that would be exercised by a reasonably prudent person.[18] Damages sustained by a negligent act are recoverable in a tort action. (See Sec. 13.) If the plaintiff was partially at fault (as in the case of *comparative negligence*), the defendant will be liable only for the portion of the damage caused by the defendant.

Punitive damages are available, however, if the breaching party was fraudulent in obtaining the contract. In addition, the injured party has the right to void (nullify) the contract entirely. A *fraudulent act* is basically a special case of misrepresentation (i.e., an intentionally false statement known to be false at the time it is made). Misrepresentation that does not result in a contract is a tort. When a contract is involved, misrepresentation can be a breach of that contract (i.e., *fraud*).

[16]The difference between a *civil tort (lawsuit)* and a *criminal lawsuit* is the alleged injured party. A *crime* is a wrong against society. A criminal lawsuit is brought by the state against a defendant.

[17]It is possible for an injury to be both a breach of contract and a tort. Suppose an owner has an agreement with a contractor to construct a building, and the contract requires the contractor to comply with all state and federal safety regulations. If the owner is subsequently injured on a stairway because there was no guardrail, the injury could be recoverable both as a tort and as a breach of contract. If a third party unrelated to the contract was injured, however, that party could recover only through a tort action.

[18]Negligence of a design professional (e.g., an engineer or architect) is the absence of a *standard of care* (i.e., customary and normal care and attention) that would have been provided by other engineers. It is highly subjective.

Unfortunately, it is extremely difficult to prove *compensatory fraud* (i.e., fraud for which damages are available). Proving fraud requires showing *beyond a reasonable doubt* (a) a reckless or intentional misstatement of a material fact (b) meant to deceive, (c) resulting in misleading the innocent party to contract (d) to the innocent party's detriment.

For example, if an engineer claims to have experience in designing steel buildings but actually has none, the court might consider the misrepresentation a fraudulent action. If, however, the engineer has some experience, but an insufficient amount to do an adequate job, the engineer probably will not be considered to have acted fraudulently.

15. STRICT LIABILITY IN TORT

Strict liability in tort means that the injured party wins if the injury can be proven. It is not necessary to prove negligence, breach of explicit or implicit warranty, or the existence of a contract (*privity of contract*). Strict liability in tort is most commonly encountered in product liability cases. A defect in a product, regardless of how the defect got there, is sufficient to create strict liability in tort.

Case law surrounding defective products has developed and refined the following requirements for winning a strict liability in tort case. The following points must be proved.

- The product was defective in manufacture, design, labeling, and so on.
- The product was defective when used.
- The defect rendered the product unreasonably dangerous.
- The defect caused the injury.
- The specific use of the product that caused the damage was reasonably foreseeable.

16. MANUFACTURING AND DESIGN LIABILITY

Case law makes a distinction between *design professionals* (architects, structural engineers, building designers, etc.) and manufacturers of consumer products. Design professionals are generally consultants whose primary product is a design service sold to sophisticated clients. Consumer product manufacturers produce a specific product line sold through wholesalers and retailers to the unsophisticated public.

The law treats design professionals favorably. Such professionals are expected to meet a *standard of care* and skill that can be measured by comparison with the conduct of other professionals. However, professionals are not expected to be infallible. In the absence of a contract provision to the contrary, design professionals are not held to be guarantors of their work in the strict sense of legal liability. Damages incurred due to design errors are recoverable through tort actions, but proving a breach of contract requires showing negligence (i.e., not meeting the standard of care).

On the other hand, the law is much stricter with consumer product manufacturers, and perfection is (essentially) expected of them. They are held to the standard of strict liability in tort without regard to negligence. A manufacturer is held liable for all phases of the design and manufacturing of a product being marketed to the public.[19]

Prior to 1916, the court's position toward product defects was exemplified by the expression *caveat emptor* ("let the buyer beware").[20] Subsequent court rulings have clarified that "... a manufacturer is strictly liable in tort when an article [it] places on the market, knowing that it will be used without inspection, proves to have a defect that causes injury to a human being."[21]

Although all defectively designed products can be traced back to a design engineer or team, only the manufacturing company is usually held liable for injury caused by the product. This is more a matter of economics than justice. The company has liability insurance; the product design engineer (who is merely an employee of the company) probably does not. Unless the product design or manufacturing process is intentionally defective, or unless the defect is known in advance and covered up, the product design engineer will rarely be punished by the courts.[22]

17. DAMAGES

An injured party can sue for *damages* as well as for specific performance. Damages are the award made by the court for losses incurred by the injured party.

- *General* or *compensatory damages* are awarded to make up for the injury that was sustained.
- *Special damages* are awarded for the direct financial loss due to the breach of contract.

[19]The reason for this is that the public is not considered to be as sophisticated as a client who contracts with a design professional for building plans.

[20]1916, *McPherson vs. Buick*. McPherson bought a Buick from a car dealer. The car had a defective wooden steering wheel, and there was evidence that reasonable inspection would have uncovered the defect. The steering wheel injured McPherson, who then sued Buick. Buick defended itself under the ancient *prerequisite of privity* (i.e., the requirement of a face-to-face contractual relationship in order for liability to exist), since the dealer, not Buick, had sold the car to McPherson, and no contract between Buick and McPherson existed. The judge disagreed, thus establishing the concept of *third party liability* (i.e., manufacturers are responsible to consumers even though consumers do not buy directly from manufacturers).

[21]1963, *Greenman vs. Yuba Power Products*. Greenman purchased and was injured by an electric power tool.

[22]Of course, the engineer can expect to be discharged from the company. However, for strategic reasons, this discharge probably will not occur until after the company loses the case.

- *Nominal damages* are awarded when responsibility has been established but the injury is so slight as to be inconsequential.
- *Liquidated damages* are amounts that are specified in the contract document itself for nonperformance.
- *Punitive* or *exemplary damages* are awarded, usually in tort and fraud cases, to punish and make an example of the defendant (i.e., to deter others from doing the same thing).
- *Consequential damages* provide compensation for indirect losses that are incurred by the injured party but are not directly related to the contract.

18. INSURANCE

Most design firms and many independent design professionals carry *errors and omissions insurance* to protect them from claims due to their mistakes. Such policies are costly, and for that reason, some professionals choose to "go bare."[23] Policies protect against inadvertent mistakes only, not against willful, knowing, or conscious efforts to defraud or deceive.

[23]Going bare appears foolish at first glance, but there is a perverted logic behind the strategy. One-person consulting firms (and perhaps, firms that are not profitable) are "judgment-proof." Without insurance or other assets, these firms would be unable to pay any large judgments against them. When damage victims (and their lawyers) find this out in advance, they know that judgments will be uncollectable. So, often the lawsuit never makes its way to trial.

87 Engineering Ethics

1. Creeds, Codes, Canons, Statutes, and Rules 87-1
2. Purpose of a Code of Ethics 87-1
3. Ethical Priorities 87-2
4. Dealing with Clients and Employers 87-2
5. Dealing with Suppliers 87-2
6. Dealing with Other Engineers 87-3
7. Dealing with (and Affecting) the Public . . 87-3
8. Competitive Bidding 87-3

1. CREEDS, CODES, CANONS, STATUTES, AND RULES

It is generally conceded that an individual acting on his or her own cannot be counted on to always act in a proper and moral manner. Creeds, statutes, rules, and codes all attempt to complete the guidance needed for an engineer to do "...the correct thing."

A *creed* is a statement or oath, often religious in nature, taken or assented to by an individual in ceremonies. For example, the *Engineers' Creed* adopted by the National Society of Professional Engineers is[1]

> I pledge...
>
> ... to give the utmost of performance;
>
> ... to participate in none but honest enterprise;
>
> ... to live and work according to the laws of man and the highest standards of professional conduct;
>
> ... to place service before profit, the honor and standing of the profession before personal advantage, and the public welfare above all other considerations.
>
> In humility and with need for Divine Guidance, I make this pledge.

A *code* is a system of nonstatutory, nonmandatory canons of personal conduct. A *canon* is a fundamental belief that usually encompasses several rules. For example, the code of ethics of the American Society of Civil Engineers (ASCE) contains the following seven canons.

(1) Engineers shall hold paramount the safety, health, and welfare of the public in the performance of their professional duties.

(2) Engineers shall perform services only in areas of their competence.

(3) Engineers shall issue public statements only in an objective and truthful manner.

(4) Engineers shall act in professional matters for each employer or client as faithful agents or trustees and shall avoid conflicts of interest.

(5) Engineers shall build their professional reputation on the merit of their service and shall not compete unfairly with others.

(6) Engineers shall act in such a manner as to uphold and enhance the honor, integrity, and dignity of the engineering profession.

(7) Engineers shall continue their professional development throughout their careers and shall provide opportunities for the professional development of those engineers under their supervision.

A *rule* is a guide (principle, standard, or norm) for conduct and action in a certain situation. A *statutory rule* is enacted by the legislative branch of state or federal government and carries the weight of law. Some U.S. engineering registration boards have statutory *rules of professional conduct.*

2. PURPOSE OF A CODE OF ETHICS

Many different sets of *codes of ethics* (*canons of ethics, rules of professional conduct*, etc.) have been produced by various engineering societies, registration boards, and other organizations.[2] The purpose of these ethical guidelines is to guide the conduct and decision making of engineers. Most codes are primarily educational. Nevertheless, from time to time they have been used

[1] The *Faith of an Engineer* adopted by the Accreditation Board for Engineering and Technology (ABET) is a similar but more detailed creed.

[2] All of the major engineering technical and professional societies in the United States (ASCE, IEEE, ASME, AIChE, NSPE, etc.) and throughout the world have adopted codes of ethics. Most U.S. societies have endorsed the *Code of Ethics of Engineers* developed by the Accreditation Board for Engineering and Technology (ABET), formerly the Engineers' Council for Professional Development (ECPD). The National Council of Examiners for Engineering and Surveying (NCEES) has developed its *Model Rules of Professional Conduct* as a guide for state registration boards in developing guidelines for the professional engineers in those states.

by the societies and regulatory agencies as the basis for disciplinary actions.

Fundamental to ethical codes is the requirement that engineers render faithful, honest, professional service. In providing such service, engineers must represent the interests of their employers or clients and, at the same time, protect public health, safety, and welfare.

There is an important distinction between what is legal and what is ethical. Many legal actions can be violations of codes of ethical or professional behavior.[3] For example, an engineer's contract with a client may give the engineer the right to assign the engineer's responsibilities, but doing so without informing the client would be unethical.

Ethical guidelines can be categorized on the basis of who is affected by the engineer's actions—the client, vendors and suppliers, other engineers, or the public at large.[4]

3. ETHICAL PRIORITIES

There are frequently conflicting demands on engineers. While it is impossible to use a single decision-making process to solve every ethical dilemma, it is clear that ethical considerations will force engineers to subjugate their own self-interests. Specifically, the ethics of engineers dealing with others need to be considered in the following order from highest to lowest priority.

- society and the public
- the law
- the engineering profession
- the engineer's client
- the engineer's firm
- other involved engineers
- the engineer personally

4. DEALING WITH CLIENTS AND EMPLOYERS

The most common ethical guidelines affecting engineers' interactions with their employer (the *client*) can be summarized as follows.[5]

- Engineers should not accept assignments for which they do not have the skill, knowledge, or time.
- Engineers must recognize their own limitations. They should use associates and other experts when the design requirements exceed their abilities.
- The client's interests must be protected. The extent of this protection exceeds normal business relationships and transcends the legal requirements of the engineer-client contract.
- Engineers must not be bound by what the client wants in instances where such desires would be unsuccessful, dishonest, unethical, unhealthy, or unsafe.
- Confidential client information remains the property of the client and must be kept confidential.
- Engineers must avoid conflicts of interest and should inform the client of any business connections or interests that might influence their judgment. Engineers should also avoid the *appearance* of a conflict of interest when such an appearance would be detrimental to the profession, their client, or themselves.
- The engineers' sole source of income for a particular project should be the fee paid by their client. Engineers should not accept compensation in any form from more than one party for the same services.
- If the client rejects the engineer's recommendations, the engineer should fully explain the consequences to the client.
- Engineers must freely and openly admit to the client any errors made.

All courts of law have required an engineer to perform in a manner consistent with normal professional standards. This is not the same as saying an engineer's work must be error-free. If an engineer completes a design, has the design and calculations checked by another competent engineer, and an error is subsequently shown to have been made, the engineer may be held responsible, but will probably not be considered negligent.

5. DEALING WITH SUPPLIERS

Engineers routinely deal with manufacturers, contractors, and vendors (*suppliers*). In this regard, engineers have great responsibility and influence. Such a relationship requires that engineers deal justly with both clients and suppliers.

An engineer will often have an interest in maintaining good relationships with suppliers since this often leads to future work. Nevertheless, relationships with suppliers must remain highly ethical. Suppliers should not be encouraged to feel that they have any special favors coming to them because of a long-standing relationship with the engineer.

[3]Whether the guidelines emphasize ethical behavior or professional conduct is a matter of wording. The intention is the same: to provide guidelines that transcend the requirements of the law.

[4]Some authorities also include ethical guidelines for dealing with the employees of an engineer. However, these guidelines are no different for an engineering employer than they are for a supermarket, automobile assembly line, or airline employer. Ethics is not a unique issue when it comes to employees.

[5]These general guidelines contain references to contractors, plans, specifications, and contract documents. This language is common, though not unique, to the situation of an engineer supplying design services to an owner-developer or architect. However, most of the ethical guidelines are general enough to apply to engineers in industry as well.

The ethical responsibilities relating to suppliers are listed as follows.

- The engineer must not accept or solicit gifts or other valuable considerations from a supplier during, prior to, or after any job. An engineer should not accept discounts, allowances, commissions, or any other indirect compensation from suppliers, contractors, or other engineers in connection with any work or recommendations.
- The engineer must enforce the plans and specifications (i.e., the *contract documents*) but must also interpret the contract documents fairly.
- Plans and specifications developed by the engineer on behalf of the client must be complete, definite, and specific.
- Suppliers should not be required to spend time or furnish materials that are not called for in the plans and contract documents.
- The engineer should not unduly delay the performance of suppliers.

6. DEALING WITH OTHER ENGINEERS

Engineers should try to protect the engineering profession as a whole, to strengthen it, and to enhance its public stature. The following ethical guidelines apply.

- An engineer should not attempt to maliciously injure the professional reputation, business practice, or employment position of another engineer. However, if there is proof that another engineer has acted unethically or illegally, the engineer should advise the proper authority.
- An engineer should not review someone else's work while the other engineer is still employed unless the other engineer is made aware of the review.
- An engineer should not try to replace another engineer once the other engineer has received employment.
- An engineer should not use the advantages of a salaried position to compete unfairly (i.e., moonlight) with other engineers who have to charge more for the same consulting services.
- Subject to legal and proprietary restraints, an engineer should freely report, publish, and distribute information that would be useful to other engineers.

7. DEALING WITH (AND AFFECTING) THE PUBLIC

In regard to the social consequences of engineering, the relationship between an engineer and the public is essentially straightforward. Responsibilities to the public demand that the engineer place service to humankind above personal gain. Furthermore, proper ethical behavior requires that an engineer avoid association with projects that are contrary to public health and welfare or that are of questionable legal character.

- Engineers must consider the safety, health, and welfare of the public in all work performed.
- Engineers must uphold the honor and dignity of their profession by refraining from self-laudatory advertising, by explaining (when required) their work to the public, and by expressing opinions only in areas of knowledge.
- When engineers issue a public statement, they must clearly indicate if the statement is being made on anyone's behalf (i.e., if anyone is benefitting from their position).
- Engineers must keep their skills at a state-of-the-art level.
- Engineers should develop public knowledge and appreciation of the engineering profession and its achievements.
- Engineers must notify the proper authorities when decisions adversely affecting public safety and welfare are made.[6]

8. COMPETITIVE BIDDING

The ethical guidelines for dealing with other engineers presented here and in more detailed codes of ethics no longer include a prohibition on *competitive bidding.* Until 1971, most codes of ethics for engineers considered competitive bidding detrimental to public welfare, since cost cutting normally results in a lower quality design.

However, in a 1971 case against the National Society of Professional Engineers that went all the way to the U.S. Supreme Court, the prohibition against competitive bidding was determined to be a violation of the Sherman Antitrust Act (i.e., it was an unreasonable restraint of trade).

The opinion of the Supreme Court does not *require* competitive bidding—it merely forbids a prohibition against competitive bidding in NSPE's code of ethics. The following points must be considered.

- Engineers and design firms may individually continue to refuse to bid competitively on engineering services.
- Clients are not required to seek competitive bids for design services.
- Federal, state, and local statutes governing the procedures for procuring engineering design services, even those statutes that prohibit competitive bidding, are not affected.

[6]This practice has come to be known as *whistle-blowing.*

- Any prohibitions against competitive bidding in individual state engineering registration laws remain unaffected.
- Engineers and their societies may actively and aggressively lobby for legislation that would prohibit competitive bidding for design services by public agencies.

88 Engineering Licensing in the United States

1. What Licensing Is 88-1
2. The U.S. Licensing Procedure 88-1
3. National Council of Examiners for Engineering and Surveying 88-1
4. Reciprocity Among States 88-2
5. Uniform Examinations 88-2
6. Applying for the Examination 88-2
7. Examination Dates 88-3
8. FE Examination Format 88-3
9. PE Examination Format 88-3

1. WHAT LICENSING IS

Engineering licensing (also known as *engineering registration*) in the United States is an examination process by which a state's *board of engineering licensing* (typically referred to as the "engineers' board" or "board of registration") determines and certifies that an engineer has achieved a minimum level of competence.[1] This process is intended to protect the public by preventing unqualified individuals from offering engineering services.

Most engineers in the United States do not need to be licensed.[2] In particular, most engineers who work for companies that design and manufacture products are exempt from the licensing requirement. This is known as the *industrial exemption*, something that is built into the laws of most states.[3]

Nevertheless, there are many good reasons for wanting to become a licensed engineer. For example, you cannot offer consulting engineering services in any state unless you are licensed in that state. Even within a product-oriented corporation, you may find that employment, advancement, and managerial positions are limited to licensed engineers.

Once you have met the licensing requirements, you will be allowed to use the titles *Professional Engineer* (PE), *Registered Engineer* (RE), or *Consulting Engineer* (CE) as permitted by your state.

Although the licensing process is similar in each of the 50 states, each has its own licensing law. Unless you offer consulting engineering services in more than one state, however, you will not need to be licensed in the other states.

2. THE U.S. LICENSING PROCEDURE

The licensing procedure is similar in all states. You will take two eight-hour written examinations. The full process requires you to complete two applications, one for each of the two examinations. The first examination is the *Fundamentals of Engineering* (FE) *examination*, formerly known (and still commonly referred to) as the *Engineer-In-Training* (E-I-T) *examination*.[4] This examination covers basic subjects from all of the mathematics, physics, chemistry, and engineering courses you took during your university years.

The second examination is the *Professional Engineering* (PE) *examination*, also known as the *Principles and Practices* (P&P) *examination*. This examination covers only the subjects in your engineering discipline (e.g., civil, mechanical, electrical, and others).

The actual details of licensing qualifications, experience requirements, minimum education levels, fees, oral interviews, and examination schedules vary from state to state. Contact your state's licensing board for more information.

3. NATIONAL COUNCIL OF EXAMINERS FOR ENGINEERING AND SURVEYING

The *National Council of Examiners for Engineering and Surveying* (NCEES) in Clemson, South Carolina, writes, prints, distributes, and scores the national FE and PE examination.[5] The individual states purchase the examinations from NCEES and administer them. NCEES does not distribute applications to take the examinations, administer the examinations or appeals, or notify examinees of the results. These tasks are all performed by the individual states.

[1] Licensing of engineers is not unique to the United States. However, the practice of requiring a degreed engineer to take an examination is not common in other countries. Licensing in many countries requires a degree and may also require experience, references, and demonstrated knowledge of ethics and law, but no technical examination.

[2] Less than one-third of the degreed engineers in the United States are licensed.

[3] Only one or two states have abolished the industrial exemption. There has always been a lot of "talk" among engineers about abolishing it, but there has been little success in actually trying to do so. One of the reasons is that manufacturers' lobbies are very strong.

[4] The terms *engineering intern* (EI) and *intern engineer* (IE) have also been used in the past to designate the status of an engineer who has passed the first exam. These uses are rarer but may still be encountered in some states.

[5] National Council of Examiners for Engineering and Surveying, P.O. Box 1686, Clemson, SC 29633, (803) 654-6824.

4. RECIPROCITY AMONG STATES

With minor exceptions, having a license from one state will not permit you to practice engineering in another state. You must have a professional engineering license from each state in which you work. For most engineers, this is not a problem, but for some it is. Luckily, it is not too difficult to get a license from every state you work in once you have a license from one of them.

All states use the NCEES examinations. If you take and pass the FE or PE examination in one state, your certificate or license will be honored by all of the other states. Upon proper application, payment of fees, and proof of your license, you will be issued a license by the new state. Although there may be other special requirements imposed by a state, it will not be necessary to retake the FE or PE examinations.[6] The issuance of an engineering license based on another state's licensing is known as *reciprocity* or *comity*.

5. UNIFORM EXAMINATIONS

Although each state has its own licensing law and is, theoretically, free to administer its own exams, none does so for the major disciplines. All states have chosen to use the NCEES exams. Each state administers the exams on the same days. The exams from all the states are sent to NCEES and are graded by the same graders. Each state adopts the cut-off passing scores recommended by NCEES. These practices have led to the term *uniform examination.*

6. APPLYING FOR THE EXAMINATION

While the exam administration process is essentially standardized among the states, there is a lot of variation in the application process. Each state has its own application forms, charges different fees, and has different age, education, and experience requirements. Therefore, you will have to request an application from the state in which you want to become licensed in order to find out what is required. It is generally sufficient for you to phone for this application; a written request is unnecessary. Telephone numbers for all U.S. boards of registration (states and territories) are given in Table 88.1. Some states have a fee for the application.

As with any other important document, it is a good idea to keep a copy of your examination application and send the original application by certified mail, requesting a receipt of delivery. Keep your proof of mailing and delivery receipt with your copy of the application.

All states make special accommodations for persons who are physically challenged or who have other special needs. Be sure to communicate your need to the state board well in advance of the examination day.

[6]For example, California requires all civil engineering applicants to pass special examinations in seismic design and surveying in addition to their regular eight-hour PE exams. Licensed engineers from other states only have to pass these two special exams. They do not need to retake the PE exam.

Table 88.1 *Phone Numbers of Boards of Registration (States and Territories)*

Alabama	(334) 242-5568

7. EXAMINATION DATES

The national FE and PE examinations are administered twice a year, on the same weekends in all states. Table 88.2 contains the dates of upcoming examination periods.

Table 88.2 *Dates of U.S. Engineering Licensing Exams*[a]

year	Spring exam	Fall exam
2000	April 14–15	October 27–28
2001	April 20–21	October 26–27
2002	April 19–20	October 25–26
2003	April 11–12	October 24–25

[a]Subject to change without notice.

8. FE EXAMINATION FORMAT

The FE examination consists of two four-hour sessions, separated by a one-hour lunch period. There are 120 multiple-choice problems in the morning and 60 multiple-choice problems in the afternoon. All problems have four answer choices, from which you are to choose the best single answer. Afternoon problems are slightly more difficult and have double weight.

Questions from all undergraduate technical courses appear in the examination, including mathematics, chemistry, physics, and engineering.[7]

The FE exam is essentially all in SI units. There are a few non-SI problems and some opportunities to choose between identical SI and non-SI problems.

NCEES provides its own reference booklet for use in the examination. You may bring your own calculator and pencils, but you are not allowed to use any of your own books or notes.

9. PE EXAMINATION FORMAT

The NCEES PE examination consists of two four-hour sessions, separated by a one-hour lunch period. It only covers subjects in your major field of study (e.g., civil engineering). There are several variations in PE exam format, but the most common type has ten complex problems in the morning session and ten complex problems in the afternoon session.[8,9] You must choose four of the morning problems and four of the afternoon problems. There are no required problems, and you are free to select which problems to work.

All problems in the morning session are of the "essay" (also known as "free response") variety, which means that the solutions are worked in the answer booklets provided. Solutions are reviewed by graders and scored according to their degree of completion and correctness.

All problems in the afternoon session are *objectively scored*. This means that each problem consists of ten multiple-choice questions, which are graded by computer. There is no penalty for guessing or wrong answers, but there is also no partial credit for correct methods and assumptions.

Unlike the FE exam where SI units are used extensively, virtually all of the problems on the PE exam are in customary U.S. units. There are a few exceptions (e.g., electrical engineering and occasional problems in chemical engineering), but most problems use pounds, feet, seconds, gallons, and British thermal units.

The PE examination is open book. While some states have a few restrictions, generally you may bring in the calculators and books of your choice.

[7]The format of the FE exam, other valuable information, and tips on passing are given in greater detail in *Engineer-in-Training Review Manual*, (Lindeburg), and *Engineer-In-Training Reference Manual* (Lindeburg), both published by Professional Publications.

[8]Other PE exam variations include twelve problems in each session (used in the civil and electrical engineering disciplines), and four problems (i.e., a *no choice exam*) in each session (as used in many of the smaller disciplines such as industrial and environmental engineering).

[9]The format of the civil engineering PE exam is scheduled to change in October 2000. Visit www.ppi2pass.com for more information.

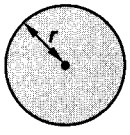
APPENDIX 7.A
Mensuration of Two-Dimensional Areas

Nomenclature

A	total surface area
b	base
c	chord length
d	distance
h	height
L	length
p	perimeter
r	radius
s	side (edge) length, arc length
θ	vertex angle, in radians
ϕ	central angle, in radians

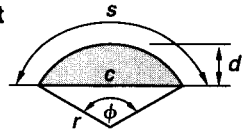
Triangle



equilateral right oblique

$A = \frac{1}{2}bh = \frac{\sqrt{3}}{4}b^2$ $A = \frac{1}{2}bh$ $A = \frac{1}{2}bh$

$h = \frac{\sqrt{3}}{2}b$ $H^2 = b^2 + h^2$

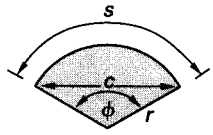


Circle

$p = 2\pi r$

$A = \pi r^2 = \frac{p^2}{4\pi}$

Circular Segment

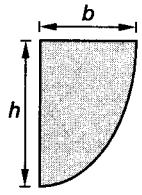


$A = \frac{1}{2}r^2(\phi - \sin\phi)$

$\phi = \frac{s}{r} = 2\left(\arccos\frac{r-d}{r}\right)$

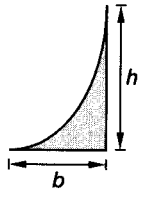
$c = 2r\sin\left(\frac{\phi}{2}\right)$

Circular Sector



$A = \frac{1}{2}\phi r^2 = \frac{1}{2}sr$

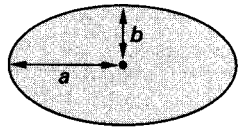
$\phi = \frac{s}{r}$



$s = r\phi$

$c = 2r\sin\left(\frac{\phi}{2}\right)$

Parabola

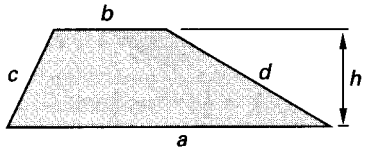


$A = \frac{2}{3}bh$

$A = \frac{1}{3}bh$

Ellipse

$A = \pi ab$



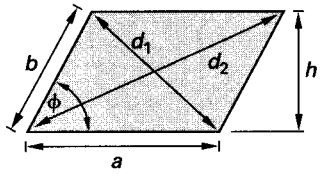
$p = 2\pi\sqrt{\frac{1}{2}(a^2 + b^2)}$

(continued)

Support Material

APPENDIX 7.A *(continued)*
Mensuration of Two-Dimensional Areas

Trapezoid



$$p = a + b + c + d$$

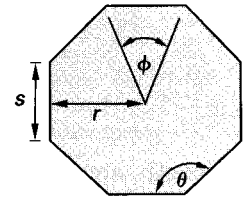
$$A = \tfrac{1}{2}h(a + b)$$

The trapezoid is isosceles if $c = d$.

Parallelogram

$$p = 2(a + b)$$

$$d_1 = \sqrt{a^2 + b^2 - 2ab\cos\phi}$$



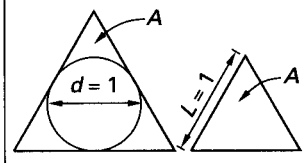
$$d_2 = \sqrt{a^2 + b^2 + 2ab\cos\phi}$$

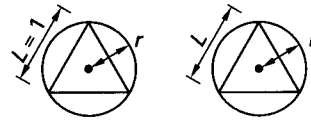
$$d_1^2 + d_2^2 = 2(a^2 + b^2)$$

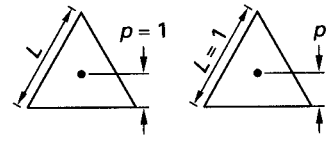
$$A = ah = ab\sin\phi$$

If $a = b$, the parallelogram is a rhombus.

Regular Polygon (*n* equal sides)







$$\phi = \frac{2\pi}{n}$$

$$\theta = \frac{\pi(n-2)}{n} = \pi - \phi$$

$$p = ns$$

$$s = 2r\tan\left(\frac{\theta}{2}\right)$$

$$A = \tfrac{1}{2}nsr$$

APPENDIX 7.B
Mensuration of Three-Dimensional Volumes

Nomenclature

A	area
b	base
h	height
r	radius
R	radius
s	side (edge) length
V	volume

Sphere

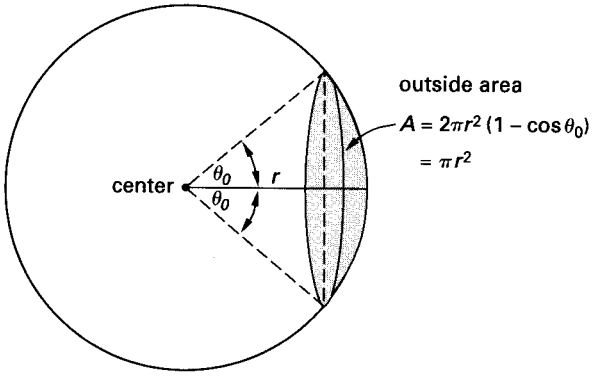
$$V = \frac{4\pi r^3}{3}$$
$$A = 4\pi r^2$$

Right Circular Cone

$$V = \frac{\pi r^2 h}{3}$$
$$A = \pi r\sqrt{r^2 + h^2}$$

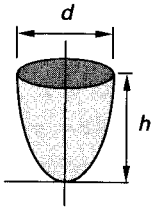
(does not include base area)

Right Circular Cylinder



$$V = \pi r^2 h$$
$$A = 2\pi r h$$

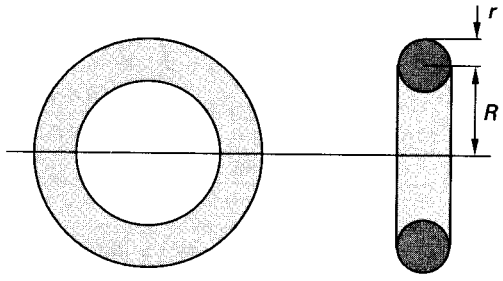
(does not include end area)



Spherical Segment

Surface area of a spherical segment of radius r cut out by an angle θ_0 rotated from the center about a radius, r, is

$$A = 2\pi r^2 (1 - \cos\theta_0)$$
$$\phi = \frac{A}{r^2} = 2\pi (1 - \cos\theta_0)$$



Paraboloid of Revolution

$$V = \frac{\pi d^2 h}{8}$$

Torus

$$A = 4\pi^2 R r$$
$$V = 2\pi^2 R r^2$$

Regular Polyhedra (identical faces)

name	number of faces	form of faces	total surface area	volume
tetrahedron	4	equilateral triangle	$1.7321s^2$	$0.1179s^3$
cube	6	square	$6.0000s^2$	$1.0000s^3$
octahedron	8	equilateral triangle	$3.4641s^2$	$0.4714s^3$
dodecahedron	12	regular pentagon	$20.6457s^2$	$7.6631s^3$
isosahedron	20	equilateral triangle	$8.6603s^2$	$2.1817s^3$

The radius of a sphere inscribed within a regular polyhedron is

$$r = \frac{3V_{\text{polyhedron}}}{A_{\text{polyhedron}}}$$

Support Material

APPENDIX 9.A

Abbreviated Table of Indefinite Integrals
(In each case, add a constant of integration.
All angles are measured in radians.)

General Formulas

1. $\int dx = x$
2. $\int c\,dx = c\int dx$
3. $\int (dx + dy) = \int dx + \int dy$
4. $\int u\,dv = uv - \int v\,du$ (integration by parts)

Algebraic Forms

5. $\displaystyle\int x^n\,dx = \frac{x^{n+1}}{n+1} \qquad [n \neq -1]$
6. $\displaystyle\int x^{-1}dx = \int \frac{dx}{x} = \ln|x|$
7. $\displaystyle\int (ax+b)^n\,dx = \frac{(ax+b)^{n+1}}{a(n+1)} \qquad [n \neq -1]$
8. $\displaystyle\int \frac{dx}{ax+b} = \frac{1}{a}\ln(ax+b)$
9. $\displaystyle\int \frac{x\,dx}{ax+b} = \frac{1}{a^2}[ax+b-b\ln(ax+b)]$
10. $\displaystyle\int \frac{x\,dx}{(ax+b)^2} = \frac{1}{a^2}\left[\frac{b}{ax+b} + \ln(ax+b)\right]$
11. $\displaystyle\int \frac{dx}{x(ax+b)} = \frac{1}{b}\ln\left(\frac{x}{ax+b}\right)$
12. $\displaystyle\int \frac{dx}{x(ax+b)^2} = \frac{1}{b(ax+b)} + \frac{1}{b^2}\ln\left(\frac{x}{ax+b}\right)$
13. $\displaystyle\int \frac{dx}{x^2+a^2} = \frac{1}{a}\tan^{-1}\left(\frac{x}{a}\right)$
14. $\displaystyle\int \frac{dx}{a^2-x^2} = \frac{1}{a}\tanh^{-1}\left(\frac{x}{a}\right)$
15. $\displaystyle\int \frac{x\,dx}{ax^2+b} = \frac{1}{2a}\ln(ax^2+b)$
16. $\displaystyle\int \frac{dx}{x(ax^n+b)} = \frac{1}{bn}\ln\left(\frac{x^n}{ax^n+b}\right)$
17. $\displaystyle\int \frac{dx}{ax^2+bx+c} = \frac{1}{\sqrt{b^2-4ac}}\ln\left(\frac{2ax+b-\sqrt{b^2-4ac}}{2ax+b+\sqrt{b^2-4ac}}\right) \qquad [b^2 > 4ac]$
18. $\displaystyle\int \frac{dx}{ax^2+bx+c} = \frac{2}{\sqrt{4ac-b^2}}\tan^{-1}\left(\frac{2ax+b}{\sqrt{4ac-b^2}}\right) \qquad [b^2 < 4ac]$
19. $\displaystyle\int \sqrt{a^2-x^2}\,dx = \frac{x}{2}\sqrt{a^2-x^2} + \frac{a^2}{2}\sin^{-1}\left(\frac{x}{a}\right)$
20. $\displaystyle\int x\sqrt{a^2-x^2}\,dx = -\tfrac{1}{3}(a^2-x^2)^{\frac{3}{2}}$
21. $\displaystyle\int \frac{dx}{\sqrt{a^2-x^2}} = \sin^{-1}\left(\frac{x}{a}\right)$
22. $\displaystyle\int \frac{x\,dx}{\sqrt{a^2-x^2}} = -\sqrt{a^2-x^2}$

[a]Based on actual densities, not on standard "cold, clear water."
[b]Can also be calculated from steam tables as $(p_{\text{saturation}})$ (144 in^2/ft^2) (v) (g/g_c).

(Multiply in by 25.4 to obtain mm.)
(Multiply in^2 by 645 to obtain mm^2.)
[a]Designations per ANSI B36.10.
[b]The "S" wall thickness was formerly designated as "standard weight." Standard weight and schedule-40 are the same for all diameters through 10 in. For diameters between 12 in and 24 in, standard weight pipe has a wall thickness of 0.75 in. The "X" wall thickness was formerly designated as "extra strong." Extra strong weight and schedule-80 are the same for all diameters through 8 in. For diameters between 10 in and 24 in, extra strong weight pipe has a wall thickness of 0.50 in. The "XX" wall thickness was formerly designed as "double extra strong." Double extra strong weight pipe does not have a corresponding schedule number.
[c]Pipe sizes and weights in most common usage listed. Other weights and sizes exist.

(Multiply in by 25.4 to obtain mm.)
(Multiply in^2 by 645 to obtain mm^2.)
[a]Abstracted from ASTM Specification D1785-85.
[b]Two strengths of PVC are in use. A maximum (bursting) stress of 6400 psig (44 MPa) applies to PVC types 1120, 1220, and 4116. A maximum (bursting) stress of 5000 psig (35 MPa) applies to PVC types 2112, 2116, and 2120.
[c]Minimum wall thickness, with tolerances of −0%, +10%.

fiberglass	0.000017	0.000017	160–150	150	150

(Multiply ft by 0.3 to obtain m.)

[a]The following guidelines are provided for selecting Hazen-Williams coefficients for cast-iron pipes of different ages. Values for welded steel pipe are similar to those of cast-iron pipe 5 years older. New pipe, all sizes: $C = 130$. 5 year-old pipe: $C = 120$ (d $<$ 24 in); $C = 115$ (d $\geq$ 24 in). 10 year-old pipe: $C = 105$ (d = 4 in); $C = 110$ (d = 12 in); $C = 85$ (d $\geq$ 30 in). 40 year-old pipe: $C = 65$ (d = 4 in); $C = 80$ (d = 16 in).

[b]C values for sludge are 20 to 40% less than the corresponding water pipe values.

(Multiply gal/min by 0.0631 to obtain L/s.)
(Multiply in by 25.4 to obtain mm.)
(Multiply ft/sec by 0.3 to obtain m/s.)
(Multiply lbf/in^2-1000 ft by 2.3 to obtain kPa/100 m.)

APPENDIX 17.E

Hazen-Williams Nomograph
($C = 100$)

Quantity (i.e., flow rate) is proportional to the C-value. For values of C other than 100, the quantity must be converted according to $\dot{V}_{\text{actual}} = \dot{V}_{\text{chart}} C_{\text{actual}}/100$. When quantity is the unknown, use the chart with known values of diameter, slope, or velocity to find $\dot{V}_{\text{chart}}$, and then convert to $\dot{V}_{\text{actual}}$. If $\dot{V}_{\text{actual}}$ is known, it must be converted to $\dot{V}_{\text{chart}}$ before this nomograph can be used. In that case, the diameter, loss, and velocity are as read from this chart.

(Multiply gal/min by 0.0631 to obtain L/s.)
(Multiply ft^3/sec by 28.3 to obtain L/s.)
(Multiply in by 25.4 to obtain mm.)
(Multiply ft/1000 ft by 0.1 to obtain m/100 m.)
(Multiply ft/sec by 0.3 to obtain m/s.)

APPENDIX 17.F
Corrugated Metal Pipe

Corrugated metal pipe (CMP, also known as *corrugated steel pipe*) is frequently used for culverts. Pipe is made from corrugated sheets of galvanized steel that are rolled and riveted together along a longitudinal seam. Aluminized steel may also be used in certain ranges of soil pH. Standard round pipe diameters range from 8 to 96 in (200 to 2450 mm). Metric dimensions of standard diameters are usually rounded to the nearest 25 or 50 mm (e.g., a 42 in culvert would be specified as a 1050 mm culvert, not 1067 mm).

Larger and noncircular culverts can be created out of curved steel plate. Standard section lengths are 10 to 20 ft (3 to 6 m). Though most corrugations are transverse (i.e., annular), helical corrugations are also used. Metal gages of 8, 10, 12, 14, and 16 are commonly used, depending on the depth of burial.

The most common corrugated steel pipe has transverse corrugations that are 1/2 in (13 mm) deep and 2 2/3 in (68 mm) from crest to crest. These are referred to as "2 1/2 inch" or "68 × 13" corrugations. For larger culverts, corrugations with a 2 in (25 mm) depth and 3, 5, and 6 in (76, 125, or 152 mm) pitches are used. Plate-based products using 6 in by 2 in (152 mm by 51 mm) corrugations are known as *structural plate corrugated steel pipe* (SPCSP) and *multiplate* after the trade-named product "Multi-Plate™."

The flow area for circular culverts is based on the nominal culvert diameter, regardless of the gage of the plate metal used to construct the pipe. Flow area is calculated to (at most) three significant digits.

A Hazen-Williams coefficient, C, of 60 is typically used with all sizes of corrugated pipe. Values of C and Manning's constant, n, for corrugated pipe are generally not affected by age. *Design Charts for Open Channel Flow* (U.S. Department of Transportation, 1979) recommends a Manning constant of $n = 0.024$ for all cases. The U.S. Department of the Interior recommends the following values. For standard (2 2/3 in by 1/2 in or 68 mm by 13 mm) corrugated pipe with the diameters given: 12 in (457 mm), 0.027; 24 in (610 mm), 0.025; 36 to 48 in (914 to 1219 mm), 0.024; 60 to 84 in (1524 to 2134 mm), 0.023; 96 in (2438 mm), 0.022. For (6 in by 2 in or 152 mm by 51 mm) multiplate construction with the diameters given: 5 to 6 ft (1.5 to 1.8 m), 0.034; 7 to 8 ft (2.1 to 2.4 m), 0.33; 9 to 11 ft (2.7 to 3.3 m), 0.32; 12 to 13 ft (3.6 to 3.9 m), 0.31; 14 to 15 (4.2 to 4.5 m), 0.030; 16 to 18 ft (4.8 to 5.4 m), 0.029; 19 to 20 ft (5.8 to 6.0 m), 0.028; 21 to 22 ft (6.3 to 6.6 m), 0.027.

If the inside of the corrugated pipe has been asphalted completely smooth 360° circumferentially, Manning's n ranges from 0.009 to 0.011. For culverts with 40% asphalted inverts, $n = 0.019$. For other percentages of paved invert, the resulting value is proportional to the percentage and the values normally corresponding to that diameter pipe. For field-bolted corrugated metal pipe arches, $n = 0.025$.

It is also possible to calculate the Darcy friction loss if the corrugation depth, 0.5 in (13 mm) for standard corrugations and 2.0 in (51 mm) for multiplate, is taken as the specific roughness.

APPENDIX 22.B
Periodic Table of the Elements
(referred to Carbon-12)

The Periodic Table of Elements (Long Form)

The number of electrons in filled shells is shown in the column at the extreme left; the remaining electrons for each element are shown immediately below the symbol for each element. Atomic numbers are enclosed in brackets. Atomic weights (rounded, based on carbon-12) are shown above the symbols. Atomic weight values in parentheses are those of the isotopes of longest half-life for certain radioactive elements whose atomic weights cannot be precisely quoted without knowledge of origin of the element.

30	7.6	7.3	6.9	0.008	32

[a]For saturation at barometric pressures other than 760 mm (29.92 in), C_s' is related to the corresponding tabulated values, C_s, by the following equation.

$$C_s' = C_s\left(\frac{P-p}{760-p}\right)$$

C_s' = solubility at barometric pressure P and given temperature, mg/L
C_s = saturation at given temperature from table, mg/L
P = barometric pressure, mm
p = pressure of saturated water vapor at temperature of the water selected from table, mm

APPENDIX 22.E
Names and Formulas of Important Chemicals

common name	chemical name	chemical formula
acetone	acetone	$(CH_3)_2CO$
acetylene	acetylene	C_2H_2
ammonia	ammonia	NH_3
ammonium	ammonium hydroxide	NH_4OH
aniline	aniline	$C_6H_5NH_2$
bauxite	hydrated aluminum oxide	$Al_2O_3 \cdot 2H_2O$
bleach	calcium hypochlorite	$CaCl(OCl)$
borax	sodium tetraborate	$Na_2B_4O_7 \cdot 10H_2O$
carbide	calcium carbide	CaC_2
carbolic acid	phenol	C_6H_5OH
carbon dioxide	carbon dioxide	CO_2
carborundum	silicon carbide	SiC
caustic potash	potassium hydroxide	KOH
caustic soda/lye	sodium hydroxide	NaOH
chalk	calcium carbonate	$CaCO_3$
cinnabar	mercuric sulfide	HgS
ether	diethyl ether	$(C_2H_5)_2O$
formic acid	methanoic acid	HCOOH
Glauber's salt	decahydrated sodium sulfate	$Na_2SO_4 \cdot 10H_2O$
glycerine	glycerine	$C_3H_5(OH)_3$
grain alcohol	ethanol	C_2H_5OH
graphite	crystalline carbon	C
gypsum	calcium sulfate	$CaSO_4 \cdot 2H_2O$
halite	sodium chloride	NaCl
iron chloride	ferrous chloride	$FeCl_2 \cdot 4H_2O$
laughing gas	nitrous oxide	N_2O
limestone	calcium carbonate	$CaCO_3$
magnesia	magnesium oxide	MgO
marsh gas	methane	CH_4
muriate of potash	potassium chloride	KCl
muriatic acid	hydrochloric acid	HCl
niter	sodium nitrate	$NaNO_3$
niter cake	sodium bisulfate	$NaHSO_4$
oleum	fuming sulfuric acid	SO_3 in H_2SO_4
potash	potassium carbonate	K_2CO_3
prussic acid	hydrogen cyanide	HCN

APPENDIX 29.A
Selected *Ten States' Standards*[a]

[11.243] **Hydraulic Load:** Use 100 gpcd (0.38 m^3/day) for new systems in undeveloped areas unless other information is available.

[42.3] **Pumps:** At least two pumps are required. Both pumps should have the same capacity if only two pumps are used. This capacity must exceed the total design flow. If three or more pumps are used, the capacities may vary, but capacity (peak hourly flow) pumping must be possible with one pump out of service.

[42.7] **Pump Well Ventilation:** Provide 30 complete air changes per hour for both wet and dry wells using intermittent ventilation. For continuous ventilation, the requirement is reduced to 12 (for wet wells) and 6 (for dry wells) air changes per hour. In general, ventilation air should be forced in, as opposed to air being extracted and replaced by infiltration.

[61.12] **Racks and Bar Screens:** All racks and screens shall have openings less than 1.75 in (45 mm) wide. The smallest opening for manually cleaned screens is 1 in (2.54 cm). The smallest opening for mechanically cleaned screens may be smaller. Flow velocity must be 1.25 to 3.0 ft/sec (38 to 91 cm/s).

[62.2–62.3] **Grinders and Shredders:** Grit chambers are required if there is no screening. Gravel traps or grit-removal equipment should precede comminutors.

[63.3–63.4] **Grit Chambers:** Grit chambers are required when combined storm and sanitary sewers are used. A minimum of two grit chambers in parallel should be used, with a provision for bypassing. For channel-type grit chambers, the optimum velocity is 1 ft/sec (30 cm/s) throughout. The detention time is dependent on the particle sizes to be removed.

[71–72] **Settling Tanks:** Multiple units are desirable, and multiple units must be provided if the average flow exceeds 100,000 gal/day (379 m^3/day). For primary settling, the sidewater depth should be 10 ft (3.0 m) or greater. For tanks not receiving activated sludge, the design average overflow rate is 1000 gal/day-ft^2 (41 m^3/day·m^2); the maximum peak settling rate is 1500–3000 gal/day-ft^2 (60–120 m^3/day·m^2). The maximum weir loading is 30,000 gal/day-ft (375 m^3/day·m). The basin size shall also be calculated based on the average design flow rate and a maximum settling rate of 1000 gal/day-ft^2. The larger of the two sizes shall be used. If the flow rate is less than 1 MGD (3785 m^3/day), the maximum weir loading is reduced to 20,000 gal/day-ft (250 m^3/day·m).

For settling tanks following trickling filters and rotating biological contactors, the maximum settling rate is 1200 gal/day-ft^2 (49 m^3/day·m^2).

For settling tanks following activated sludge processes, the maximum hydraulic loadings are: 1200 gal/day-ft^2 (49 m^3/day·m^2) for conventional, step, complete mix, and contact units; 1000 gal/day-ft^2 (41 m^3/day·m^2) for extended aeration units; and 800 gal/day-ft^2 (33 m^3/day·m^2) for separate two-stage nitrification units.

[84] **Anaerobic Digesters:** Multiple units are required. For completely mixed digesters, maximum loading of volatile solids is 80 lbm/day-1000 ft^3 (1.3 kg/day·m^3) of digester volume. For moderately mixed digesters, the limit is 40 lbm/day-1000 ft^3 (0.65 kg/day·m^3). Minimum sidewater depth is 20 ft (6.1 m).

[88.22] **Sludge Drying Beds:** For design purposes, the maximum sludge depth is 8 in (200 mm).

[91.3] **Trickling Filters:** All media should have a minimum depth of 6 ft (1.8 m). Rock media depth should not exceed 10 ft (3 m). Manufactured media depth should not exceed the manufacturer's recommendations. The rock media should be 1 to 4.5 in (2.5 to 11.4 cm) in size. Freeboard of 4 ft (1.2 ft) or more is required for manufactured media. The drain should slope at 1% or more, and the average drain velocity should be 2 ft/sec (0.6 m/s).

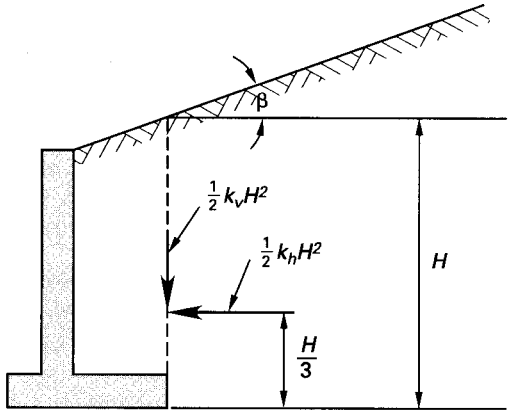
[92.3] **Activated Sludge Processes:** The maximum BOD loading shall be 40 lbm/day-1000 ft^3 (0.64 kg/day·m^3) for conventional, step, and complete-mix units; 50 lbm/day-1000 ft^3 (0.8 kg/day·m^3) for contact stabilization units; and 15 lbm/day-1000 ft^3 (0.24 kg/day·m^3) for extended aeration units and oxidation ditch designs.

(continued)

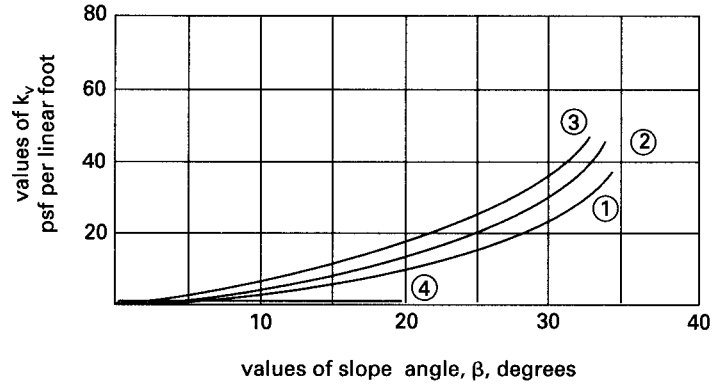
APPENDIX 29.A *(continued)*
Selected *Ten States' Standards*[a]

Aeration tank depths should be 10 to 30 ft (3 to 9 m). At least two aeration tanks shall be used. The dissolved oxygen contract should not be allowed to drop below 2 mg/L at any time. The aeration rate should be 1500 ft^3 of oxygen per pound of BOD_5 (94 m^3/kg). For extended aeration, the rate should be 2050 ft^3 of oxygen per pound of BOD_5 (128 m^3/kg).

[93.3] **Facultative Treatment Ponds:** BOD loading for lagoons following primary treatment is 15 to 35 lbm BOD/day-ac (17 to 40 kg/day·ha) for both controlled-discharge and flow-through stabilization ponds.



[102.4] **Chlorination:** Minimum contact time is 15 min at peak flow.



[a]Numbers in square brackets refer to sections in *Recommended Standards for Sewage Works*, 1997 ed., Great Lakes-Upper Mississippi River Board of State Sanitary Engineers, published by Health Education Service, NY, from which these guidelines were extracted. Refer to the original document for complete standards.

APPENDIX 43.B

Typical Mechanical Properties of Representative Metals
(room temperature)

The following mechanical properties are not guaranteed since they are averages for various sizes, product forms, and methods of manufacture. Thus, this data is not for design use, but is intended only as a basis for comparing alloys and tempers.

material designation, composition, typical use, and source if applicable	condition, heat treatment	S_{ut} (ksi)	S_{yt} (ksi)
IRON BASED			
Armco ingot iron, for fresh and saltwater piping	normalized	44	24
AISI 1020, plain carbon steel, for general machine parts and screws and carburized parts	hot rolled cold worked	65 78	43 66
AISI 1030, plain carbon steel, for gears, shafts, levers, seamless tubing, and carburized parts	cold drawn	87	74
AISI 1040, plain carbon steel, for high-strength parts, shafts, gears, studs, connecting rods, axles, and crane hooks	hot rolled cold worked hardened	91 100 113	58 88 86
AISI 1095, plain carbon steel, for handtools, music wire springs, leaf springs, knives, saws, and agricultural tools such as plows and disks	annealed hot rolled hardened	100 142 180	53 84 118
AISI 1330, manganese steel, for axles and drive shafts	annealed cold drawn hardened	97 113 122	83 93 100
AISI 4130, chromium-molybdenum steel, for high-strength aircraft structures	annealed hardened	81 161	52 137
AISI 4340, nickel-chromium-molybdenum steel, for large-scale, heavy-duty, high-strength structures	annealed as rolled hardened	119 192 220	99 147 200
AISI 2315, nickel steel, for carburized parts	as rolled cold drawn	85 95	56 75
AISI 2330, nickel steel	as rolled cold drawn annealed normalized	98 110 80 95	65 90 50 61
AISI 3115, nickel-chromium steel for carburized parts	cold drawn as rolled annealed	95 75 71	70 60 62
STAINLESS STEELS			
AISI 302, stainless steel, most widely used, same as 18-8	annealed cold drawn	90 105	35 60
AISI 303, austenitic stainless steel, good machineability	annealed cold worked	90 110	35 75
AISI 304, austenitic stainless steel, good machineability and weldability	annealed cold worked	85 110	30 75
AISI 309, stainless steel, good weldability, high strength at high temperatures, used in furnaces and ovens	annealed cold drawn	90 110	35 65
AISI 316, stainless steel, excellent corrosion resistance	annealed cold drawn	85 105	35 60
AISI 410, magnetic, martensitic, can be quenched and tempered to give varying strength	annealed cold drawn oil quenched and drawn	60 180 110	32 150 91
AISI 430, magnetic, ferritic, used for auto and architectural trim and for equipment in food and chemical industries	annealed cold drawn	60 100	35
AISI 502, magnetic, ferritic, low cost, widely used in oil refineries	annealed	60	25

APPENDIX 44.A

Elastic Beam Deflection Equations

(w is the load per unit length.)

Case 1: Cantilever with End Load

reactions:

$$R_l = 0$$

$$R_r = P$$

shear:

$$V = -P \text{ (constant)}$$

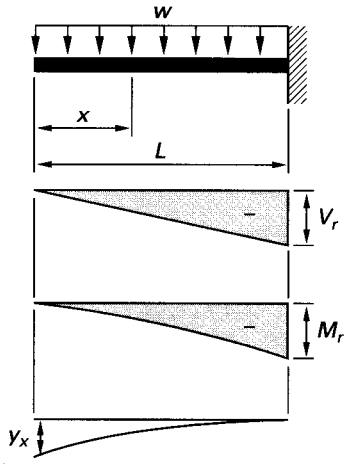
moments:

$$M_x = -Px$$

$$M_{\max} = -PL$$

end slope:

$$\phi_l = +\frac{PL^2}{2EI}$$



$$\phi_r = 0$$

deflection:

$$y_x = \left(-\frac{P}{6EI}\right)(2L^3 - 3L^2x + x^3)$$

$$y_{\max} = -\frac{PL^3}{3EI} \text{ at } x = 0$$

Case 2: Cantilever with Uniform Load

reactions:

$$R_l = 0$$

$$R_r = wL$$

shear:

$$V_x = -wx$$

$$V_{\max} = -wL = V_r$$

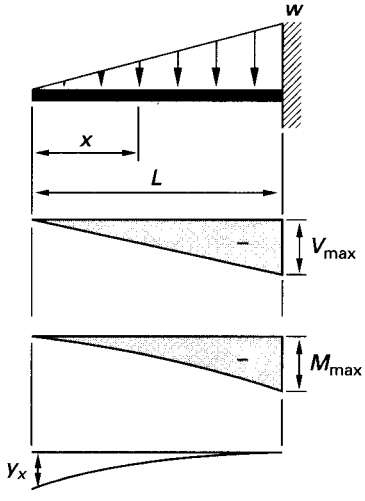
moments:

$$M_x = -\frac{wx^2}{2}$$

$$M_{\max} = -\frac{wL^2}{2} = M_r$$

end slope:

$$\phi_l = +\frac{wL^3}{6EI}$$



$$\phi_r = 0$$

deflection:

$$y_x = \left(\frac{w}{24EI}\right)(3L^4 - 4L^3x + x^4)$$

$$y_{\max} = -\frac{wL^4}{8EI} \text{ at } x = 0$$

Case 3: Cantilever with Triangular Load

reactions:

$$R_l = 0$$

$$R_r = \frac{wL}{2}$$

shear:

$$V_x = -\frac{wx^2}{2L}$$

$$V_{\max} = \frac{wL}{2} \text{ at } x = L$$

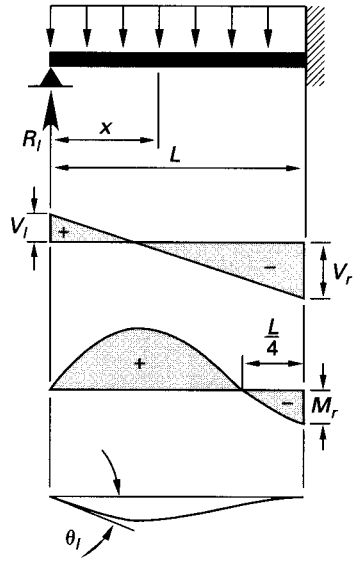
moments:

$$M_x = -\frac{wx^3}{6L}$$

$$M_{\max} = \frac{wL^2}{6} \text{ at } x = L$$

end slope:

$$\phi_l = +\frac{wL^3}{24EI}$$



$$\phi_r = 0$$

deflection:

$$y_x = \left(-\frac{w}{120EIL}\right)(4L^5 - 5L^4x + x^5)$$

$$y_{\max} = -\frac{wL^4}{30EI} \text{ at } x = 0$$

Case 4: Propped Cantilever with Uniform Load

reactions:

$$R_l = \frac{3}{8}wL$$

$$R_r = \frac{5}{8}wL$$

shear:

$$V_l = -\frac{3}{8}wL$$

$$V_r = +\frac{5}{8}wL$$

$$V_x = w\left(\frac{3L}{8} - x\right)$$

moments:

$$M_r = M_{\max} = -\frac{wL^2}{8}$$

$$M_x = \left(-\frac{w}{8}\right)(3xL - 4x^2)$$

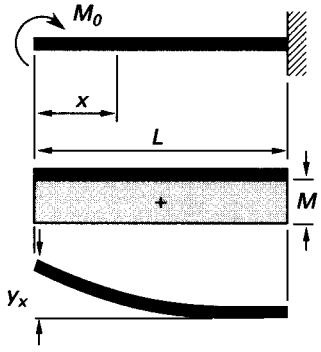
$$M = \frac{9wL^2}{128} \text{ at } x = 0.375\,L$$

end slope:

$$\phi_l = +\frac{wL^3}{48EI}$$

$$\phi_r = 0$$

deflection:



$$y_x = \left(\frac{w}{48EI}\right)(L^3x - 3Lx^3 + 2x^4)$$

$$y_{\max} = \frac{wL^4}{185EI} \text{ at } x = 0.4215\,L$$

(continued)

APPENDIX 44.A *(continued)*
Elastic Beam Deflection Equations
(w is the load per unit length.)

Case 5: Cantilever with End Moment

reactions:

$$R_l = 0$$

$$R_r = 0$$

shear:

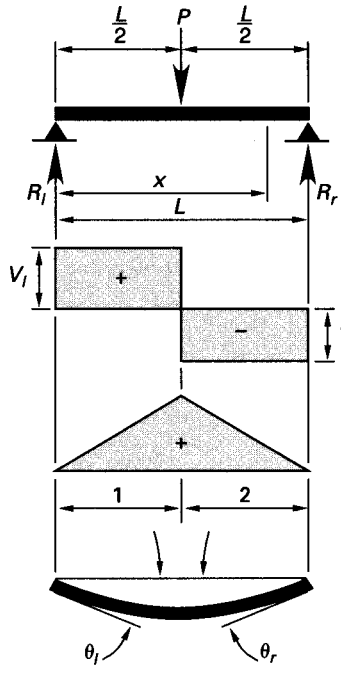
$$V = 0$$

moments:

$$M = M_0 = M_{\max}$$

end slope:

$$\phi_l = -\frac{M_0 L}{EI}$$



$$\phi_r = 0$$

deflection:

$$y_x = \left(+\frac{M_0}{2EI}\right) \times (L^2 - 2xL + x^2)$$

$$y_{\max} = +\frac{M_0 L^2}{2EI} \text{ at } x = 0$$

Case 6: Simple Beam with Center Load

reactions:

$$R_l = R_r = \frac{P}{2}$$

shear:

$$V_l = \frac{P}{2}$$

$$V_r = -\frac{P}{2}$$

moments:

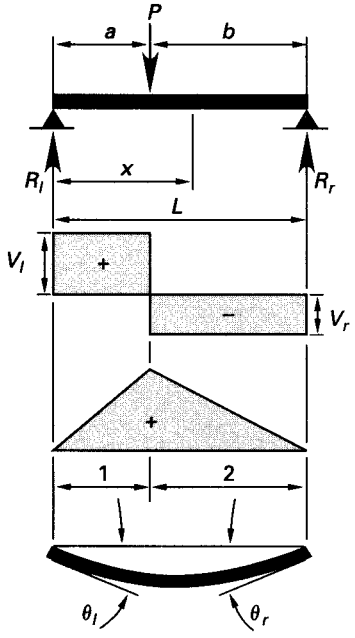
$$M_{x1} = \frac{Px}{2}$$

$$M_{x2} = \left(\frac{P}{2}\right)(L - x)$$

$$M_{\max} = \frac{PL}{4}$$

end slope:

$$\phi_l = -\frac{PL^2}{16EI}$$



$$\phi_r = +\frac{PL^2}{16EI}$$

deflection:

$$y_{x1} = \left(-\frac{P}{48EI}\right)(3xL^2 - 4x^3)$$

$$y_{\max} = -\frac{PL^3}{48EI} \text{ at } x = \frac{L}{2}$$

Case 7: Simple Beam with Intermediate Load

reactions:

$$R_l = \frac{Pb}{L}$$

$$R_r = \frac{Pa}{L}$$

shear:

$$V_l = +\frac{Pb}{L}$$

$$V_r = -\frac{Pa}{L}$$

moments:

$$M_{x1} = \frac{Pbx}{L}$$

$$M_{x2} = \frac{Pa(L - x)}{L}$$

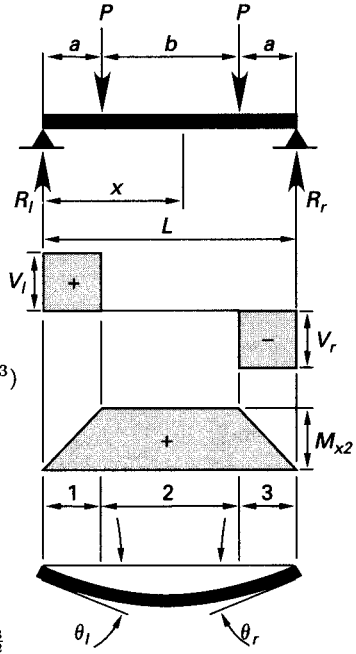
$$M_{\max} = \frac{Pab}{L} \text{ at } x = a$$

end slope:

$$\phi_l = -\frac{Pab\left(1 + \frac{b}{L}\right)}{6EI}$$

$$\phi_r = \frac{Pab\left(1 + \frac{a}{L}\right)}{6EI}$$

deflection:



$$y_{x1} = \left(\frac{Pb}{6EIL}\right)(L^2 x - b^2 x - x^3)$$

$$y_{x2} = \left(\frac{Pb}{6EIL}\right)\left[\left(\frac{L}{b}\right)(x - a)^3 + (L^2 - b^2)x - x^3\right]$$

$$y = \frac{Pa^2 b^2}{3EIL} \text{ at } x = a$$

$$y_{\max} = \left(\frac{0.06415\,Pb}{EIL}\right)(L^2 - b^2)^{\frac{3}{2}} \text{ at } x = \sqrt{\frac{a(L + b)}{3}}$$

Case 8: Simple Beam with Two Loads

reactions:

$$R_l = R_r = P$$

shear:

$$V_l = +P$$

$$V_r = -P$$

moments:

$$M_{x1} = Px$$

$$M_{x2} = Pa$$

$$M_{x3} = P(L - x)$$

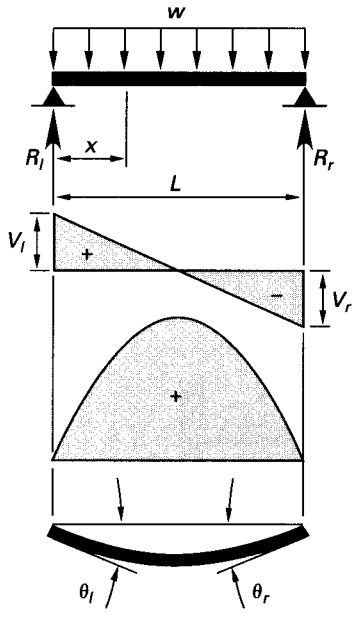
end slope:

$$\phi_l = -\frac{Pa(a + b)}{2EI}$$

$$\phi_r = +\frac{Pa(a + b)}{2EI}$$

deflection:

$$y_{x1} = \left(\frac{P}{6EI}\right)(3Lax - 3a^2 x - x^3)$$



$$y_{x2} = \left(\frac{P}{6EI}\right)(3Lax - 3ax^2 - a^3)$$

$$y_{\max} = \left(\frac{P}{24EI}\right)(3L^2 a - 4a^3) \text{ at } x = \frac{L}{2}$$

(continued)

APPENDIX 44.A *(continued)*
Elastic Beam Deflection Equations
(w is the load per unit length.)

Case 9: Simple Beam with Uniform Load

reactions:

$$R_l = R_r = \frac{wL}{2}$$

shear:

$$V_l = +\frac{wL}{2}$$

$$V_r = -\frac{wL}{2}$$

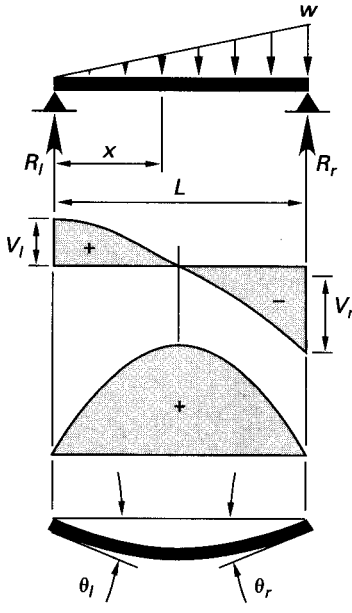
moments:

$$M = \left(\frac{w}{2}\right)(x^2 - Lx)$$

$$M_{\max} = \frac{wL^2}{8}$$

end slope:

$$\phi_l = \frac{wL^3}{24EI}$$



$$\phi_r = +\frac{wL^3}{24EI}$$

deflection:

$$y_x = \left(-\frac{w}{24EI}\right)(L^3x - 2Lx^3 + x^4)$$

$$y_{\max} = \frac{5wL^4}{384EI} \text{ at } x = \frac{L}{2}$$

Case 10: Simple Beam with Triangular Load

reactions:

$$R_l = \frac{wL}{6}$$

$$R_r = \frac{wL}{3}$$

shear:

$$V_l = +\frac{wL}{6}$$

$$V_r = -\frac{wL}{3}$$

$$V_x = \left(\frac{wL}{6}\right)\left(1 - 3\left(\frac{x}{L}\right)^2\right)$$

moments:

$$M_x = \left(\frac{w}{6}\right)\left(Lx - \frac{x^3}{L}\right)$$

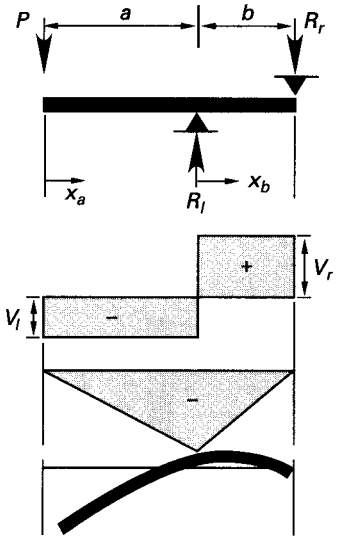
$$M_{\max} = \frac{wL^2}{9\sqrt{3}} = 0.0642wL^2$$

at $x = 0.577L$

end slope:

$$\phi_l = \frac{7wL^3}{360EI}$$

$$\phi_r = +\frac{wL^3}{45EI}$$



deflection:

$$y_x = \left(-\frac{w}{360EI}\right)\left(7L^3x - 10Lx^3 + \frac{3x^5}{L}\right)$$

$$y_{\max} = -(0.00652)\left(\frac{wL^4}{EI}\right)$$

at $x = 0.519L$

Case 11: Simple Beam with Overhung Load

reactions:

$$R_l = \left(\frac{P}{b}\right)(b + a)$$

$$R_r = \frac{-Pa}{b}$$

shear:

$$V_l = -P$$

$$V_r = \frac{Pa}{b}$$

moments:

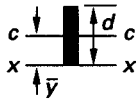
$$M_a = Px_a$$

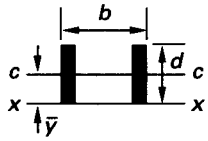
$$M_b = \left(\frac{Pa}{b}\right)(b - x_b)$$

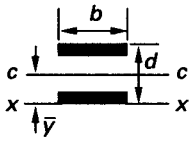
$$M_{\max} = Fa \text{ at } x_a = a$$

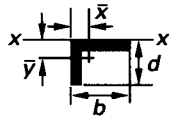
deflections:

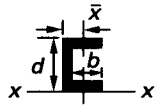
$$y_a = \left(\frac{F}{3EI}\right)\left((a^2 + ab)(a - x_a) + \left(\frac{x_a}{2}\right)(x_a^2 - a^2)\right)$$

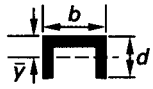


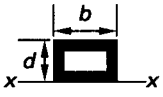


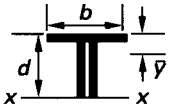


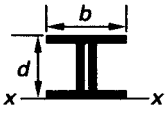






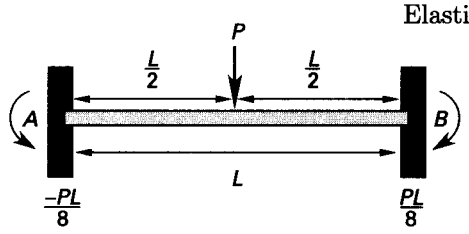






$$y_b = \left(\frac{Fax_b}{6EI}\right)\left(3x_b - \left(\frac{x_b^2}{b}\right) - 2b\right)$$

$$y_{\text{tip}} = \left(\frac{Fa^2}{3EI}\right)(a + b) \text{ [max down]}$$



$$y_{\max} = (0.06415)\left(\frac{Fab^2}{EI}\right) \text{ at } x_b = 0.4226b \text{ [max up]}$$

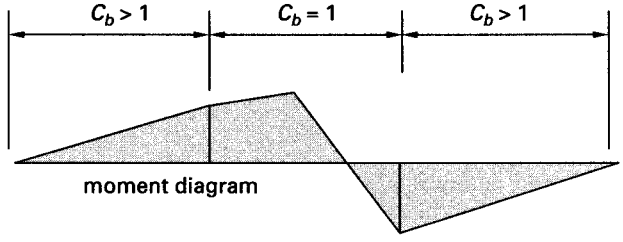
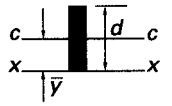
APPENDIX 59.A
The Moment Gradient Multiplier

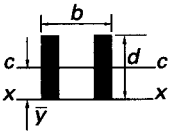
If a concentrated load is applied to a beam at a point of lateral support, there will be less tendency for the beam to buckle than if the load is applied between points of lateral support. The moment gradient multiplier, C_b, is an optional refinement that accounts for the less-critical conditions. The moment gradient multiplier increases the maximum allowable spacing between supports, L_u. (C_b is not used in calculating L_c.) C_b varies between 1.0 and 2.3 (its maximum). Conservative designs use $C_b = 1.0$.

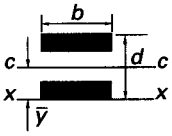


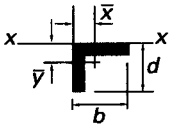
$$C_b = 1.75 + 1.05\left(\frac{M_1}{M_2}\right) + 0.3\left(\frac{M_1}{M_2}\right)^2 \quad \text{[F1.3]}$$

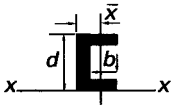
M_1 is the absolute value of the smaller moment at the ends of an unbraced beam section. M_2 is the absolute value of the larger moment at the opposite end of the unbraced section. The quantity M_1/M_2 is negative for simple bending (i.e., single curvature, when M_1 and M_2 have opposite signs) and positive when M_1 and M_2 have the same sign (i.e., reverse curvature).

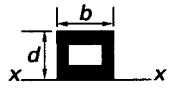


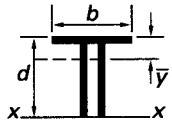


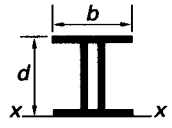


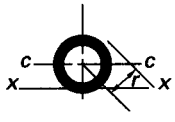












If the moment on a section of beam is maximum between the points of lateral support, $C_b = 1$.

• = points of lateral support

APPENDIX 78.A
Oblique Triangle Equations

given	equation
A, B, a	$C = 180^\circ - (A + B)$
	$b = \left(\frac{a}{\sin A}\right) \sin B$
	$c = \left(\frac{a}{\sin A}\right) \sin(A + B) = \left(\frac{a}{\sin A}\right) \sin C$
	$\text{area} = \frac{1}{2}ab \sin C = \frac{a^2 \sin B \sin C}{2 \sin A}$
A, a, b	$\sin B = \left(\frac{\sin A}{a}\right) b$
	$C = 180^\circ - (A + B)$
	$c = \left(\frac{a}{\sin A}\right) \sin C$
	$\text{area} = \frac{1}{2}ab \sin C$
C, a, b	$c = \sqrt{a^2 + b^2 - 2ab \cos C}$
	$\frac{1}{2}(A + B) = 90^\circ - \frac{1}{2}C$
	$\tan \frac{1}{2}(A - B) = \left(\frac{a - b}{a + b}\right) \tan \frac{1}{2}(A + B)$
	$A = \frac{1}{2}(A + B) + \frac{1}{2}(A - B)$
	$B = \frac{1}{2}(A + B) - \frac{1}{2}(A - B)$
	$c = (a + b)\left(\frac{\cos \frac{1}{2}(A + B)}{\cos \frac{1}{2}(A - B)}\right) = (a - b)\left(\frac{\sin \frac{1}{2}(A + B)}{\sin \frac{1}{2}(A - B)}\right)$
	$\text{area} = \frac{1}{2}ab \sin C$
a, b, c	Let $s = \frac{a + b + c}{2}$
	$\sin \frac{1}{2}A = \sqrt{\frac{(s - b)(s - c)}{bc}}$
	$\cos \frac{1}{2}A = \sqrt{\frac{s(s - a)}{bc}}$
	$\tan \frac{1}{2}A = \sqrt{\frac{(s - b)(s - c)}{s(s - a)}}$
	$\sin A = 2\sqrt{\frac{s(s - a)(s - b)(s - c)}{bc}}$
	$\cos A = \frac{b^2 + c^2 - a^2}{2bc}$
	$\text{area} = \sqrt{s(s - a)(s - b)(s - c)}$

APPENDIX 83.A
Polyphase Motor Classifications and Characteristics

speed regulations	speed control	starting torque	breakdown torque	application
general-purpose squirrel cage (NEMA design B)				
Drops about 3% for large to 5% for small sizes.	None, except multi-speed types, designed for two to four fixed speeds.	100% for large; 275% for 1 hp 4 pole unit.	200% of full load.	Constant-speed service where starting is not excessive. Fans, blowers, rotary compressors, and centrifugal pumps.
high-torque squirrel cage (NEMA design C)				
Drops about 3% for large to 6% for small sizes.	None, except multi-speed types, designed for two and four fixed speeds.	250% of full load for high-speed to 200% for low-speed designs.	200% of full load.	Constant-speed where fairly high starting torque is required infrequently with starting current about 550% of full load. Reciprocating pumps and compressors, crushers, etc.
high-slip squirrel cage (NEMA design D)				
Drops about 10 to 15% from no load to full load.	None, except multi-speed types, designed for two to four fixed speeds.	225 to 300% full load, depending on speed with rotor resistance.	200%. Will usually not stall until loaded to max torque, which occurs at standstill.	Constant-speed and high starting torque, if starting is not too frequent, and for high-peak loads with or without flywheels. Punch presses, shears, elevators, etc.
low-torque squirrel cage (NEMA design F)				
Drops about 3% for large to 5% for small sizes.	None, except multi-speed types, designed for two to four fixed speeds.	50% of full load for high-speed to 90% for low-speed designs.	135 to 170% of full load.	Constant-speed service where starting duty is light. Fans, blowers, centrifugal pumps and similar loads.
wound rotor				
With rotor rings short circuited, drops about 3% for large to 5% for small sizes.	Speed can be reduced to 50% by rotor resistance. Speed varies inversely as load.	Up to 300% depending on external resistance in rotor circuit and how distributed.	300% when rotor slip rings are short circuited.	Where high starting torque with low starting current or where limited speed control is required. Fans, centrifugal and plunger pumps, compressors, conveyors, hoists, cranes, etc.
synchronous				
Constant.	None, except special motors designed for two fixed speeds.	40% for slow to 160% for medium-speed 80% pf. Specials develop higher.	Unity-pf motors 170%, 80%-pf motors 225%. Specials, up to 300%	For constant-speed service, direct connection to slow-speed machines and where pf correction is required.

Support Material

APPENDIX 83.B
DC and Single-Phase Motor Classifications and Characteristics

speed regulations	speed control	starting torque	breakdown torque	application
		series		
Varies inversely as load. Races on light loads and full voltage.	Zero to maximum depending on control and load.	High. Varies as square of voltage. Limited by commutation, heating, and line capacity.	High. Limited by commutation, heating, and line capacity.	Where high starting torque is required and speed can be regulated. Traction, bridges, hoists, gates, car dumpers, car retarders.
		shunt		
Drops 3 to 5% from no load to full load.	Any desired range depending on design, type of system.	Good. With constant field, varies directly as voltage applied to armature.	High. Limited by commutation, heating, and line capacity.	Where constant or adjustable speed is required and starting conditions are not severe. Fans, blowers, centrifugal pumps, conveyors, wood- and metal-working machines, elevators.
		compound		
Drops 7 to 20% from no load to full load depending on amount of compounding.	Any desired range, depending on design, type of control.	Higher than for shunt, depending on amount of compounding.	High. Limited by commutation, heating and line capacity.	Where high starting torque and fairly constant speed is required. Plunger pumps, punch presses, shears, bending rolls, geared elevators, conveyors, hoists.
		split-phase		
Drops about 10% from no load to full load.	None.	75% for large to 175% for small sizes.	150% for large to 200% for small sizes.	Constant-speed service where starting is easy. Small fans, centrifugal pumps and light-running machines, where polyphase is not available.
		capacitors		
Drops about 5% for large to 10% for small sizes.	None.	150 to 350% of full load depending on design and size.	150% for large to 200% for small sizes.	Constant-speed service for any starting duty and quiet operation, where polyphase current cannot be used.
		commutator type		
Drops about 5% for large to 10% for small sizes.	Repulsion induction, none. Brush-shifting types, four to one at full load.	250% for large to 350% for small sizes.	150% for large to 250%.	Constant-speed service for any starting duty where speed control is required and polyphase current cannot be used.

Glossary

A

AASHTO: American Association of State and Highway Transportation Officials.

Abandonment: The reversion of title to the owner of the underlying fee where an easement for highway purposes is no longer needed.

Absorbed dose: The energy deposited by radiation as it passes through a material.

Absorption: The process by which a liquid is drawn into and tends to fill permeable pores in a porous body. Also, the increase in weight of a porous solid body resulting from the penetration of liquid into its permeable pores.

Abutment: A retaining wall that also supports a vertical load.

Accelerated flow: A form of varied flow in which the velocity is increasing and the depth is decreasing.

Acid: Any compound that dissociates in water into H^+ ions. (The combination of H^+ and water, H_3O^+, is known as the hydronium ion.) Acids conduct electricity in aqueous solutions, have a sour taste, turn blue litmus paper red, have a pH between 0 and 7, and neutralize bases, forming salts and water.

Activated sludge: Solids from aerated settling tanks that are rich in bacteria.

Active pressure: Pressure causing a wall to move away from the soil.

Adenosine triphosphate (ATP): The macromolecule that functions as an energy carrier in cells. The energy is stored in a high-energy bond between the second and third phosphates.

Adiabatic expansion: The process that occurs when an air mass rises and expands without exchanging heat with its surroundings.

Admixture: Material added to a concrete mixture to increase its workability, strength, or imperviousness, or to lower its freezing point.

Adsorbed water: Water held near the surface of a material by electrochemical forces.

Advection: The transport of solutes along stream lines at the average linear seepage flow velocity.

Aerated lagoon: A holding basin into which air is mechanically introduced to speed up aerobic decomposition.

Aeration: Mixing water with air, either by spraying water or diffusing air through water.

Aerobe: A microorganism whose growth requires free oxygen.

Aerobic: Requiring oxygen. Descriptive of a bacterial class that functions in the presence of free dissolved oxygen.

Aggregate: Inert material that is mixed with portland cement and water to produce concrete.

Aggregate, coarse: Aggregate retained on a no. 4 sieve.

Aggregate, fine: Aggregate passing the no. 4 sieve and retained on the no. 200 sieve.

Aggregate, lightweight: Aggregate having a dry density of 70 lbm/ft^3 (32 kg/m^3) or less.

Agonic line: A line with no magnetic declination.

Algae: Simple photosynthetic plants having neither roots, stems, nor leaves.

Alidade: A tachometric instrument consisting of a telescope similar to a transit, an upright post that supports the standards of the horizontal axis of the telescope, and a straightedge whose edges are essentially in the same direction as the line of sight. An alidade is used in the field in conjunction with a plane table.

Alkalinity: A measure of the capacity of a water to neutralize acid without significant pH change. It is usually associated with the presence of hydroxyl, carbonate and/or bicarbonate radicals in the water.

Alternate depths: For a particular channel geometry and discharge, two depths at which water flows with the same specific energy in uniform flow. One depth corresponds to subcritical flow; the other corresponds to supercritical flow.

Anabolism: The phase of metabolism involving the formation of organic compounds; usually an energy-utilizing process.

Anabranch: The intertwining channels of a braided stream.

Anaerobe: A microorganism that grows only or best in the absence of free oxygen.

Anaerobic: Not requiring oxygen. Descriptive of a bacterial class that functions in the absence of free dissolved oxygen.

Anion: Negative ion that migrates to the positive electrode (anode) in an electrolytic solution.

Anticlinal spring: A portion of an exposed aquifer (usually on a slope) between two impervious layers.

Apparent specific gravity of asphalt mixture: A ratio of the unit weight of an asphalt mixture (excluding voids permeable to water) to the unit weight of water.

Appurtenance: That which belongs with or is designed to complement something else. For example, a manhole is a sewer appurtenance.

Apron: An underwater "floor" constructed along the channel bottom to prevent scour. Aprons are almost always extensions of spillways and culverts.

Aquiclude: A saturated geologic formation with insufficient porosity to support any significant removal rate or contribute to the overall groundwater regime. In groundwater analysis, an aquiclude is considered to confine an aquifer at its boundaries.

Aquifer: Rock or sediment in a formation, group of formations, or part of a formation that is saturated and sufficiently permeable to transmit economic quantities of water to wells and springs.

Aquifuge: An underground geological formation that has absolutely no porosity or interconnected openings through which water can enter or be removed.

Aquitard: A saturated geologic unit that is permeable enough to contribute to the regional groundwater flow regime, but not permeable enough to supply a water well or other economic use.

Arterial highway: A general term denoting a highway primarily for through traffic, usually on a continuous route.

Artesian formation: An aquifer in which the piezometric height is greater than the aquifer height. In an artesian formation, the aquifer is confined and the water is under hydrostatic pressure.

Artesian spring: Water from an artesian formation that flows to the ground surface naturally, under hydrostatic pressure, due to a crack or other opening in the formation's confining layer.

Asphalt emulsion: A mixture of asphalt cement with water. Asphalt emulsions are produced by adding a small amount of emulsifying soap to asphalt and water. The asphalt sets when the water evaporates.

Atomic mass unit (AMU): One AMU is one twelfth the atomic weight of carbon.

Atomic number: The number of protons in the nucleus of an atom.

Atomic weight: Approximately, the sum of the numbers of protons and neutrons in the nucleus of an atom.

Autotroph: An organism than can synthesize all of its organic components from inorganic sources.

Auxiliary lane: The portion of a roadway adjoining the traveled way for truck climbing, speed change, or other purposes supplementary to through traffic movement.

Avogadro's law: A gram-mole of any substance contains 6.022×10^{23} molecules.

Azimuth: The horizontal angle measured from the plane of the meridian to the vertical plane containing the line. The azimuth gives the direction of the line with respect to the meridian and is usually measured in a clockwise direction with respect to either the north or south meridian.

B

Backwater: Water upstream from a dam or other obstruction that is deeper than it would normally be without the obstruction.

Backwater curve: A plot of depth versus location along the channel containing backwater.

Base: (a) A layer of selected, processed, or treated aggregate material of planned thickness and quality placed immediately below the pavement and above the subbase or subgrade soil. (b) Any compound that dissociates in water into OH^- ions. Bases conduct electricity in aqueous solutions, have a bitter taste, turn red litmus paper blue, have a pH between 7 and 14, and neutralize acids, forming salts and water.

Base course: The bottom portion of a pavement where the top and bottom portions are not the same composition.

Base flow: Component of stream discharge that comes from groundwater flow. Water infiltrates and moves through the ground very slowly; up to 2 years may elapse between precipitation and discharge.

Batter pile: A pile inclined from the vertical.

Bell: An enlarged section at the base of a pile or pier used as an anchor.

Belt highway: An arterial highway carrying traffic partially or entirely around an urban area.

Bentonite: A volcanic clay that exhibits extremely large volume changes with moisture content changes.

Berm: A shelf, ledge, or pile.

Bifurcation ratio: The average number of streams feeding into the next side (order) waterway. The range is usually 2 to 4.

Binary fission: An asexual reproductive process in which one cell splits into two independent daughter cells.

Bioactivation process: A process using sedimentation, trickling filter, and secondary sedimentation before adding activated sludge. Aeration and final sedimentation are the follow-up processes.

Biochemical oxygen demand (BOD): The quantity of oxygen needed by microorganisms in a body of water to decompose the organic matter present. An index of water pollution.

Biosorption process: A process that mixes raw sewage and sludge that have been pre-aerated in a separate tank.

Biota: The flora and fauna of a region, process, or tank.

Bleeding: A form of segregation in which some of the water in the mix tends to rise to the surface of freshly placed concrete.

Blind drainage: Geographically large (with respect to the drainage basin) depressions that store water during a storm and therefore stop it from contributing to surface runoff.

Braided stream: A wide, shallow stream with many anabranches.

Branch sewer: A sewer off the main sewer.

Breaking chain: A technique used when the slope is too steep to permit bringing the full length of the chain or tape to a horizontal position. When breaking chain, the distance is measured in partial tape lengths.

Breakpoint chlorination: Application of chlorine that results in a minimum of chloramine residuals. No significant free chlorine residual is produced unless the breakpoint is reached.

Bulking: *See* Sludge bulking.

Bulk specific gravity of asphalt mixture: Ratio of the unit weight of an asphalt mixture (including permeable and impermeable voids) to the unit weight of water.

C

Caisson: An air- and watertight chamber used as a foundation and/or used to work or excavate below the water level.

Capillary water: Water just above the water table that is drawn up out of an aquifer due to capillary action of the soil.

Carbonaceous demand: Oxygen demand due to biological activity in a water sample.

Carbonate hardness: Hardness associated with the presence of bicarbonate radicals in the water.

Carcinogen: A cancer-causing agent.

Carrier (biological): An individual harboring a disease agent without apparent symptoms.

Cased hole: An excavation whose sides are lined or sheeted.

Catabolism: The chemical reactions by which food materials or nutrients are converted into simpler substances for the production of energy and cell materials.

Catena: A group of soils of similar origin occurring in the same general locale but that differ slightly in properties.

Cation: Positive ion that migrates to the negative electrode (cathode) in an electrolytic solution.

Cell wall: The cell structure exterior to the cell membrane of plants, algae, bacteria, and fungi. It give cells form and shape.

Cement-treated base: A base layer constructed with good-quality, well-graded aggregate mixed with up to 6% cement.

Channelization: The separation or regulation of conflicting traffic movements into definite paths of travel by use of pavement markings, raised islands, or other means.

Check: A short section of built-up channel placed in a canal or irrigation ditch and provided with gates or flashboards to control flow or raise upstream level for diversion.

Chemical precipitation: Settling out of suspended solids caused by adding coagulating chemicals.

Chloramine: Compounds of chlorine and ammonia (e.g., NH_2Cl, $NHCl_2$, or NCl_3).

Chlorine demand: The difference between applied chlorine and the chlorine residual. Chlorine demand is chlorine that has been reduced in chemical reactions and is no longer available for disinfection.

Class: A major taxonomic subdivision of a phylum. Each class is composed of one or more related orders.

Clean-out: A pipe through which snakes can be pushed to unplug a sewer.

Coliform: Gram-negative, lactose-fermenting rods, including escherichieae coli and similar species that normally inhabit the colon (large intestine). Commonly included in the coliform are Enterobacteria aerogenes, Klebsiella species, and other related bacteria.

Colloid: A fine particle ranging in size from 1 to 500 millimicrons. Colloids cause turbidity because they do not easily settle out.

Combined residuals: Compounds of an additive (such as chlorine) that have combined with something else. Chloramines are examples of combined residuals.

Combined system: A system using a single sewer for disposal of domestic waste and storm water.

Comminutor: A device that cuts solid waste into small pieces.

Compaction: Densification of soil by mechanical means, involving the expulsion of excess air.

Complete mixing: Mixing accomplished by mechanical means (stirring).

Compound: A homogeneous substance composed of two or more elements that can be decomposed by chemical means only.

Concrete: A mixture of portland cement, fine aggregate, coarse aggregate, and water, with or without admixtures.

Concrete, normal weight: Concrete having a hardened density of approximately 150 lbm/ft^3.

Concrete, plain: Concrete that is not reinforced with steel.

Concrete, structural lightweight: A concrete containing lightweight aggregate.

Condemnation: The process by which property is acquired for public purposes through legal proceedings under power of eminent domain.

Cone of depression: The shape of the water table around a well during and immediately after use. The cone's water surface level differs from the original water table by the well's drawdown.

Confined water: Artesian water overlaid with an impervious layer, usually under pressure.

Confirmed test: A follow-up test used if the presumptive test for coliforms is positive.

Conjugate depths: The depths on either side of a hydraulic jump.

Connate water: Water, frequently saline, present in rock at its formation.

Consolidation: Densification of soil by mechanical means, involving expulsion of excess water.

Contraction: A decrease in the width or depth of flow caused by the geometry of a weir, orifice, or obstruction.

Control of access: The condition where the right of owners or occupants of abutting land or other persons to access in connection with a highway is fully or partially controlled by public authority.

Critical depth: The depth that minimizes the specific energy of flow.

Critical flow: Flow at the critical depth and velocity. Critical flow minimizes the specific energy and maximizes discharge.

Critical slope: The slope that produces critical flow.

Critical velocity: The velocity that minimizes specific energy. When water is moving at its critical velocity, a disturbance wave cannot move upstream since the wave moves at the critical velocity.

Cunette: A small channel in the invert of a large combined sewer for dry weather flow.

Curing: The process and procedures used for promoting the hydration of cement. It consists of controlling the temperature and moisture from and into the concrete.

D

Dead load: An inert, inactive load, primarily due to the structure's own weight.

Decision sight distance: Sight distance allowing for additional decision time in cases of complex conditions.

Deoxygenation: The act of removing dissolved oxygen from water.

Depression storage: Initial storage of rain in small surface puddles.

Depth-area-duration analysis: A study made to determine the maximum amounts of rain within a given time period over a given area.

Dewatering: Removal of excess moisture from sludge waste.

Digestion: Conversion of sludge solids to gas.

Dilatancy: The tendency of a material to increase in volume when undergoing shear.

Dilution disposal: Relying on a large water volume (lake or stream) to dilute waste to an acceptable concentration.

Dimple spring: A depression in the earth below the water table.

Divided highway: A highway with separated roadbeds for traffic in opposing directions.

Domestic waste: Waste that originates from households.

Downpull: A force on a gate, typically less at lower depths than at upper depths due to increased velocity, when the gate is partially open.

Drainage density: The total length of streams in a watershed divided by the drainage area.

Drawdown: The lowering of the water table level of an unconfined aquifer (or of the potentiometric surface of a confined aquifer) by pumping of wells.

Drawdown curve: *See* Cone of depression.

Dredge line: *See* Mud line.

Dry weather flow: *See* Base flow.

E

Easement: A right to use or control the property of another for designated purposes.

Effective specific gravity of an asphalt mixture: Ratio of the unit weight of an asphalt mixture (excluding voids permeable to asphalt) to the unit weight of water.

Effluent: That which flows out of a process.

Effluent stream: A stream that intersects the water table and receives groundwater. Effluent streams seldom go completely dry during rainless periods.

Element: A pure substance that cannot be decomposed by chemical means.

Elutriation: A counter-current sludge washing process used to remove dissolved salts.

Embankment: A raised structure constructed of natural soil from excavation or borrow sources.

Eminent Domain: The power to take private property for public use without the owner's consent upon payment of just compensation.

Emulsion: *See* Asphalt emulsion.

Encroachment: Use of the highway right-of-way for non-highway structures or other purposes.

Energy gradient: The slope of the specific energy line (i.e., the sum of the potential and velocity heads).

Enteric: Intestinal.

Enzyme: An organic (protein) catalyst that causes changes in other substances without undergoing any alteration itself.

Ephemeral stream: A stream that goes dry during rainless periods.

Equivalent weight: The amount of substance (in grams) that supplies one mole of reacting units. It is calculated as the molecular weight divided by the change in oxidation number experienced in a chemical reaction. An alternative calculation is the atomic weight of an element divided by its valence or the molecular weight of a radical or compound divided by its valence.

Escherichieae coli (E. coli): *See* Coliform.

Evapotranspiration: Evaporation of water from a study area due to all sources including water, soil, snow, ice, vegetation, and transpiration.

F

Facultative: Able to live under different or changing conditions. Descriptive of a bacterial class that functions either in the presence or absence of free dissolved oxygen.

Fecal coliform: *See* Coliform. Those categories of coliform found in the digestive tract of warm-blooded animals, typically E. coli.

Fines: Silt- and/or clay-sized particles.

First-stage demand: *See* Carbonaceous demand.

Flexible pavement: A pavement having sufficiently low bending resistance to maintain intimate contact with the underlying structure, yet having the required stability furnished by aggregate interlock, internal friction, and cohesion to support traffic.

Floc: Agglomerated colloidal particles.

Flotation: Addition of chemicals and bubbled air to liquid waste in order to get solids to float to the top as scum.

Flowing well: A well that flows under hydrostatic pressure to the surface. Also called an Artesian well.

Flume: In general, any open channel for carrying water. More specifically, an open channel constructed above the earth's surface, usually supported on a trestle or on piers.

Force main: A sewer line that is pressured.

Forebay: A reservoir holding water for subsequent use after it has been discharged from a dam.

Freeboard distance: The vertical distance between the water surface and the crest of a dam or top of a channel side. The distance the water surface can rise before it overflows.

Free residuals: Ions or compounds not combined or reduced. The presence of free residuals signifies excess dosage.

Freeway: A divided arterial highway with full control of access.

Freeze (in piles): A large increase in the ultimate capacity (and required driving energy) or a pile after it has been driven some distance.

Friable: Easily crumbled.

Frontage road: A local street or road auxiliary to and located on the side of an arterial highway for service to abutting property and adjacent areas, and for control of access.

Frost susceptibility: Susceptible to having water continually drawn up from the water table by capillary action, forming ice crystals below the surface (but above the frost line).

Fungi: Aerobic, multicellular, nonphotosynthetic heterotrophic, eucaryote protists that degrade dead organic matter, releasing carbon dioxide and nitrogen.

G

Gap-graded: A soil with a discontinuous range of soil particle sizes; for example, containing large particles and small particles but no medium-sized particles.

Geographic Information System (GIS): A digital database containing geographic information.

Glacial till: Soil resulting from a receding glacier, consisting of mixed clay, sand, gravel, and boulders.

Gore: The area immediately beyond the divergence of two roadways bounded by the edges of those roadways.

Gradient: The energy (head) loss per unit distance. *See also* Slope.

Gravel: Granular material retained on a no. 4 sieve.

Gravitational water: Free water in transit downward through the vadose (unsaturated) zone.

Grillage: A footing or part of a footing consisting of horizontally laid timbers or steel beams.

Groundwater: Loosely, all water that is underground as opposed to on the surface of the ground. Usually refers to water in the saturated zone below the water table.

Gumbo: Silty soil that becomes soapy, sticky, or waxy when wet.

H

Hard water: Water containing dissolved salts of calcium and magnesium, typically associated with bicarbonates, sulfates, and chlorides.

Head: (Total hydraulic) the sum of the elevation head, pressure head, and velocity head at a given point in an aquifer.

Headwall: Entrance to a culvert or sluiceway.

Heat of hydration: The exothermic heat given off by concrete as it cures.

Horizon: A layer of soil with different color or composition than the layers above and below it.

Humus: A grayish-brown sludge consisting of relatively large particle biological debris, such as the material sloughed off from a trickling filter.

Hydration: The chemical reaction between water and cement.

Hydraulic depth: Ratio of area in flow to the width of the channel at the fluid surface.

Hydraulic jump: An abrupt increase in flow depth that occurs when the velocity changes from supercritical to subcritical.

Hydraulic radius: Ratio of area in flow to wetted perimeter.

Hydrogen ion: The hydrogen atom stripped of its one orbital electron (H^+). It associates with a water molecule to form the hydronium ion (H_3O^+).

Hydrological cycle: The cycle experienced by water in its travel from the ocean, through evaporation and precipitation, percolation, runoff, and return to the ocean.

Hydrometeor: Any form of water falling from the sky.

Hydronium ion: *See* hydrogen ion.

Hydrophilic: Seeking or liking water.

Hydrophobic: Avoiding or disliking water.

Hygroscopic water: Moisture tightly adhering in a thin film to soil grains that is not removed by gravity or capillary forces.

I

Impervious layer: A geologic layer through which no water can pass.

Infiltration: Ground water that enters sewer pipes through cracks and joints. Also, the movement of water downward from the ground surface through the upper soil.

Influent: Flow entering a process.

Influent stream: A stream above the water table that contributes to groundwater recharge. Influent streams may go dry during the rainless season.

Initial loss: The sum of interception and depression loss, excluding blind drainage.

In situ: As found naturally in the ground.

Interception: The process by which precipitation is captured on the surfaces of vegetation and other impervious surfaces and evaporates before it reaches the land surface.

Interflow: Infiltrated subsurface water that travels to a stream without percolating down to the water level.

Inverse condemnation: The legal process that may be initiated by a property owner to compel the payment of fair compensation when the owner's property has been taken or damaged for a public purpose.

Inverted siphon: A sewer line that drops below the hydraulic grade line.

Ion: An atom that has either lost or gained one or more electrons, becoming an electrically charged particle.

Isogonic line: A line representing the magnetic declination.

Isotopes: Atoms of the same atomic number but having different atomic weights due to a variation in the number of neutrons.

J

Juvenile water: Water formed chemically within the earth from magma that has not participated in the hydrologic cycle.

K

Kingdom: A major taxonomic category consisting of several phyla or divisions.

Krause process: Mixing raw sewage, activated sludge, and material from sludge digesters.

L

Lagging: Heavy planking used to construct walls in excavations and braced cuts.

Lamp holes: Sewer inspection holes large enough to lower a lamp into but too small for a person.

Lapse rate, dry: The rate that the atmospheric temperature decreases with altitude for a dry, adiabatic air mass.

Lapse rate, wet: The rate that the atmospheric temperature decreases with altitude for a moist, adiabatic air mass. The exact rate is a function of the moisture content.

Lateral: A sewer line that branches off from another.

Lipids: A group of organic compounds composed of carbon and hydrogen (e.g., fats, phospholipids, waxes, and steroids).

Live load: The weight of all nonpermanent objects in a structure, including people and furniture. Live load does not include seismic or wind loading.

Loess: A deposit of wind-blown silt.

Lysimeter: A soil-vegetation container used to observe and measure percolation and leaching losses.

M

Main: A large sewer at which all other branches terminate.

Malodorous: Offensive smelling.

Meander corner: A survey point set where boundaries intersect the bank of a navigable stream, wide river, or large lake.

Meandering stream: A stream with large curving changes of direction.

Median: The portion of a divided highway separating traffic traveling in opposite directions.

Median lane: A lane within the median to accommodate left-turning vehicles.

Meridian: A great circle of the earth passing through the poles.

Mesophyllic bacteria: Bacteria growing between 10°C and 40°C, with an optimum temperature of 37°C. 40°C is, therefore, the upper limit for most wastewater processes.

Metabolism: All cellular chemical reactions by which energy is provided for vital processes and new cell substances are assimilated.

Meteoric water: *See* Hydrometeor.

Microorganism: A microscopic form of life.

Mixture: A heterogeneous physical combination of two or more substances, each retaining its identity and specific properties.

Mohlman index: *See* Sludge volume index.

Mole: A quantity of substance equal to its molecular weight in grams (gmole or gram-mole) or in pounds (pmole or pound-mole).

Molecular weight: The sum of the atomic weights of all atoms in a molecule.

Mud line: The lower surface of an excavation or braced cut.

N

Net rain: Rain that contributes to surface runoff.

Nitrogen fixation: The formation of nitrogen compounds (NH_3, organic nitrogen) from free atmospheric nitrogen (N_2).

Nitrogenous demand: Oxygen demand from nitrogen consuming bacteria.

Nonpathogenic: Not capable of causing disease in humans.

Nonstriping sight distance: Nonstriping sight distances are in between stopping and passing distances, and they exceed the minimum sight distances required for marking no-passing zones. They provide a practical distance to complete the passing maneuver in a reasonably safe manner, eliminating the need for a no-passing zone pavement marking.

Normal depth: The depth of uniform flow. This is a unique depth of flow for any combination of channel conditions. Normal depth can be determined from the Manning equation.

Normally consolidated soil: Soil that has never been consolidated by a greater stress than presently existing.

O

Observation well: A nonpumping well used to observe the elevation of the water table or the potentiometric surface. An observation well is generally of larger diameter than a piezometer well and typically is screened or slotted throughout the thickness of the aquifer.

Order: In taxonomy, a major subdivision of a class. Each order consists of one or more related families.

Osmosis: The flow of a solvent through a semipermeable membrane separating two solutions of different concentrations.

Outfall: A pipe that discharges completely treated wastewater into a lake, stream, or ocean.

Overchute: A flume passing over a canal to carry floodwaters away without contaminating the canal water below. An elevated culvert.

Overland flow: Water that travels over the ground surface to a stream.

Oxidation: The loss of electrons in a chemical reaction. Opposite of *reduction*.

Oxidation number: An electrical charge assigned by a set of prescribed rules, used in predicting the formation of compounds in chemical reactions.

P

Pan: A container used to measure surface evaporation rates.

Parkway: An arterial highway for noncommercial traffic, with full or partial control of access, usually located within a park or a ribbon of park-like development.

Partial treatment: Primary treatment only.

Passing sight distance: The length of roadway ahead required to pass another vehicle without meeting an oncoming vehicle.

Passive pressure: A pressure acting to counteract active pressure.

Pathogenic: Capable of causing disease in humans.

Pathway: An environmental route by which chemicals from the site can reach receptors.

Pedology: The study of the formation, development, and classification of natural soils.

Penetration treatment: Application of light liquid asphalt to the roadbed material. Used primarily to reduce dust.

Perched spring: A localized saturated area that occurs above an impervious layer.

Percolation: Downward movement of water through the soil.

Permanent hardness: Hardness that cannot be removed by heating.

Person-rem: The amount of total radiation received by a population. It is the product of the average radiation dose in rems times the number of people exposed in the population group.

pH: A measure of a solution's hydrogen ion concentration (acidity).

Phreatic zone: The layer below the water table down to an impervious layer.

Phreatophytes: Trees with root systems that extend into the water table.

Pier shaft: The part of a pier structure that is supported by the pier foundation.

Piezometer: A nonpumping well, generally of small diameter, that is used to measure the elevation of the water table or potentiometric surface. A piezometer generally has a short well screen through which water can enter.

Piezometer nest: A set of two or more piezometers set close to each other but screened to different depths.

Piezometric level: The level to which water will rise in a pipe due to its own pressure.

Planimeter: A device used to measure the area of a drawn shape.

Plant mix: A paving mixture that is not prepared at the paving site.

Plat: (a) A plan showing a section of land. (b) A small plot of land.

pOH: A measure of a solution's hydroxyl radical concentration (alkalinity).

Pollutant: Any solute or cause of change in physical properties that renders water, soil, or air unfit for a given use.

Porosity: The ratio of pore volume to total rock, sediment, or formation volume.

Post-chlorination: Addition of chlorine after all other processes have been completed.

Potable: Suitable for human consumption.

Pre-chlorination: Addition of chlorine prior to sedimentation to help control odors and to aid in grease removal.

Presumptive test: A first-stage test in coliform fermentation. If positive, it is inconclusive without follow-up testing. If negative, it is conclusive.

Prime coat: The initial application of a low-viscosity liquid asphalt to an absorbent surface, preparatory to any subsequent treatment, for the purpose of hardening or toughening the surface and promoting adhesion between it and the superimposed constructed layer.

Probable maximum rainfall: The rainfall corresponding to some given probability (e.g., 1 in 100 years).

Protozoa: Single-celled aquatic animals that reproduce by binary fission. Several classes are known pathogens.

Putrefaction: Anaerobic decomposition of organic matter with accompanying foul odors.

Pycnometer: A closed flask with graduations.

Q

q-curve: A plot of depth of flow versus quantity flowing for a channel with a constant specific energy.

R

Rad: Abbreviation for "radiation absorbed dose." The amount of energy deposited in or absorbed by a material. A rad is equal to 62.5×10^6 MeV per gram of material.

Radical: A charged group of atoms that act together as a unit in chemical reactions.

Ranger: *See* Wale.

Rapid flow: Flow at less than critical depth, typically occurring on steep slopes.

Rating curve: A plot of quantity flowing versus depth for a natural watercourse.

Reach: A straight section of a channel, or a section that is uniform in shape, depth, slope, and flow quantity.

Redox reaction: A chemical reaction in which oxidation and reduction occur.

Reduction: The loss of oxygen or the gain of electrons in a chemical reaction. Opposite of *oxidation*.

Refractory: Dissolved organic materials that are biologically resistant and difficult to remove.

Regulator: A device or weir that diverts large volume flows into a special high-capacity sewer.

Rem: Abbreviation for "Roentgen equivalent mammal." A measurement of the amount of energy absorbed by human tissue. It is the product of the absorbed dose (rad) times the quality factor.

Residual: An chemical that is left over after some of it has been combined or inactivated.

Resilient modulus: The modulus of elasticity of the soil.

Respiration: Any biochemical process in which energy is released. Respiration may be aerobic (in the presence of oxygen) or anaerobic (in the absence of oxygen).

Resurfacing: A supplemental surface or replacement placed on an existing pavement to restore its riding qualities or increase its strength.

Retarded flow: A form of varied flow in which the velocity is decreasing and the depth increasing.

Right of access: The right of an abutting land owner for entrance to or exit from a public road.

Rigid pavement: A pavement structure having portland cement concrete as one course.

Rip rap: Pieces of broken stone used as lining to protect the sides of waterways from erosion.

Roadbed: That portion of a roadway extending from curb line to curb line or shoulder line to shoulder line. Divided highways are considered to have two roadbeds.

Road mix: A low-quality asphalt surfacing produced from liquid asphalts and used when plant mixes are not available or economically feasible and where volume is low.

Roentgen: The amount of energy absorbed in air by the passage of gamma or x-rays. A roentgen is equal to 5.4×10^7 MeV per gram of air or 0.87 rad for air and 0.96 rad for tissue.

S

Safe yield: The maximum rate of water withdrawal that is economically, hydrologically, and ecologically feasible.

Sag pipe: *See* Inverted siphon.

Salt: An ionic compound formed by direct union of elements, reactions between acids and bases, reaction of acids and salts, and reactions between different salts.

Sand: Granular material passing through a no. 4 sieve but predominantly retained on a no. 200 sieve.

Sand trap: A section of channel constructed deeper than the rest of the channel to allow sediment to settle out.

Scour: Erosion typically occurring at the exit of an open channel or toe of a spillway.

Seal coat: An asphalt coating, with or without aggregate, applied to the surface of a pavement for the purpose of waterproofing and preserving the surface, altering the surface texture of the pavement, providing delineation, or providing resistance to traffic abrasion.

Second-stage demand: *See* Nitrogenous demand.

Seed: The activated sludge initially taken from a secondary settling tank and returned to an aeration tank to start the activated sludge process.

Seep: *See* Spring.

Sensitivity: The ratio of a soil's undisturbed strength to its disturbed strength.

Separate system: A system with separate sewers for domestic and storm wastewater.

Septic: Produced by putrefaction.

Settling basin: A large, shallow basin through which water passes at low velocity, where most of the suspended sediment settles out.

Sheeted pit: *See* Cased hole.

Shooting flow: *See* Rapid flow.

Sight distance: The length of roadway that a driver can see.

Sinuosity: The stream length divided by the valley length.

Slickenside: A surface (plane) in stiff clay that is a potential slip plane.

Slope: The tangent of the angle made by the channel bottom. *See also* Gradient.

Sludge: The precipitated solid matter produced by water and sewage treatment.

Sludge bulking: Failure of suspended solids to completely settle out.

Sludge volume index (SVI): The volume of sludge that settles in 30 min out of an original volume of 1000 mL. May be used as a measure of sludge bulking potential.

Soldier pile: An upright pile used to hold lagging.

Solution: A homogeneous mixture of solute and solvent.

Specific activity: The activity per gram of a radioisotope.

Specific yield: (a) The ratio of water volume that will drain freely (under gravity) from a sample to the total volume. Specific yield is always less than porosity. (b) The volume of water obtained by lowering one square foot of the water table by one foot.

Split chlorination: Addition of chlorine prior to sedimentation and after final processing.

Spring: A place where water flows or ponds on the surface due to the intersection of an aquifer with the earth surface.

Stadia method: Obtaining horizontal distances and differences in elevation by indirect geometric methods.

Stage: Elevation of flow surface above a fixed datum.

Standing wave: A stationary wave caused by an obstruction in a water course. The wave cannot move (propagate) because the water is flowing at its critical speed.

Steady flow: Flow in which the flow quantity does not vary with time at any location along the channel.

Stilling basin: An excavated pool downstream from a spillway used to decrease tailwater depth and to produce an energy-dissipating hydraulic jump.

Stoichiometry: The study of how elements combine in fixed proportions to form compounds.

Stopping sight distance: The distance that allows a driver traveling at the maximum speed to stop before hitting an observed object.

Storage, specific: The amount of water released from or taken into storage per unit volume of a porous medium per unit change in head.

Stratum: Layer.

Stream gaging: A method of determining the velocity in an open channel.

Stream order: An artificial categorization of stream genealogy. Small streams are first order. Second-order streams are fed by first-order streams, third-order streams are fed by second-order streams, and so on.

Stringer: *See* Wale.

Structural section: The planned layers of specific materials, normally consisting of subbase, base, and pavement, placed over the subbase soil.

Subbase: A layer of aggregate placed on the existing soil as a foundation for the base.

Subcritical flow: Flow with depth greater than the critical depth and velocity less than the critical velocity.

Subgrade: The portion of a roadbed surface that has been prepared as specified, upon which a subbase, base, base course, or pavement is to be constructed.

Submain: *See* Branch sewer.

Substrate: A substance acted upon by an organism, chemical, or enzyme. Sometimes used to mean organic food.

Subsurface runoff: *See* Interflow.

Superchlorination: Chlorination past the breakpoint.

Supercritical flow: Flow with depth less than the critical depth and velocity greater than the critical velocity.

Superelevation: Roadway banking on a horizontal curve for the purpose of allowing vehicles to maintain the traveled speed.

Supernatant: The clarified liquid rising to the top of a digesting sludge layer.

Surcharge: A surface loading that is additional to the soil load behind a retaining wall.

Surface detention: *See* Surface retention.

Surface retention: That part of a storm which is retained. Retention is made up of depression storage, interception, and evaporation.

Surface runoff: Water flow over the surface that reaches a stream after a storm.

Swale: (a) A low-lying portion of land, below the general elevation of the surroundings. (b) A natural ditch or long, shallow depression through which accumulated water from adjacent watersheds drains to lower areas.

T

Tack coat: The initial application of asphalt material to an existing asphalt or concrete surface to provide a bond between the existing surface and the new material.

Tail race: An open waterway leading water out of a dam spillway and back to a natural channel.

Tail water: The water into which a spillway or outfall discharges.

Taxonomy: The description, classification, and naming of organisms.

Temporary hardness: Hardness that can be removed by heating.

Theodolite: A survey instrument used to measure or lay off both horizontal and vertical angles.

Thermophilic bacteria: Bacteria that thrive in the 45°C to 75°C range. The optimum temperature is near 55°C.

Thixotropy: A property of a soil that regains its strength over time after being disturbed and weakened.

Till: *See* Glacial till.

Time of concentration: The time required for water to flow from the most distant point on a runoff area to the measurement or collection point.

Township: A square parcel of land 6 mi on each side.

Toxin: A toxic or poisonous substance.

Tranquil flow: Flow at greater than the critical depth.

Transmissivity: The rate at which water moves through a unit width of an aquifer or confining bed under a unit hydraulic gradient. It is a function of properties of the liquid, the porous media, and the thickness of the porous media.

Transpiration: The process in which plants give off internal moisture to the atmosphere.

Traveled way: The portion of the roadway for the movement of vehicles, exclusive of shoulders and auxiliary lanes.

Turbidity: (a) Cloudiness in water caused by suspended colloidal material. (b) A measure of the light-transmitting properties of water.

Turnout: (a) A location alongside a traveled way where vehicles may stop off of the main road surface without impeding following vehicles. (b) A pipe placed through a canal embankment to carry water from the canal for other uses.

U

Uniform flow: Flow that has constant velocity along a streamline. For an open channel, uniform flow implies constant depth, cross-sectional area, and shape along its course.

Unit stream power: The product of velocity and slope, representing the rate of energy expenditure per unit mass of water.

V

Vadose water: All underground water above the water table, including soil water, gravitational water, and capillary water.

Vadose zone: A zone above the water table containing both saturated and empty soil pores.

Valence: The relative combining capacity of an atom or group of atoms compared to that of the standard hydrogen atom. Essentially equivalent to the oxidation number.

Varied flow: Flow with different depths along the water course.

Volatile organic chemicals (VOCs): A class of toxic chemicals that easily evaporate or mix with the atmosphere and environment.

Volatile solid: Solid material in a water sample or in sludge that can be burned away or vaporized at high temperature.

W

Wale: A horizontal brace used to hold timbers in place against the sides of an excavation or to transmit the braced loads to the lagging.

Wasteway: A canal or pipe that returns excess irrigation water to the main channel.

Water table: The piezometric surface of an aquifer, defined as the locus of points where the water pressure is equal to the atmospheric pressure.

Waving the rod: A survey technique used when reading a rod reading for elevation data. By waving the rod, the lowest rod reading will indicate the point at which the rod is most vertical. The reading at that point is then used to determine the difference in elevation.

Wet well: A short-term storage tank containing a pump into which the raw influent is brought.

Wetted perimeter: The length of the channel that has water contact. The air-water interface is not included in the wetted perimeter.

X

Xerophytes: Drought-resistant plants, typically existing with root systems well above the water table.

Z

Zone of aeration: *See* Vadose zone.

Zone of saturation: *See* Phreatic zone.

Zoogloea: The gelatinous film (i.e., "slime") of aerobic organisms that covers the exposed surfaces of a biological filter.

Z
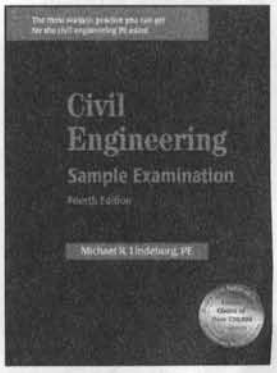
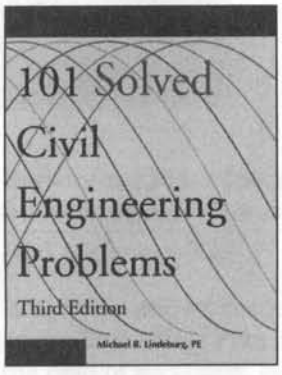
z-values for confidence levels, 11-12



Your Preparation Isn't Complete Without These Supplements!

Practice Problems for the Civil Engineering PE Exam: A Companion to the Civil Engineering Reference Manual

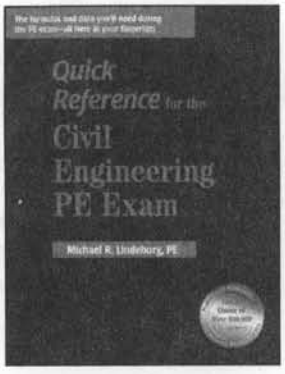
Michael R. Lindeburg, PE — 592 pages, paperback



The 440 practice problems in the **Civil Engineering Reference Manual** are presented here with step-by-step solutions. With this book handy, you get immediate feedback on your problem-solving skills and learn the most efficient way to approach a wide variety of problems.

Civil Engineering Sample Examination

Michael R. Lindeburg, PE — 55 pages, paperback

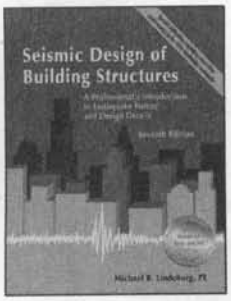


Testing yourself with a realistic simulation of the PE exam is an essential part of your preparation. There's no better way to get ready for the time pressure of the exam. **Civil Engineering Sample Exam** includes 24 PE-format problems (12 essay, 12 multiple-choice), each designed to be solved in one hour. Fully worked-out solutions are included.

101 Solved Civil Engineering Problems

Michael R. Lindeburg, PE — 185 pages, paperback

The more problems you solve in practice, the less likely you'll be to find something unexpected on the exam. This collection of 101 original problems, written in realistic PE format, covers all exam subjects. Every problem is followed by a complete solution.



Quick Reference for the Civil Engineering PE Exam

Michael R. Lindeburg, PE — 80 pages, paperback

During the exam, it's vital to have fast access to the information you need to work problems. **Quick Reference** puts all the necessary formulas, tables, and data at your fingertips, conveniently organized by subject.

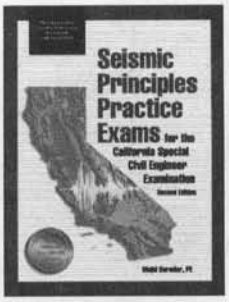
Professional Publications, Inc.
1250 Fifth Avenue • Belmont, CA 94002
(800) 426-1178 • fax (650) 592-4519
Order on-line at www.ppi2pass.com

Here's Help for the Seismic and Surveying Sections of the Civil PE Exam!



Seismic Design of Building Structures: A Professional's Introduction to Earthquake Forces and Design Details

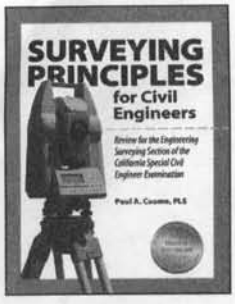
Michael R. Lindeburg, PE — 216 pages, paperback

Seismic Design of Building Structures provides essential background instruction for the seismic problems on the civil PE exam. Topics covered range from basic seismic concepts through detailing requirements, showing application of the relevant codes. Over 100 practice problems, with solutions, offer valuable preparation for the exam.

Seismic Principles Practice Exams for the California Special Civil Engineer Examination

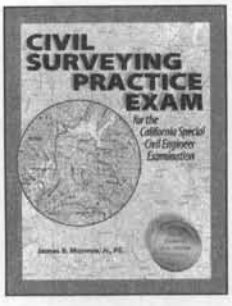
Majid Baradar, PE — 69 pages, paperback

Engineers agree that taking a simulated test is the best way to determine their readiness for the real thing. **Seismic Principles Practice Exams** consists of two complete tests for the special seismic section of the California civil PE exam. Solutions are provided.



345 Solved Seismic Design Problems

Majid Baradar, PE — 167 pages, paperback



You can always use extra practice solving problems when you are preparing for the special seismic section of the California civil PE exam. The problems in **345 Solved Seismic Design Problems** cover every exam subject and reflect the format and level of difficulty of the actual test. Detailed solutions are provided.

Surveying Principles for Civil Engineers: Review for the Engineering Surveying Section of the California Special Civil Engineer Examination

Paul A. Cuomo, PLS — 139 pages, paperback

Here is the perfect resource for the special surveying section of the California civil PE exam. **Surveying Principles for Civil Engineers** provides a comprehensive review of the field of surveying, especially those topics found on the exam. More than 120 practice problems, with worked-out solutions, prepare you for what you'll find on the exam.

Civil Surveying Practice Exam for the California Special Civil Engineer Examination

James R. Monroe, Jr., PE — 24 pages, paperback

Test your readiness for the special surveying section of the California civil PE exam with this **Practice Exam**. It gives you a complete 2½ hour, 53-problem practice exam, with problems using the same format and level of difficulty as the actual test. Fully worked-out solutions are provided.

Civil Engineering Reference Manual

for the PE Exam

Seventh Edition

The seventh edition of the *Civil Engineering Reference Manual*, completely revised and updated, is the most thorough reference and study guide available to engineers preparing for the civil PE examination. Eighty-eight chapters cover the breadth and depth of civil engineering. Nearly 500 solved example problems demonstrate how to arrive at solutions most efficiently, and another 440 practice problems help you sharpen your solving skills. More than 80 key charts, tables, and graphs included in the appendices make it possible for you to solve most problems using the *Reference Manual* alone. And when you take this book into the exam, two detailed indexes let you find the information you need quickly and easily.

The *Civil Engineering Reference Manual* and its companion products are part of Professional Publications' best-selling exam review series, used by more than 600,000 engineers to prepare for their licensing exams.

Among the Exam Topics Covered

Background: Mathematics, Units
Water Resources: Fluid Properties, Statics & Dynamics, Hydraulic Machines, Open Channel Flow, Groundwater, Chemistry, Combustion & Incineration, Water Supply
Environmental: Biochemistry, Wastewater, Sludge & Solid Waste, Hazardous Materials
Geotechnical: Soil Properties & Special Topics, Piles & Foundations, Retaining Walls, Excavations
Structural: Determinate Statics, Material Properties, Strength of Materials, Basic Design, Structural Analysis, Reinforced Concrete, Pretensioned Concrete, Structural Steel, Steel Design, Masonry
Transportation: Kinematics, Kinetics, Roads & Highways, Vehicle Dynamics & Accident Analysis, Pavement Design, Plane Surveying, Curves, Construction Earthwork
Systems, Management, Professional: Project Management, Instrumentation & Measurements, Engineering Economic Analysis, Law, Ethics

About the Author

Michael R. Lindeburg, PE, is widely acknowledged by the engineering community as the leading authority on licensing exam preparation. Mr. Lindeburg holds a BS and MS in Industrial Engineering from Stanford University. Over the last 25 years, he has taught and supervised hundreds of FE and PE exam review courses and has written dozens of books for exam preparation.
